Metadinitrobenzene, when heated with potassium iodide and acetic acid in a sealed tube at 200°, yields paranitraniline. If, however, it is reduced in alcoholic solution with stannous chloride without the addition of hydrochloric acid, it yields dinitrosoazobenzene.

The author is engaged in examining the action of alcoholic stannous chloride without the addition of acid on a series of aromatic nitro-derivatives. E. C. R.

Propoxy-derivatives of Cumonitrile. By M. Fileti and V. Abbona (*Gazzetta*, **21**, ii, 399—402).— The authors had previously failed to obtain a propoxy-derivative of cumonitrile by treating a strongly alkaline solution with potassium permanganate, the cyanogen radicle being attacked under these conditions.

Propoxybenzonitrile, $OPr{\cdot}C_6H_4{\cdot}CN$, has now been isolated by leaving a mixture of water (200 c.c.), potassium permanganate (6·4 grams), and cumonitrile (4 grams) for 18 to 20 days at the ordinary temperature, with occasional agitation, decolorising the product with alcohol, distilling off the unaltered cumonitrile, and concentrating. The propoxy-compound separates as an oily liquid which, after crystallisation from light petroleum, forms lustrous, flattened needles, melts at 51—52°, and dissolves readily in alcohol, ether, and water. On boiling with potash (50 per cent.), it is hydrolysed, propoxybenzoic acid (m. p. 155—156°) being formed.

Propoxybenzamide, $OPr{\cdot}C_6H_4{\cdot}CONH_2$, is obtained by leaving a mixture of cumonitrile and potassium permanganate in the proportions given before, with water (800 c.c.) and potash (2·4 grams) for 10 to 12 days, decolorising with alcohol, and concentrating. The amide crystallises out in long needles, melts when pure at 144—145°, dissolves readily in alcohol and sparingly in benzene and ether, but is insoluble in light petroleum. On boiling with 50 per cent. solution of potash, it is converted into propoxybenzoic acid. A mercury derivative, $(C_{10}H_{12}O_2N)_2Hg$, forms minute crystals melting at about 240°. S. B. A. A.

Bromamidocarvacrol. By G. Mazzara (*Gazzetta*, **21**, ii, 378—380).—The author previously found (Abstr., 1890, 884), that, on reducing bromonitrosocarvacrol, amidobromocarvacrol hydrochloride was formed, and from this the base was prepared as a red liquid, setting in a few days to an amorphous mass which melted at 60°. The melting point of the compound, which is lower than that of the corresponding thymol derivative, and its amorphous character led the author to suspect its purity. On preparing it by the action of fuming

hydrobromic acid on nitrosocarvacrol, it crystallises from light petroleum in yellow needles with a violet tinge, and melts at 136—137°. An unsuccessful attempt was made to oxidise the base with ferric chloride, and convert it into the bromothymoquinone melting at 54°, the product resisting purification, and melting at a low temperature.

S. B. A. A.

Penta-derivatives of Benzene. By R. Nietzki and L. Kurtenacker (*Ber.*, **25**, 282—285).—When Habermann's trinitrodimethylquinol is heated for some hours in a sealed tube at 110—120° with alcoholic ammonia, it decomposes in a manner analogous to the diethyl derivative (Abstr., 1883, 466), and yields *dinitrodiamidoanisoïl*, $C_6H(NO_2)_2(NH_2)_2{\cdot}OMe$, which crystallises from glacial acetic acid in red leaflets having a blue shimmer, and melts at 250°. It dissolves in boiling aqueous alkalis with evolution of ammonia, and on adding acid to the solution, a compound is precipitated which crystallises from dilute alcohol in golden-yellow leaflets, melts at 130°, and is a *dinitrodihydroxyanisoïl*, $C_6H(NO_2)_2(OH)_2{\cdot}OMe$; the *barium* salt crystallises in reddish-yellow leaflets. When the dihydroxy-derivative is reduced with tin and hydrochloric acid, a product is obtained which does not react with orthodiketones. When the above-described dinitrodiamidoanisoïl is reduced with tin and hydrochloric acid, and sulphuric acid and alcohol are added to the resulting solution, a sparingly soluble sulphate, $2OMe{\cdot}C_6H(NH_2)_4,3H_2SO_4$, is precipitated in colourless leaflets. The tetramido-derivative reacts with orthodiketones, forming diquinoxalines thus:—it forms a compound, $OMe{\cdot}C_6H(N_2C_{14}H_{10})_2$, with benzile which crystallises in orange-yellow needles, is sparingly soluble in glacial agetic acid, and melts at 242°; and a compound, $OMe{\cdot}C_6H(N_2C_3H_4O)_2$, with pyruvic acid, which dissolves in alkalis, and is reprecipitated in orange-yellow flocks on the addition of an acid, but is practically insoluble in indifferent solvents. The formation of diquinoxalines indicates that in the tetramido-derivative, the four NH_2 groups are in consecutive positions. A symmetrical constitution is indeed excluded by that of the trinitrodimethylquinol $[(OMe)_2 : (NO_2)_3 = 1 : 4 : 2 : 3 : 5]$; it follows therefore that the methoxyl group in position 4 in the latter is the one displaced by NH_2, and since the compound formed by reducing dinitrodihydroxyanisoïl does not yield an azine, it is probably the NO_2 group in position 2 which is simultaneously displaced by NH_2; the constitution of the diamidodinitroanisoïl would then be

$$[OMe : (NH_2)_2 : (NO_2)_2 = 1 : 2 : 4 : 3 : 5].$$

Condensation Products of Dicyanophenylhydrazine with Aliphatic Aldehydes. By J. A. Bladin (*Ber.*, **25**, 183—188).—Aliphatic aldehydes react with dicyanophenylhydrazine in exactly the same manner as the aromatic aldehydes (Abstr., 1889, 702), yielding condensation products which are readily converted by oxidising agents into triazole derivatives.

Acetaldehyde and dicyanophenylhydrazine readily react in alcoholic solution, forming *ethylidenedicyanophenylhydrazine*,

$$NC{\cdot}C(NH){\cdot}NPh{\cdot}N{:}CHMe,$$

which crystallises from light petroleum in pale-yellow plates, and melts at 95·5—96·5°. By the action of oxidising agents, such as silver nitrate and ferric chloride, it is quickly converted into phenylmethylcyanotriazole.

Œnanthaldehyde unites with dicyanophenylhydrazine, forming the condensation product $NC{\cdot}C(NH){\cdot}NPh{\cdot}N{:}CH{\cdot}[CH_2]_4{\cdot}CH_2Me$; this was oxidised with ferric chloride to phenylhexylcyanotriazole, and the latter at once converted into *phenylhexyltriazolecarboxylic acid*, $C_6H_{13}{\cdot}C_2N_3Ph{\cdot}COOH$, which crystallises from water in silvery plates, and melts at 126° with slight evolution of gas. Its *methyl* and *ethyl* salts are colourless oils; the alkali salts are readily soluble in water; the *silver* salt is an almost insoluble precipitate, and the *copper* salt, with 1 mol. H_2O, a pale-blue, microcrystalline precipitate. The *hydrochloride* crystallises in colourless, matted needles which are decomposed by water; the *amide*, $C_6H_{13}{\cdot}C_2N_3Ph{\cdot}CONH_2$, obtained by the action of ammonia on the ethyl salt, crystallises from benzene in lustrous plates containing benzene of crystallisation, which is evolved when the crystals are melted, the substance, after solidification, remelting at 82—82·5°. The *thiamide*, $C_6H_{13}{\cdot}C_2N_3Ph{\cdot}CSNH_2$, forms sulphur-yellow plates, and melts at 76—77°. H. G. C.

Action of Ethyl Acetoacetate on Dicyanophenylhydrazine. By J. A. Bladin (*Ber.*, **25**, 189—196).—When dicyanophenylhydrazine is warmed with twice its weight of ethyl acetoacetate, alcohol is evolved; the product, after distilling off the excess of ethyl acetoacetate, consists of a crystalline mass saturated with an oily substance. On treatment with alcohol, the oily portion and some of the crystals dissolve, leaving a residue which is almost insoluble in cold alcohol, but crystallises from the hot liquid in small, lustrous plates. It has the composition $C_{12}H_{12}N_4O_2$, melts at 208—209°, and has the properties of an acid.

The portion of the original product soluble in alcohol consists of phenylmethylcyanotriazole, and an oil which was not obtained pure, but which, on treatment with alkalis, yields the acid $C_{12}H_{12}N_4O_2$, described above, and is therefore probably its ethyl salt. The formation of this ethyl salt and of the acid is readily understood, the ordinary hydrazone condensation taking place between ethyl acetoacetate and dicyanophenylhydrazine, the ethyl salt being partially hydrolysed at the temperature employed. The formation of phenylmethylcyanotriazole, which is always obtained in smaller quantity, probably takes place as follows: the ethyl acetoacetate decomposes to some extent on boiling, and the acetic acid set free converts the dicyanophenylhydrazine into the acetyl derivative

$$NC{\cdot}C(NH){\cdot}NPh{\cdot}NH{\cdot}COMe,$$

which then loses water, forming phenylmethylcyanotriazole; this would be exactly analogous to the reaction between dicyanophenyl-

hydrazine and pyruvic acid (Abstr., 1887, 138). A further possibility is that it is formed from the acid $C_{12}H_{12}N_4O_2$ by elimination of acetic acid, but this compound is very stable, and, although decomposed by boiling acids and alkalis, does not yield phenylmethylcyanotriazole among the products of decomposition.

A number of derivatives of the acid $C_{12}H_{12}N_4O_2$ have been prepared; the *ammonium* salt, $C_{12}H_{11}N_4O_2{\cdot}NH_4$, forms spherical groups of crystals, and the *potassium* salt, $C_{12}H_{11}N_4O_2K$, a matted mass of slender, colourless needles, both salts being very unstable. The acid is converted by nitrous acid into an *isonitroso*-compound,

$$NC{\cdot}C(NH){\cdot}NPh{\cdot}N{:}CMe{\cdot}C(NOH){\cdot}COOH,$$

which, after recrystallisation from alcohol, melts at 217—218°, forming a brown oil; it dissolves very sparingly in water, but readily in aqueous alkalis.

When the acid is boiled with dilute hydrochloric acid or potash, the imido-group is replaced by oxygen, with formation of the compound $NC{\cdot}CO{\cdot}NPh{\cdot}N{:}CMe{\cdot}CH_2{\cdot}COOH$, which crystallises from alcohol in flat, colourless needles, melts at 187—188° with evolution of gas, and is sparingly soluble in water. With nitrous acid, it yields the *isonitroso*-derivative $NC{\cdot}CO{\cdot}NPh{\cdot}N{:}CMe{\cdot}C(NOH){\cdot}COOH$, which forms small, colourless prisms, readily soluble in alcohol, but sparingly in water, and melts at 209° with decomposition.

H. G. C.

Stereoisomeric Nitrogen Compounds other than Oximes. By K. Auwers and V. Meyer (*Ber.*, **24**, 4225—4230).—Hantzsch and Kraft (this vol., p. 338) describe two isomeric hydrazones of anisyl phenyl ketone, which they regard as stereochemical isomerides, and represent by formulæ similar to those ascribed to the isomeric oximes of benzile by Hantzsch and Werner. The authors point out that Hantzsch and Kraft state in support of the structural identity of the two hydrazones, that they exhibit the same reactions, without, however, giving any details as to these reactions, and that they are similar in physical properties, an observation which has no significance when it is considered that the isomeric benziloximes are compounds differing widely in physical properties. The authors further contend that stereoisomeric hydrazones can be represented by formulæ similar to those assigned by them to derivatives of hydroxylamine (Abstr., 1890, 1263), thus:— $\begin{matrix} X{\cdot}C{\cdot}Y \\ \| \\ N \\ | \\ H{\cdot}N{\cdot}Ph \end{matrix}$ and $\begin{matrix} X{\cdot}C{\cdot}Y \\ \| \\ N \\ | \\ N{<}{}^{H}_{Ph} \end{matrix}$ (compare Abstr., 1890, 1117; 1891, 302).

A. R. L.

Oximes and so-called Stereochemistry. By A. Claus (*J. pr. Chem.* [2], **45**, 1—20).—The author replies to Auwers and Meyer (this vol., p. 186), who have criticised his previous paper on the subject (this vol., p. 50), and maintains his former position. The paper contains no new facts.

A. G. B.

Amidotolyloxamic and Urethanotolyloxamic Acids. By U. Schiff and A. Vanni (*Gazzetta*, **21**, ii, 409—451). Amidotolyloxamethane was prepared by Tiemann (*Ber.*, 1870, 222) by boiling a solution of tolylenediamine and ethyl oxalate in absolute alcohol. The action proceeds much more rapidly if aqueous alcohol is employed. Tolylenediamine (40 parts) and ethyl oxalate (50 parts) are dissolved in 93—95 per cent. alcohol (170—200 parts), and boiled in a reflux apparatus for several days. From time to time the liquid is cooled, the crude amidotolyloxamethane (44 parts) which separates is filtered off, and the filtrate again heated, after adding a little ethyl oxalate and alcohol. The alcohol and ethyl oxalate are finally distilled off, leaving a syrupy residue, which partially solidifies after a time. On extracting this with dilute hydrochloric acid, amidotolyloxamethane dissolves, and may be precipitated by sodium carbonate solution; the residue, insoluble in acid, consists of tolylenedioxamethane and amidotolyloxamic acid. Amidotolyloxamethane is also formed on boiling a concentrated solution of tolylenediamine and oxamethane in molecular proportion in absolute alcohol.

Acetamidotolyloxamethane, $NHAc{\cdot}C_6H_3Me{\cdot}NH{\cdot}C_2O_2{\cdot}OEt$, is prepared by dissolving amidotolyloxamethane in boiling acetic anhydride. It crystallises from boiling alcohol in colourless scales, and melts at 192°.

Thiocarbaniltolyloxamethane, $NHPh{\cdot}CS{\cdot}NH{\cdot}C_6H_3Me{\cdot}NH{\cdot}C_2O_2{\cdot}OEt$, is formed when a solution in absolute alcohol of amidotolyloxamethane and phenylthiocarbamide in molecular proportion is heated for a short time. On cooling, it separates in colourless prisms which, after crystallisation from alcohol, melt at 154—155°. The alcoholic mother liquors yield a small quantity of a yellow powder, which melts at 138°, and on fusion with caustic potash gives aniline and potassium oxalate. This is probably formed from the preceding compound by elimination of alcohol, and may be represented as $C_7H_6<^{NH{\cdot}C_2O_2}_{NH-CS}>NPh$. When the thiocarbaniltolyloxamethane is crystallised from alcohol, the mother liquor yields two crystalline compounds, one of which is in the form of bright scales containing sulphur and melting at 136—138°. The small quantities of these substances obtained precluded further examination.

An alcoholic solution of amidotolyloxamethane and carbon bisulphide, when heated in a closed tube at 100° for two days, yields much hydrogen sulphide. A crystalline substance containing sulphur is also obtained, but was not further studied owing to the difficulty of purifying it.

When amidotolyloxamethane is heated at 180° for a day, alcohol is eliminated, and the dark brown residue is found to be partially soluble in boiling alcohol, leaving a yellow powder probably consisting of *tolyleneoxamide*,

$$C_7H_6<^{NH}_{NH}>C_2O_2 \text{ or } C_7H_6<^{NH{\cdot}C_2O_2{\cdot}NH}_{NH{\cdot}C_2O_2{\cdot}NH}>C_7H_6.$$

It is insoluble in the ordinary solvents, but dissolves in concentrated sulphuric acid; on adding nitric acid to this solution, it turns blood-

red, and yields a nitro-derivative which crystallises from boiling alcohol in yellow needles. Tolyleneoxamide carbonises and evolves gas at about 266°. It dissolves slowly in boiling aqueous potash, without evolution of ammonia. It is also formed on boiling amidotolyloxamethane with water for eight hours, and, together with a little amidotolyloxamic acid, on heating tolylenediamine oxalate at 160°.

An alcoholic solution of tolylenediamine and ethyl malonate, heated in a closed tube at 120°, yields a small quantity of a substance which separates from boiling acetic acid in minute, colourless needles, and is sparingly soluble in boiling alcohol. It is probably *tolylenemalonamide*, $C_7H_6<^{NH\cdot CO}_{NH\cdot CO}>CH_2$. When its solution in concentrated sulphuric acid is treated with nitric acid, a nitro-derivative crystallising in yellow needles is obtained.

Lussy (this Journal, 1875, 254) prepared tolylenediurethane by dropping ethyl chlorocarbonate into a cooled alcoholic solution of tolylenediamine. The authors find that the mother liquor on concentration deposits first tolylyenediamine hydrochloride and then *amidotolylurethane hydrochloride*. The mother liquor, after further concentration, is dissolved in water and potash added, when a mixture of tolylenediamine and *amidotolylurethane*, $NH_2\cdot C_6H_3Me\cdot NH\cdot COOEt$, is precipitated; this crystallises from alcohol in long, flat needles of pearly lustre. It melts at 91°, and is very soluble in hot alcohol, less so in ether and hot water. Its hydrochloride is very soluble in water and crystallises badly. The *platinochloride* forms straw-coloured crystals. Amidotolylurethane is not altered by heating with alcoholic ammonia in a closed tube at 120°; when heated for several hours with aniline, it yields diphenylcarbamide and tolylenediamine. Attempts to prepare it from tolylenediurethane by heating with alcoholic ammonia in a sealed tube at 140° or by boiling with aniline failed.

Thiocarbaniltolylurethane, $NHPh\cdot CS\cdot NH\cdot C_6H_3Me\cdot NH\cdot COOEt$

$$[Me : NH\cdot CS : NH\cdot CO = 1:2:4],$$

is prepared by boiling for a short time an alcoholic solution of amidotolylurethane and phenylthiocarbamide in molecular proportion. It separates from alcohol in colourless prisms melting at 154—155°. If excess of phenylthiocarbamide is used and the boiling prolonged, *diphenylthiocarbamide*, $CS(NHPh)_2$, is obtained, together with other compounds containing sulphur which could not be separated. The former crystallises from alcohol in lustrous scales, melts at 148—150°, and yields aniline when fused with potash.

An alcoholic solution of tolylenediurethane and phenylthiocarbamide when heated gives a mixed product, one of the constituents of which is *phenylthiourethane*, $OEt\cdot CS\cdot NHPh$, a well-crystallised substance melting at 64—65°. A little diphenylthiocarbamide and an oil, which is probably ethyl carbonate, together with other compounds containing sulphur, are also present. The reaction is represented by the equation $C_7H_6(NH\cdot COOEt)_2 + 4CSNPh + 4EtOH = 2CO(OEt)_2 + 2EtO\cdot CS\cdot NHPh + C_7H_6(NH\cdot CS\cdot NHPh)_2$. The latter substance, tolylenedithiophenylcarbamide, decomposes at once into tolylenethiocarbamide and diphenylthiocarbamide.

Oxamethanotolylurethane, $OEt{\cdot}C_2O_2{\cdot}NH{\cdot}C_6H_3Me{\cdot}NH{\cdot}COOEt$

$[Me : NH{\cdot}C_2O_2 : NH{\cdot}CO = 1 : 2 : 4]$,

is prepared by boiling a concentrated alcoholic solution of amidotolylurethane with a little more than the equivalent proportion of ethyl oxalate. It is deposited on concentrating the solution, and when recrystallised from alcohol is obtained in long, colourless prisms which melt at 128°. Its alcoholic solution, on treatment with alcoholic ammonia, deposits small, colourless prisms of *oxamidotolylurethane*, $NH{\cdot}C_2O_2{\cdot}NH{\cdot}C_6H_3Me{\cdot}NH{\cdot}COOEt$, which melts at 223°, and gives off ammonia when heated with dilute caustic potash.

Urethanotolyloxamethane, $COOEt{\cdot}NH{\cdot}C_6H_3Me{\cdot}NH{\cdot}C_2O_2{\cdot}OEt$

$[Me : NH{\cdot}CO : NH{\cdot}C_2O_2 = 1 : 2 : 4]$,

is prepared by slowly dropping ethyl chlorocarbonate (2·5 c.c.) into an ice-cold solution of amidotolyloxamethane (5 grams) in absolute alcohol. The green, fluorescent liquid is evaporated to dryness, and the unaltered amidotolyloxamethane hydrochloride extracted by boiling with very dilute hydrochloric acid. The urethanotolyloxamethane remains undissolved, and crystallises from dilute alcohol in colourless, spherical aggregates melting at 131°. It is very soluble in alcohol, sparingly so in water. On treatment with cold alcoholic ammonia, it yields colourless crystals of *urethanotolyloxamide*, $COOEt{\cdot}NH{\cdot}C_6H_3Me{\cdot}NH{\cdot}C_2O_2{\cdot}NH_2$, which melts at 209°.

Paranitrotolylurethane, $COOEt{\cdot}NH{\cdot}C_6H_3Me{\cdot}NO_2$ $[CH_3 : NH : NO_2 = 1 : 2 : 4]$, is prepared by the action of ethyl chlorocarbonate on nitrotoluidine. It crystallises in colourless needles, melts at 137°, and is very soluble in alcohol and ether, less so in boiling water. Its alcoholic solution, when boiled with ethyl oxalate, yields *nitrotolyloxamethane*; this can be converted into *nitrotolyloxamide* by treatment with cold alcoholic ammonia.

Paramidotolylurethane, $COOEt{\cdot}NH{\cdot}C_6H_3Me{\cdot}NH_2$, is formed on reducing paranitrotolylurethane (1 mol.) in boiling hydrochloric acid solution by means of stannous chloride (3 mols.). After the addition of much water, the tin is removed by hydrogen sulphide, the filtered solution concentrated, excess of sodium carbonate solution added, and the liquid extracted with ether. The residue left on evaporating the ethereal solution, is purified by conversion into the hydrochloride, treatment with sodium carbonate, and extraction with ether. The oil thus obtained soon solidifies over sulphuric acid, and on crystallisation from chloroform, is obtained in large, hard prisms, which melt at 91° and turn yellow in the air. The yield of amidotolylurethane is about 15 per cent. of the nitro-derivative employed. On boiling with alcohol and ethyl oxalate, it gives the urethanotolyloxamethane melting at 131°, described above, and so establishes the constitutions both of that substance and its isomeride melting at 128°.

Amidotolyloxamic acid, $NH_2{\cdot}C_6H_3Me{\cdot}NH{\cdot}C_2O_2{\cdot}OH$ $[Me : NH_2 : NH = 1 : 2 : 4]$, is formed during the preparation of amidotolyoxamethane if aqueous alcohol be used. The crude acid contains amidotolyloxamethane; this is eliminated by solution in alcoholic ammonia, when the oxamethane is converted into insoluble amidotolyloxamide, which

is filtered off. On treating the filtrate with acetic acid, amidotolyloxamic acid separates as a crystalline powder. It decomposes at 223°, and yields tolylenediamine and oxalate on boiling with solutions of alkali carbonates; when heated in a closed tube with alcoholic ammonia, a mixture of amidotolyloxamide, oxamide, and oxalic acid is obtained. It yields oxanilide and tolylenediamine on boiling with aniline. A small quantity of the acid is formed on prolonged boiling of an alcoholic solution of tolylenediamine (15 grams) and anhydrous oxalic acid (11 grams).

Amidotolyloxamide, $NH_2 \cdot C_6H_3Me \cdot NH \cdot C_2O_2 \cdot NH_2$, formed by the action of alcoholic ammonia on amidotolyloxamethane, crystallises from boiling alcohol in splendid scales which melt at 203°. It is also formed on heating a mixture of tolylenediamine and ethyl oxamate in molecular proportion for several hours at 110—115°.

Amidotolyloxanilide, $NH_2 \cdot C_6H_3Me \cdot NH \cdot C_2O_2 \cdot NHPh$, is prepared by boiling amidotolyloxamethane or its amide for a short time with aniline. It is also formed by fusing together phenyloxamethane and tolylenediamine. When crystallised from acetic acid, it melts at 185—186°; if crystallised from alcohol, at 183°. It yields a *hydrochloride* which loses about one-half its hydrogen chloride over sulphuric acid at the ordinary temperature. All the preceding compounds which contain one amido-group of the tolylenediamine intact give a red or violet colour with furfuraldehyde in presence of an acid.

Urethanotolyloxamic acid, $COOEt \cdot NH \cdot C_6H_3Me \cdot NH \cdot C_2O_2 \cdot OH$

$[Me : NH \cdot CO : NH \cdot C_2O_2 = 1 : 2 : 4]$,

is prepared by slowly adding ethyl chlorocarbonate (1 mol.) to finely-powdered potassium amidotolyloxamate (1 mol.) suspended in ether. The ether is distilled off, and the residue dissolved in dilute ammonia solution after extraction with acidified water. The acid is then precipitated by hydrochloric acid, and on crystallisation from alcohol is obtained in colourless scales, which are very soluble in alcohol, less so in ether, and only sparingly in water. It melts at 168—170°, and contains half a molecule of water of crystallisation, which it loses at 90—100°, but retains over sulphuric acid. The *silver* salt is a white, crystalline powder, and the *copper* salt a green, flocculent precipitate. If, in the preparation of the oxamethanotolylurethane melting at 128°, as described above, 90 per cent. alcohol is used, the mother liquors contain a substance of very sweet taste, which seems to be this urethanotolyloxamic acid. The analytical numbers obtained, however, differ much among themselves.

Uramidotolyloxamic acid, $NH_2 \cdot CO \cdot NH \cdot C_6H_3Me \cdot NH \cdot C_2O_2 \cdot OH$

$[Me : NH \cdot CO : NH \cdot C_2O_2 = 1 : 2 : 4]$,

is formed on adding the equivalent quantity of potassium cyanate solution to amidotolyloxamic acid suspended in ice-cold water. The new acid separates on adding hydrochloric acid to the solution, and when recrystallised from alcohol melts at 203°. It is insoluble in water, but readily dissolves in dilute alkalis and solutions of the alkali carbonates.

On mixing aqueous solutions of potassium cyanate and amidotolyloxamethane sulphate in molecular proportion, a crystalline separation

of *uramidotolyloxamethane*, $NH_2{\cdot}CO{\cdot}NH{\cdot}C_6H_3Me{\cdot}NH{\cdot}C_2O_2{\cdot}OEt$, is obtained. This, when washed with water and alcohol, yields colourless crystals which melt at 218°, and are sparingly soluble in alcohol and water. When this substance is heated in a closed tube at 80—100° with alcoholic ammonia, a partial conversion into *uramidotolyloxamide*, $NH_2{\cdot}CO{\cdot}NH{\cdot}C_6H_3Me{\cdot}NH{\cdot}C_2O_2{\cdot}NH_2$, occurs. This compound is, however, best prepared by the action of potassium cyanate solution on amidotolyloxamide sulphate. It melts at 239°, and is sparingly soluble in boiling alcohol.

Tolylenedioxamethane, $C_6H_3Me(NH{\cdot}C_2O_2{\cdot}OEt)_2$ [Me : NH : NH = 1 : 2 : 4], is formed on boiling a solution of amidotolyloxamethane in absolute alcohol with ethyl oxalate. It is found, as above mentioned, in the last mother liquors obtained in the preparation of amidotolyloxamethane, and may be conveniently extracted therefrom. These mother liquors are evaporated to dryness, and extracted with dilute hydrochloric acid to remove the tolylenediamine and amidotolyloxamethane. The residue is repeatedly extracted with ether, and on evaporating the ethereal solution, the substance is obtained in small needles melting at 130°. It is also formed in small quantity on heating amidotolyloxamethane with ethyl oxamate at 160°. It is very soluble in alcohol, but insoluble in hot water. Its alcoholic solution is fluorescent.

Oxamethanotolyloxamide, $EtO{\cdot}C_2O_2{\cdot}NH{\cdot}C_6H_3Me{\cdot}NH{\cdot}C_2O_2{\cdot}NH_2$

[Me : EtO : NH_2 = 1 : 2 : 4],

can be prepared by boiling an alcoholic solution of amidotolyloxamide with ethyl oxalate. It crystallises from dilute alcohol in groups of colourless needles, and melts with decomposition at about 210°. It is also formed, together with other substances, on prolonged boiling of an alcoholic solution of amidotolyloxamide and ethyl oxamate.

Amidotolyloxamethane, $NH_2{\cdot}C_2O_2{\cdot}NH{\cdot}C_6H_3Me{\cdot}NH{\cdot}C_2O_2{\cdot}OEt$

[Me : NH_2 : OEt = 1 : 2 : 4],

an isomeride of the preceding compound, is prepared by directly heating together amidotolyloxamethane (4 grams) and ethyl oxamate (2·25 grams) at 160—170° for three hours. On cooling, the crystalline mass is dissolved in boiling alcohol, from which the pure substance separates in colourless, interlacing needles decomposing at about 200°. On heating it with dilute potash, it is decomposed with evolution of ammonia.

Tolylenedioxamide, $C_6H_3Me(NH{\cdot}C_2O_2{\cdot}NH_2)_2$ [Me : NH : NH = 1 : 2 : 4], may be prepared by the action of alcoholic ammonia on either of the three preceding compounds. It is a white powder, sparingly soluble in alcohol and insoluble in water and hydrochloric acid; it decomposes at about 220°. When heated for a short time with aniline, it evolves ammonia and alcohol vapour, and probably yields the corresponding dianilide; prolonged boiling causes the formation of oxanilide. In the preparation of tolylenedioxamide by the action of alcoholic ammonia on tolylenedioxamethane, a substance of intensely sweet taste is found in the last mother liquors. When these are evaporated, and the residue extracted with water, a solution is obtained which, on concentration over sulphuric acid, yields crystalline crusts

consisting probably of *tolylenedioxamic acid*, $C_6H_3Me(NH\cdot C_2O_2\cdot OH)_2$. The numbers obtained on analysis of the *silver*, *barium*, and *lead* salts, however, do not agree very well. These salts are crystalline, and sparingly soluble in water. They decompose slightly on washing with hot water, oxalate being formed. W. J. P.

Commercial Benzoic Chloride. By V. Meyer (*Ber.*, **24**, 4251).—Commercial benzoic chloride is generally contaminated with chlorobenzoic chloride, and the benzoyl compounds prepared with it, especially if the Schotten-Baumann method be employed, often contain chlorinated derivatives, which, by reason of their more sparing solubility than the simple benzoyl compounds, cannot be got rid of by crystallisation. The author instances a case of a benzoyl derivative which, after being several times recrystallised, was found to contain 1·5 per cent. of chlorine. A. R. L.

Benzoyl Compounds. By E. Hoffmann and V. Meyer (*Ber.*, **25**, 209—213).—Benzoic chloride frequently contains, in addition to chlorobenzoic chloride (compare preceding abstract), small quantities of benzaldehyde. The occurrence of the last-named compound is, perhaps, due to the fact that benzoic chloride is sometimes prepared commercially by treating benzotrichloride with lead or zinc oxide; commercial benzotrichloride contains a little benzal chloride, which, under these conditions, would be converted into benzaldehyde.

The presence of the benzaldehyde in benzoic chloride was discovered in studying the action of the chloride on very dilute ammonia; in addition to benzamide, the authors obtained a small quantity of benzylidenedibenzamide, $CHPh(NH\cdot COPh)_2$. F. S. K.

Oxidation Products of Paradibromohomocumic Acid. By M. Fileti and L. Boniscontro (*Gazzetta*, **21**, ii, 389—398).—By the oxidation of dibromohomocumic acid with potassium permanganate, Fileti and Basso (Abstr., 1891, 1057) obtained paradibromocumic and hydroxypropylparadibromobenzoic acids. The latter, when treated with hydrochloric acid, instead of giving rise to the unsaturated propenyldibromobenzoic acid, left a product undistinguishable from paradibromocumic acid. The authors have accordingly reinvestigated the subject.

Hydroxypropylparadibromobenzoic acid, $COOH\cdot C_6H_2Br_2\cdot CMe_2\cdot OH$ [$COOH : Br_2 : CMe_2\cdot OH = 1 : 2 : 5 : 4$]. Solutions of potassium permanganate (6·25 grams) in water (150 c.c.) and of dibromohomocumic acid (5 grams) in soda (150 c.c. of 4 per cent. solution) are gradually mixed, left on the water-bath for 12 hours, the excess of permanganate decomposed with a little alcohol, and the liquid concentrated and precipitated with hydrochloric acid in the cold. The precipitate consists of a mixture of dibromocumic and hydroxypropyldibromobenzoic acids, from which the latter may be dissolved out by boiling light petroleum. The other acid crystallises from a mixture of equal volumes of alcohol and water in prisms melting at 214—215°; it dissolves in alcohol, acetone, and methyl alcohol, sparingly in boiling chloroform and benzene, and not at all in water or light petroleum. The *barium* salt, $(C_{10}H_9Br_2O_3)_2Ba,2H_2O$, crystal-

lises in very soluble, lustrous prisms, becomes anhydrous at 100°, and at 150° loses a further quantity of water without blackening, and is partly converted into a salt of propenyldibromobenzoic acid. The *calcium* salt, with 3 mols. H_2O, crystallises in prisms, becomes anhydrous at 130°, and at 150° undergoes similar changes to the barium salt. The *magnesium* salt, with 5 mols. H_2O, crystallises in slender needles, which become anhydrous at 100°. The *acetyl* derivative [CMe_2·OAc = 4], prepared by the action of acetic chloride on the acid, crystallises from light petroleum in tufts of lustrous needles melting at 92°. It is decomposed by boiling with water, especially if acidified with acetic or hydrochloric acid.

Paradibromocumic acid, $C_6H_2PrBr_2$·COOH [COOH : Br_2 : Pr = 1 : 2 : 5 : 4], obtained in the preparation of the preceding compound, has already been described (Abstr., 1891, 1055). The *barium* salt, with 1 mol. H_2O, crystallises in long needles, which become anhydrous at 100°. The *calcium* salt forms tufts of microscopic crystals with 1 mol. H_2O; the *potassium* salt forms large, very soluble, tabular crystals; the *silver*, *lead*, and *copper* salts are insoluble. The *acid chloride* is a heavy liquid, decomposed by water; the *amide*, $C_{10}H_{11}Br_2ON$, crystallises from aqueous alcohol in needles melting at 191—192°, and is very soluble in alcohol, benzene, and chloroform, but only sparingly in light petroleum.

Parapropenylparadibromobenzoic acid, $C_6H_2Br_2Pr$,COOH, prepared by boiling hydroxypropyldibromobenzoic acid with hydrochloric acid [1 : 2] for three hours, crystallises in triclinic prisms resembling those of dibromocumic acid in appearance, and melting like them at 149°. It is very soluble in benzene, chloroform, ether, acetone, and acetic acid, but only very sparingly in boiling water. Contrary to what was stated previously, a solution of the acid in chloroform absorbs bromine at the ordinary temperature, no trace of hydrobromic acid being formed; the crude product melts between 120° and 140°. The *barium* salt crystallises in needles containing $2\frac{1}{2}$ mols. H_2O; the *calcium* salt forms acicular crystals with 3 mols. H_2O; both salts are more soluble in water than the corresponding dibromocumates. The *amide*, $C_{10}H_9Br_2ON$, crystallises in needles melting at 201—203°; it is very soluble in alcohol, benzene, and chloroform, but almost insoluble in light petroleum.

Mononitropropenyldibromobenzoic acid, NO_2·C_6HBr_2Pr·COOH, prepared by treating the preceding acid with a large excess of nitric acid (1·52), crystallises in needles, melts at 176—177°, dissolves readily in alcohol, ether, and acetone, and moderately in boiling water, but is almost insoluble in light petroleum. The corresponding derivative of dibromocumic acid melts at 199—200°.

S. B. A. A.

Paramethylhydratropic Acid. By G. Errera and G. Baldracco (*Gazzetta*, **21**, ii, 465—473).—Paramethylhydratropic acid and paramethylhydratropaldehyde, according to the constitution assigned to them by Miller and Rohde (Abstr., 1891, 898), and by Errera (Abstr., 1891, 1020), contain an asymmetrical carbon atom. The following attempts were made to split the acid and aldehyde into their active constituents.

A few grams of the acid and a little ammonia were added to a nutritive liquid containing 2·5 grams per litre of a mixture of potassium phosphate (50 parts), magnesium sulphate (48 parts), and calcium chloride (2 parts). The solution was then sown with *Penicillium glaucum* and left for a month at the ordinary temperature. Similar experiments were made with the aldehyde, acidifying the solution with a little phosphoric acid. No trace of vegetation was, however, observed in either case.

Negative results were also obtained from the following experiment. An alcoholic solution of quinine and paramethylhydratropic acid in molecular proportion, on evaporation, left a viscous oil which soon solidified. This, when fractionally crystallised from dilute alcohol, yielded beautiful, waxy needles, extremely soluble in alcohol, insoluble in water, and melting at 113—116°. The acid separated from different fractions of the salt never showed any deviation of polarised light.

Metadinitroparamethylhydratropic acid, $C_6H_2Me(NO_2)_2{\cdot}CHMe{\cdot}COOH$ [$CH : (NO_2)_2 : Me_2 = 1 : 2 : 6 : 4$ or $1 : 3 : 5 : 4$], is prepared by dissolving paramethylhydratropic acid in nitric acid (sp. gr. 1·52), cooled with water. On pouring the solution into water, the nitro-derivative separates as a flocculent precipitate or as an oil which immediately solidifies. The crude product is collected and dissolved in a little boiling benzene; hot petroleum (boiling at 80—110°) is now added until a permanent precipitate is almost formed. The nitro-derivative separates from this solution in large, straw-coloured, acicular crystals melting at 122—123°, and turning brown in the air. It is very soluble in benzene and alcohol, sparingly so in boiling water. When heated above its melting point, it deflagrates. Its *barium* salt, $(C_{10}H_9N_2O_6)_2Ba + 4H_2O$, is soluble in water and loses 2 mols. H_2O below 160°. The *methyl* salt is formed by saturating a solution of the acid in methyl alcohol with hydrogen chloride. It is a dense liquid which solidifies on cooling in a mixture of ice and salt.

Metadiamidoparamethylhydratropic acid is prepared by saturating an ammoniacal solution of the preceding acid with hydrogen sulphide. The solution thus obtained is heated, filtered from sulphur, and treated with dilute acetic acid, when the amido-acid separates as a grey, flocculent precipitate, very soluble in mineral acids and alkalis, sparingly so in the ordinary solvents.

Metadiamidoparamethylethylbenzene,

$C_6H_2MeEt(NH_2)_2$ [$Et : (NH_2)_2 : Me = 1 : 2 : 6 : 4$ or $1 : 3 : 5 : 4$],

is prepared by distilling the barium salt of the preceding acid with baryta. The oily liquid thus obtained soon solidifies and crystallises from water in colourless, rhombic laminæ, which turn slightly brown on exposure to light. It melts at 71—72°, boils at about 300°, and is very soluble in alcohol, sparingly so in water. Its aqueous solution is precipitated by alkalis. The *hydrochloride*, *sulphate*, and *oxalate* are very soluble in water. The base does not yield an insoluble phenanthrazine when boiled with phenanthraquinone and acetic acid in alcoholic solution, and is, therefore (Hinsberg, *Annalen*, **237**, 342), not an orthodiamine. On heating

the hydrochloride at 120° with ammonium thiocyanate, extracting with water, dissolving the residue in potash solution, and adding lead acetate, a precipitate of lead sulphide is obtained. This reaction is common to both meta- and para-diamines (Abstr., 1885, 976). The hydrochloride, however, evolves hydrogen chloride on heating at 100—120° with benzaldehyde. This is Ladenburg's reaction for orthodiamines (Abstr., 1878, 571), but has been shown by Lellmann (Abstr., 1885, 973) not to hold universally. On treating an aqueous solution of the base with diazobenzene nitrate, a yellow precipitate, which dissolves to a red solution on adding excess of acid, is obtained. This reaction shows that the base is a metamido-derivative, but the position of the amido-groups, with respect to the methyl group, could not be determined. W. J. P.

Action of Nitric Acid on Phenylglycollic Acid. By I. Pratesi (*Gazzetta*, **21**, ii, 402—404).—On nitrating phenylglycollic acid with fuming nitric acid (44° B.) in the ordinary way, a mixture of two nitro-derivatives may, contrary to Fritzsche's statement (*Jahresb. der Chem.*, 1879, 694), be separated with ease. By fractional crystallisation from alcohol and water, this is split up into paranitrophenylglycollic acid melting at 183° and a compound melting at 141—142°. The latter consists of a mixture of the orthonitro-acid melting at 156·5° and of the para-acid. This is shown by the identity of its reduction products with those of such a mixture, by the fractional crystallisation and decomposition of the mixed barium salts, and by acting on the mixture melting at 141—142° with potash, acidifying, and distilling, when orthonitrophenol passes over, and paranitrophenol remains in the residue. If the nitration is performed with nitric acid of 48° B., orthoparadinitrophenylglycollic acid is formed. S. B. A. A.

α-Methylphthalic Acid. By S. v. Niementowski (*Monatsh.*, **12**, 620—636).—The author has prepared homophthalonitrile according to Glock's method (Abstr., 1888, 1290), and finds that its melting point is 120°, that is, 3° higher than given by that author. On heating the nitrile (3 grams) with hydrochloric acid of sp. gr. 1·19 (16 grams) for three hours at 140° in sealed tubes, *α-methylphthalic acid* was obtained. The pure acid melts at 152°, is readily soluble in water, alcohol, ethyl acetate, and acetone, is dissolved sparingly by chloroform and benzene, but crystallises well from hot xylene. On dry distillation, it loses water, and is converted into the corresponding *anhydride*, $C_6H_3Me{:}C_2O_2{:}O$, which dissolves readily in most of the common organic solvents, crystallises in needles, melts at 92°, and, on heating with water, is reconverted into the acid.

α-Methylphthalimide, $C_6H_3Me{:}C_2O_2{:}NH$, is formed on heating a mixture of α-methylphthalic anhydride (2 mols.) and carbamide (1 mol.). It is soluble in boiling water and in acetone, crystallises from spirit in short needles, and melts at 196°.

α-Methylphthalodiamide, $C_6H_3Me(CONH_2)_2$, is obtained by the action of strong ammonia on α-methylorthophthalimide. It is readily solu-

ble in water, crystallises in needles, and melts at 188° with evolution of ammonia.

Paratolyl-α-methylphthalimide, $C_6H_3Me{:}C_2O_2{:}N{\cdot}C_6H_4Me$ [N : Me = 1 : 4], is formed on heating a mixture of α-methylorthophthalic acid with paratoluidine in molecular proportion. It is insoluble in water, dissolves readily in cold chloroform, benzene, and ethyl acetate, forms colourless crystals, and melts at 180°.

α-Methylhydroxyphthalanil, $C_6H_3Me{:}C_2O_2{:}N{\cdot}C_6H_4{\cdot}OH$ [N : OH = 1 : 3], is obtained by the action of orthoamidophenol on α-methyl orthophthalic anhydride in molecular proportion. It dissolves in alcohol, from which it crystallises in groups of colourless, six-sided scales, and melts at 205°.

α-Methylhydroxyphthalanilic acid, $COOH{\cdot}C_6H_3Me{\cdot}CO{\cdot}NH{\cdot}C_6H_4{\cdot}OH$, is formed when the preceding compound is boiled with soda, and the filtered solution is acidified with hydrochloric acid. It is insoluble in water, dissolves in hot spirit, acetone, and solutions of the alkalis and of the alkali carbonates, crystallises in slender, white needles, and melts at 200°, with evolution of gas and formation of the corresponding anhydride. G. T. M.

Action of Ethyl Acetoacetate on Quinone: Synthesis of Benzofurfuran Derivatives. By M. Ikuta (*J. pr. Chem.* [2], **45**, 65—83).—When chloranil is treated with ethyl acetoacetate, one or two chlorine atoms are replaced by the acetoacetate group, and from the mono- and di-substitution products thus obtained, a number of furfuran derivatives can be synthesised.

Ethyl trichloroquinoneacetoacetate, $C_6Cl_3O_2{\cdot}C_6H_9O_3$, is obtained as follows:—Ethyl acetoacetate (10 grams) is dissolved in benzene (100 c.c.), and converted into the sodium compound by the addition of sodium wire: finely powdered chloranil (18 grams) is then gradually added to the emulsion with careful shaking. The mixture turns blue, then dark-green, and finally brown, and the reaction is completed by warming on the water-bath or by allowing the mixture to remain some hours in the cold. The product is filtered, the benzene distilled off, and the dark orange oil thus obtained, which consists of a mixture of ethyl acetoacetate and the mono- and di-acetoacetate derivatives of chloranil, is mixed with a little alcohol, and, on stirring it with a glass rod, is obtained crystalline. By crystallisation from alcohol, large, orange rhombohedra of ethyl dichloroquinonediacetoacetate are obtained, and can be easily separated mechanically. The red monacetoacetate is then recrystallised from alcohol until it melts at 14°. It is easily soluble in benzene, chloroform, and hot alcohol, more sparingly in acetic acid, and least so in ether. It dissolves in alkalis and ammonia with a blue coloration, which soon changes to orange-yellow; the alcoholic solution gives a blood-red coloration with ferric chloride. With aniline, it yields a colourless additive product, melting at 146°, and with fuming nitric acid a yellow, very unstable substance. By reducing agents, it is easily converted into the corresponding quinol.

Ethyl trichloroquinolacetoacetate, $C_6Cl_3(OH)_2{\cdot}C_6H_9O_3$, is obtained by adding zinc-dust and sulphuric acid in small quantities at a time to a

solution of the preceding compound in 6 parts of alcohol. The product is precipitated with water and crystallised from benzene. It forms colourless rhombohedra, melts at 132°, is sparingly soluble in most organic solvents in the cold, dissolves in alkalis with a pale-yellow colour, which soon changes to dark-green, and then to yellow, and easily loses the elements of water, being converted into a benzofurfuran derivative.

Ethyl trichloroparahydroxybenzofurfuran-α-methyl-β-carboxylate,

$$OH\cdot C_6Cl_3<\begin{matrix}\text{——O——}\\ C(COOEt)\end{matrix}>CMe,$$

is obtained by boiling the above quinol derivative with 10 parts of acetic acid containing a few drops of concentrated sulphuric acid until it no longer gives a coloration with alcoholic ferric chloride. On dilution with a small quantity of water, it separates in colourless, transparent needles. It melts at 138°, is easily soluble in chloroform, less so in alcohol, ether, and cold acetic acid, gives no coloration with ferric chloride, yields a colourless solution in alkalis, and is easily hydrolysed by alcoholic potash. When warmed with concentrated sulphuric acid, it gives a dark, reddish-blue coloration. The author points out that Hantzsch's method of synthesis (*Ber.*, **19**, 1292, 2930, **20**, 1332) yields α-ethylcarboxylate-β-methyl derivatives, whilst the above synthesis yields α-methyl-β-ethylcarboxylate derivatives.

Trichloroparahydroxybenzofurfuran-α-methyl-β-carboxylic acid is obtained by heating the preceding ethyl salt with twice the calculated quantity of alcoholic potash. It crystallises from acetic acid in colourless, transparent needles, melts at 258°, distils without decomposition, and behaves like its ethyl salt towards organic solvents, concentrated sulphuric acid, and alkalis.

Ethyl paradichloroquinonediacetoacetate, $C_6Cl_2O_2(C_6H_9O_3)_2$, is prepared in the same way as the monacetoacetate, except that double the proportion of ethyl sodacetoacetate is used. It crystallises in pure yellow rhombohedra or in rhombic tablets, melts at 127—128°, is easily soluble in benzene and chloroform, less so in alcohol, acetic acid, and ether. In dilute alkalis, it dissolves with a deep bluish-violet coloration, which soon changes to brown. With sodium nitrite, it yields a compound which crystallises in yellow prisms, melts at 184°, and contains chlorine and nitrogen. Fuming nitric acid converts it into a very unstable yellow substance. With ferric chloride, it gives a deep blood-red coloration. It yields additive compounds with great ease.

Ethyl paradichloroquinoldiacetoacetate is obtained by reducing the preceding compound. It crystallises from benzene in transparent, colourless rhombohedra, melts at 154°, resembles ethyl trichloroquinolacetoacetate in its behaviour towards ferric chloride, alkalis, and solvents, and easily loses 2 mols. of water yielding a furfuran derivative.

Diethyl paradichlorobenzoparadifurfuran-α-dimethyl-β-dicarboxylate, $C_6Cl_2(<\begin{matrix}\text{——O——}\\ C(COOEt)\end{matrix}>CMe)_2$, is obtained in theoretical quantity by boiling the preceding quinol derivative with acetic acid containing a

few drops of concentrated sulphuric acid. It crystallises from acetic acid in transparent needles, melts at 175°, is insoluble in alkalis, gives a deep bluish-green coloration with concentrated sulphuric acid, is sparingly soluble in most organic solvents with the exception of chloroform, and, when treated with chlorine in chloroform solution, yields a pale-yellow, oily additive product which is converted into the original substance by reduction with zinc-dust and acetic acid.

Paradichlorobenzoparadifurfuran-α-dimethyl-β-dicarboxylic acid is obtained by heating its diethyl salt with twice the theoretical quantity of alcoholic potash on the water-bath. On distilling off the alcohol and adding water, and then acetic acid, the acid is obtained as a white, crystalline powder consisting of microscopic needles. It sublimes at high temperatures without melting, is quite insoluble in water and organic solvents, and gives a bluish-green solution with concentrated sulphuric acid.

Additive Products of Ethyl Paradichloroquinonediacetoacetate.—If the diacetoacetate is treated with bromine (1 mol.) in chloroform solution, the bromine is completely absorbed without the evolution of hydrogen bromide, and a colourless compound is obtained which crystallises in leaflets and melts at 216°. The author believes this compound to be a *dibromide* mixed with some tetrabromide. It is volatile without decomposition, and when treated with zinc-dust and acetic acid, or with zinc-dust and dilute sulphuric acid, yields diethyl dichlorobenzodifurfurandimethyldicarboxylate.

Diethyl quinoneparadifurfuran-α-dimethyl-β-dicarboxylate hydrochloride is obtained by warming ethyl dichloroquinonediacetoacetate with 3 parts of acetic acid (95 per cent.) containing a few drops of dilute sulphuric acid (1 : 5) until the orange solution has become nearly colourless. On diluting with water, it is obtained in oily drops which soon solidify. It crystallises from a mixture of chloroform and ether in stellate groups of leaflets or short prisms, melts at 171°, sublimes without decomposition, is easily soluble in organic solvents, insoluble in water and carbonates, and gives a deep-blue coloration when warmed with concentrated sulphuric acid. When heated with alcoholic potash, the *bibasic acid*, $C_{14}H_{10}Cl_2O_8$, is obtained. This crystallises from hot water in colourless needles, and decomposes at 220° with evolution of carbonic anhydride.

v. Pechmann (*Ber.*, **21**, 3005) has described a condensation product, obtained by the action of zinc chloride on a mixture of quinone and ethyl acetoacetate, which yields a bibasic acid on hydrolysis. He gives the formulæ $C_{16}H_{16}O_6$ and $C_{14}H_{12}O_6$ respectively for these compounds. The author has studied the above reaction, and finds that these compounds have the formulæ $C_{18}H_{18}O_6$ and $C_{14}H_{10}O_6$ respectively.

Ethyl benzoparadifurfuran-α-dimethyl-β-dicarboxylate,

$$C_6H_2(<\overline{\underline{\quad O \quad}}\!\!>\!\!C(COOEt)\!\!>CMe)_2,$$

is obtained by heating quinone (1 mol.) with alcohol and ethyl acetoacetate (2 mols.) in the presence of zinc chloride, as suggested by v. Pechmann, who has accurately described the properties of the

compound. The alcoholic mother liquors contain quinol and a new substance of the formula $C_{12}H_{12}O_4$. The above constitution is proved by the fact that, when treated with chlorine, the compound yields a dichlorinated compound which is identical with the diethyl para-dichlorobenzoparadifurfuran-α-dimethyl-β-dicarboxylate described above. When hydrolysed with alcoholic potash, it yields the corresponding dicarboxylic acid, $C_{14}H_{10}O_6$.

Ethyl parahydroxybenzofurfuran-α-methyl-β-carboxylate,

$$OH\cdot C_6H_3<\begin{matrix}\text{——O——}\\ C(COOEt)\end{matrix}>CMe,$$

is contained in the alcoholic mother liquors from the preparation of the preceding compound. It is best obtained by treating quinone (1 mol.) and ethyl acetoacetate (1 mol.) in alcoholic solution with zinc chloride. The insoluble compound, $C_{18}H_{18}O_6$, is separated, and the filtrate allowed to evaporate spontaneously. It crystallises from petroleum (b. p. 70—80°) in colourless leaflets or flat needles, melts at 137°, is insoluble in water, soluble in alkalis, easily soluble in most organic solvents except light petroleum, and gives a purple-red coloration with concentrated sulphuric acid. E. C. R.

Trithioorthoformates. By E. Laves (*Ber.*, **25**, 347—360; compare Abstr., 1890, 988).—Phenyl trithioorthoformate is dissolved in benzene and treated with a mixture consisting of equal parts of 5 per cent. potassium permanganate solution and dilute sulphuric acid (2 per cent.); the liquid is well shaken and cooled, and the permanganate added in excess; the precipitated manganese dioxide is dissolved by sulphurous acid, and the sparingly soluble diphenylsulphonethiophenylmethane collected, dried, and purified by solution in chloroform and precipitation with ether. The properties of the compound have been previously described; on heating with soda and phenyl thiochloride, methyldiphenylsulphone and phenyl bisulphide are formed; with concentrated nitric acid, an oxidation product is obtained, which melts at 160° and contains nitrogen. The trisulphone, $CH(SO_2Ph)_3$, is formed by the oxidation of the disulphone sulphide with potassium permanganate in alkaline solution, and crystallises from alcohol or chloroform in colourless, rhombic plates. It has well-marked acid properties, and in aqueous solution reddens litmus paper and decomposes carbonates and acetates; it may be crystallised from concentrated sulphuric acid.

The *sodium salt* is readily soluble in water; the *potassium salt*, $CK(SO_2Ph)_3$, crystallises from dilute alcohol in small plates; the *silver salt* is obtained in long, thick, lustrous needles, which quickly decompose on exposure to light. The *barium* salt is deposited in rhombic plates.

Triphenylsulphonechloromethane, $CCl(SO_2Ph)_3$, is prepared by the action of chlorine on the sulphone in aqueous solution at ordinary temperatures; it is a colourless, amorphous, insoluble powder, melting at 260°; on heating with alcoholic soda, it decomposes into the trisulphone, benzenesulphonic acid, and carbonic anhydride.

The *bromo*-derivative, $CBr(SO_2Ph)_3$, is formed by the addition of bromine-water to a solution of the trisulphone; it melts at 255° with

decomposition, and resembles the chlorine compound in general properties, but is more unstable.

Triphenylsulphonemethylmethane, $CMe(SO_2Ph)_3$, may be obtained in small quantity by heating methyl iodide and alcoholic soda with triphenylsulphonemethane in a sealed tube at 115°, but is best prepared by the oxidation of phenyl trithioacetate (see below) with potassium permanganate in acid solution; it crystallises from alcohol in colourless, lustrous needles, melts at 182°, is insoluble in water or alkalis, and is not acted on by acids; with alkaline oxidising agents, benzenesulphonic acid and acetic acid are formed.

Trithiophenyl orthorthioacetate, $CMe(SPh)_3$, is obtained by the interaction of phenyl mercaptan (3 mols.) and ethenyl trichloride (2 mols.) in alkaline solution; it crystallises from alcohol in small, colourless, lustrous plates melting at 71·5°; the yield is quantitative. The compound gives a violet coloration with concentrated sulphuric acid, and is oxidised by nitric acid, but is not acted on by alkalis or dilute acids.

Triethyl orthothioacetate, $CMe(SEt)_3$, is prepared in a similar manner to the phenyl derivative by the mutual action of ethenyl trichloride, ethyl mercaptan, and soda, and is a brown, viscid liquid with an offensive smell; on oxidation, it yields the corresponding *trisulphone*, $CMe(SO_2Et)_3$, which crystallises in lustrous needles melting at 140°. On heating phenyl mercaptan with benzenyl trichloride and soda at 115° under pressure, a viscid liquid is obtained which, on oxidation, yields *benzylidenediphenylsulphone*, $CHPh(SO_2Ph)_2$, together with phenyl bisulphide and benzoic acid; the product is purified by extraction with soda and precipitation with carbonic anhydride, and crystallises from alcohol in small, colourless needles which melt at 262°; the same compound is also formed by the oxidation of phenyl mercaptan; it has feebly acid properties, is decomposed on heating with concentrated sulphuric acid, and does not yield haloïd substitution derivatives.

The product obtained from ethyl mercaptan, benzenyl trichloride and soda yields diethylsulphonephenylmethane, $CHPh(SO_2Et)_2$, on oxidation.

Benzyl trithioformate on oxidation yields a mixture of *dibenzylsulphonemethane*, $CH_2(SO_2C_7H_7)_2$, and *dibenzylsulphonethiobenzylmethane*, $C_7H_7{\cdot}S{\cdot}CH(SO_2C_7H_7)_2$, which may be separated by fractional crystallisation from chloroform; the former is readily soluble and is precipitated on the addition of ether as a colourless, amorphous powder which melts at 207·5°, dissolves readily in alcoholic soda, and is identical with the oxidation product of *methylene dibenzyl sulphide*, $CH_2(SC_7H_7)_2$. The disulphone sulphide is more sparingly soluble in chloroform, and crystallises from dilute acetic acid in small needles melting at 214°; it is not converted into a trisulphone by the action of alkaline permanganate.

Tribenzyl orthothioacetate, $CHMe(SC_7H_7)_3$, is formed by heating benzyl mercaptan (3 mols.) dissolved in soda (20 per cent.), with ethenyl trichloride (2 mols.) under pressure for five days at 115°; it is deposited from benzene at low temperatures in lustrous crystals which melt at 46°.

Benzylsulphonethiobenzylmethylmethane, $C_7H_7{\cdot}S{\cdot}CHMe{\cdot}SO_2{\cdot}C_7H_7$, is extracted from the oxidation product of the preceding compound by treatment with alcohol; it crystallises in colourless needles, melts at 151°, and is decomposed by sulphuric or nitric acid.

Tribenzylsulphonemethylmethane, $CMe(SO_2C_7H_7)_3$, is the chief compound obtained by the oxidation of the corresponding sulphide; it is sparingly soluble in alcohol, but readily dissolves in acetic acid, and crystallises from chloroform in slender needles melting at 218°.

The compound obtained from benzenyl trichloride and sodium benzylmercaptan could not be purified; on oxidation, *dibenzylsulphonephenylmethane*, $CHPh(SO_2C_7H_7)_2$, is formed, and is separated from the following compound by solution in alcoholic soda; it melts at 213°. *Tribenzylsulphonephenylmethane*, $CPh(SO_2C_7H_7)_3$, is readily soluble in chloroform, and crystallises in slender needles melting at 207°. The yield is very small. The above results show that the behaviour of trithioformates and trithioacetates towards oxidising agents is not identical; in presence of phenyl groups, the latter compounds yield trisulphone sulphides, whilst in presence of ethyl groups, disulphones are formed; in the case of the benzyl derivatives of trithioformic acid, disulphones and disulphone sulphides are formed, but benzyl trithioacetate yields a trisulphone together with bye-products different from those obtained by the oxidation of other trithioacetates.

J. B. T.

Formation of Trisulphones from Disulphones. By E. Laves (*Ber.*, **25**, 361—366).—*Diethylsulphonethiophenylmethylmethane*, $SPh{\cdot}CMe(SO_2Et)_2$, is prepared by heating diethylsulphonethiophenylmethane with methyl iodide and alcoholic soda in a sealed tube for two days at 90°; it crystallises from alcohol in colourless needles, melts at 113°, and is insoluble in alkalis at ordinary temperatures, and on heating yields acetic acid, sulphuric acid, ethylsulphonic acid, and phenyl bisulphide.

Diethylsulphonephenylsulphonemethane has previously been described by Fromm; it has well-marked acid properties, and decomposes carbonates and acetates; the *potassium salt*, $SO_2Ph{\cdot}CK(SO_2Et)_2$, crystallises from dilute alcohol in small prisms; the *barium salt* is deposited in rhombic plates.

Diethylsulphonephenylsulphonechloromethane, $SO_2Ph{\cdot}CCl(SO_2Et)_2$, is formed by the action of chlorine on the trisulphone in aqueous solution at the ordinary temperature; it crystallises from alcohol in small, lustrous plates melting at 130°.

The *bromo-derivative* is prepared in a similar manner to the preceding compound, which it closely resembles; it melts at 135°, crystallises from alcohol in lustrous scales, from water in slender needles, and from benzene in thick plates.

Diethylsulphonephenylsulphonemethylmethane, $SO_2Ph{\cdot}CMe(SO_2Et)_2$, could not be obtained from the preceding trisulphone, but is formed by the partial oxidation of diethylsulphonethiophenylmethylmethane, $SPh{\cdot}CMe(SO_2Et)_2$; it is purified by solution in chloroform and precipitation with ether, and crystallises from water in slender, white needles melting at 109°.

Attempts to introduce mercaptan or sulphone groups into the tri-

sulphone molecule were unsuccessful. Attempts to prepare a tetrasulphone by the action of sodium on haloïd trisulphones and of phenyl thiochloride on trisulphonates was also attended with negative results.

J. B. T.

Action of Methyl Iodide on α-Methylindole. By C. Zatti and A. Ferratini (*Gazzetta*, **21**, ii, 309—330; compare Abstr., 1891, 311).—It was shown by Ciamician and Zatti (Abstr., 1889, 1187), and by the authors (Abstr., 1890, 1292), that indole, on methylation, undergoes similar changes to pyrroline, the product being presumably a trimethyldihydroquinoline. The same product was also obtained from α- and β-methylindole and from αβ-dimethylindole (Abstr., 1889, 58, and 1890, 1431), but its constitution was not definitely ascertained.

The experiments which the authors made to prepare from the supposed trimethyldihydroquinoline a quinoline derivative of known composition were unsuccessful. On distilling the hydriodide with zinc powder, the principal product consists of trimethyltetrahydroquinoline; but above 300° an oily product of unknown composition passes over. On treating the base with sodium nitrite, a base of unknown composition is formed; this melts at 118° with decomposition, and may be converted into trimethyltetrahydroquinoline by reduction. Treatment with nitric acid gives rise to an amorphous, yellow substance which melts at 199—200°, and deflagrates when heated on platinum foil. By the action of an ethereal solution of bromine, the compound $C_{12}H_{15}NBr_2$ is obtained in tufts of large, yellow crystals which melt in a closed tube at 165—166°, but sublime and decompose at 172—173° in an open vessel. It is rapidly decomposed by warm water, but dissolves readily in the cold. The *platinochloride*, $(C_{12}H_{14}BrN)_2,H_2PtCl_6$, melts at 173—174°. *Trimethyldihydroquinoline* is unaffected by heating with hydrochloric or hydriodic acid at 180°, but a mixture of hydriodic acid and amorphous phosphorus converts it into a feebly basic compound which distils between 228° and 233°, and does not redden on exposure to the air. It yields a *nitrosamine* which gives Liebermann's reaction, and by the action of reducing agents is converted into a *dimethyltetrahydroquinoline*, $C_9NH_9Me_2$. This distils between 232° and 242° under a pressure of 758 mm., and forms an unstable *platinochloride*, which begins to decompose at 160° and melts at 192—195°. By the action of hydriodic acid and phosphorus, trimethyldihydroquinoline, therefore, loses the methyl group attached to the nitrogen, and is converted into a secondary base containing dimethyltetrahydroquinoline. On heating the latter with methyl iodide, trimethyltetrahydroquinoline methiodide is formed, together with small quantities of a product melting at 209°.

Dihydrotrimethylindole methiodide, $C_6H_4<\begin{matrix}CHMe\\NMe_2I\end{matrix}>CHMe$, prepared from dihydro-αβ-dimethylindole for comparison with the preceding bye-product, forms a white, crystalline mass, very soluble in alcohol, and melts with decomposition at 167—168° in a closed vessel, and at 170—171° in an open tube.

As no known quinoline derivative was isolated in the above experiments, an attempt was made to establish that the reduction product

of trimethyldihydroquinoline had the properties of a tetrahydroquinoline by comparing the reactions of the two compounds. No colouring matter is formed by trimethyldihydroquinoline, either on treatment with diazobenzene chloride or with zinc chloride, benzaldehyde, and ferric chloride; in the latter case, the yellow compound described by Fischer and Steche (Abstr., 1888, 298) may be isolated. On treating trimethyltetrahydroquinoline with amyl nitrite according to Baeyer and Caro's method, the *nitroso*-derivative, $NO{\cdot}C_9NH_7Me_3$, is formed; the corresponding *picrate* crystallises in shining, brownish-green scales which melt at 141—142° with decomposition. With zinc chloride, benzaldehyde, and ferric chloride, it yields an intensely green compound with a blue metallic reflex. With diazobenzene chloride, a compound is obtained of a deep violet colour with a metallic reflex; the *hydrochloride* of the azo-base forms large, deliquescent, violet crystals; the *picrate* crystallises in reddish-violet, rhomboïdal tables, which commence to decompose at 158°, and melt at 170°. The authors are of opinion that the analogies between the reactions of trimethyltetrahydroquinoline and the substituted aniline compounds, with sodium nitrite, diazobenzene chloride, and benzaldehyde sufficiently prove that the base is a tetrahydrogenated quinoline.

Pentamethyldihydroquinoline hydriodide, $C_{14}H_{20}NI$, prepared by heating trimethyldihydroquinoline with methyl iodide and previously described by the authors, melts at 173° with decomposition. The base is a light oil which reddens on exposure to the air and boils at 270° under a pressure of 762 mm. It forms no colouring matter with diazobenzene chloride or benzaldehyde. On heating its hydrochloric acid solution with picric acid, a yellowish, uncrystallisable oil is formed; a hydrochloric acid solution of ferric chloride produces an orange-yellow crystalline precipitate closely resembling that obtained from trimethyldihydroquinoline. It yields an unstable *aurochloride* and *platinochloride*.

Pentamethyltetrahydroquinoline, $C_9NH_6Me_5$, is obtained by reducing the hydriodide of the preceding base with tin and hydrochloric acid. It is a colourless, oily liquid which is unaffected by exposure to the air, and boils at 253—254° under a pressure of 759 mm. The *picrate* crystallises from alcohol in yellow scales which melt at 132—133°. With diazobenzene chloride, &c., the base behaves like tetrahydroquinoline and its trimethyl derivative.

On heating pentamethyldihydroquinoline with excess of methyl iodide, a methiodide, $C_6H_4{:}C_3NMe_5,MeI$ is formed, which melts with decomposition at 174—175°. It is hydrolysed by potash with the formation of a new base. The latter may be distilled in a current of steam, and forms a heavy, semi-solid mass which is not reddened by the air and is feebly alkaline to litmus paper. It is insoluble in water, but dissolves in ether and readily in acids forming the salts corresponding with the methiodide. The *platinochloride*, $(C_{15}H_{21}N)_2,H_2PtCl_6$, crystallises in tufts of yellow needles, and melts at 175—176°; the *aurochloride*, $C_{15}H_{21}N,HAuCl_4$, forms yellow needles melting at 144—145°. This base, which may be regarded as the oxide or hydroxide of a quaternary ammonium, differs from the other non-hydrogenated alkaloïds derived from the indoles in its marked basic properties

and its indifference to the action of the air. On heating it with gaseous hydriodic acid, the methiodide is not re-formed, the product melting at 183°. It appears to be incapable of further methylation, as, on heating with methyl iodide, pentamethyldihydroquinoline methiodide is reproduced. S. B. A. A.

Carbazole. By G. Mazzara and A. Leonardi (*Gazzetta*, **21**, ii, 380—388).—It has been previously shown (Abstr., 1891, 570) that on treating benzoylcarbazole with fuming nitric acid, a mononitrobenzoylcarbazole is formed, which, on hydrolysis by treatment with potash, yields a mononitrocarbazole melting at 209°.

Amidocarbazole, $NH<^{C_6H_4}_{C_6H_3\cdot NH_2}$, prepared by reducing the nitro-compound with tin and hydrochloric acid, when pure crystallises from alcohol in tufts of minute, rose-coloured scales, which turn reddish-brown on exposure to the air. From chloroform, it separates in thin, transparent, colourless plates; it is only sparingly soluble in ether, and moderately in chloroform, but freely so in acetic acid or benzene. When heated in a capillary tube, it turns brown at 220°, and decomposes at 240—245°. When heated rapidly, it becomes discoloured at 235°, and melts at 246—248° with decomposition. With tin chloride, the hydrochloride yields the *salt*, $(C_{12}H_{11}N_2)_2,H_2SnCl_6$, which crystallises in yellowish-white, lustrous scales. The *platinochloride*, $(C_{12}H_{11}N_2)_2,H_2PtCl_6$, is a brownish-green powder which is decomposed on washing.

Benzilidenamidocarbazole, $NH<^{C_6H_4}_{C_6H_3\cdot N:CHPh}$, is prepared by heating amidocarbazole with benzaldehyde at 120—140°; the product, when pure, crystallises from alcohol in somewhat greenish-yellow, lustrous scales, and from light petroleum in clear, yellow needles, melts at 209—210°, dissolves freely in benzene and moderately in ether. On boiling it with dilute hydrochloric acid, it is easily decomposed into benzaldehyde and amidocarbazole hydrochloride.

Benzoylamidocarbazole, $NH<^{C_6H_4}_{C_6H_3\cdot NHBz}$, is prepared by heating amidocarbazole and benzoic anhydride in molecular proportions at 160—200°. After purification by precipitating the alcoholic solution with dilute potash, and by repeated crystallisation from alcohol and concentrated acetic acid, it crystallises in leaden-grey plates with a metallic lustre, and melts at 250—251°.

Acetylamidocarbazole, $NH<^{C_6H_4}_{C_6H_3\cdot NHAc}$, is prepared by heating together amidocarbazole with acetic anhydride in molecular proportion. When pure, it crystallises in translucent, white plates, with a pale, pinkish tinge, melts at 213—214°, and dissolves very readily in concentrated acetic acid. It is not affected by prolonged boiling with methyl iodide.

Acetylamidonitrosocarbazole, $NO\cdot N<^{C_6H_4}_{C_6H_3\cdot NHAc}$, prepared by

treating an acetic acid solution of the preceding compound with potassium nitrite, separates from alcohol as a yellowish, crystalline powder, and melts with decomposition at 162—164°. It dissolves in concentrated acetic acid, and sparingly in benzene and light petroleum. It also dissolves in concentrated sulphuric acid, forming a bright-green solution. On heating it with an aqueous solution of stannous chloride, the acetamido-derivative is re-formed. The formation of the nitroso-derivative shows that the acetyl group is connected with the amido-group in these compounds. From the above experiments, it further appears that the amido-group in these compounds is not in the ortho-position with regard to the imido-group.

On treating a glacial acetic acid solution of amidocarbazole with a well-cooled solution of diazobenzene chloride, the product, after purification, crystallises from light petroleum in minute, pale-yellow prisms, and melts at 228—230°. It is very soluble in chloroform and benzene, but only sparingly in ether and light petroleum. It probably has the constitution of diazobenzeneamidocarbazole,

$$NH<\begin{matrix}C_6H_4\\ |\\ C_6H_3\cdot NH\cdot N_2Ph\end{matrix}$$

Carbazacridines. III. Dehydration of Amides in contact with Diphenyl Derivatives. By D. Bizzari (*Gazzetta*, **21**, ii, 351—359).—The analogy between diphenylene oxide and carbazole rendered it probable that if diphenylene oxide were an ortho-derivative, the substitution of amidogen or an amido-group for oxygen would result in the formation of a carbazole derivative, which might be converted by dehydration into a carbazacridine derivative. When, however, acetamide and diphenylene oxide are heated with excess of phosphoric anhydride and zinc chloride, the diphenylene oxide remains in great part unaltered, only small quantities of resinous products being formed.

On heating carbazole (8 grams), acetamide (4 grams), and dry phosphoric anhydride (7 grams) at 150—160°, the products consist of methylcarbazacridine, together with unaltered carbazole, resinous products, and traces of ethyl acetate. When carbazole is heated with benzamide and phosphoric anhydride at 150°, phenolcarbazacridine is formed together with a little benzonitrile. The formation of the carbazacridines may be supposed to occur in two stages, the first product being an asymmetric amidine of the type NH:CR′·N:R″, which subsequently loses ammonia, thus

$$NH{:}CPh\cdot N<\begin{matrix}C_6H_4\\ |\\ C_6H_4\end{matrix} - NH_3 = \begin{matrix}C_6H_5\cdot C\!\!-\!\!C_6H_3\\ \quad\diagdown\diagup\\ \quad N\!\!-\!\!C_6H_3\end{matrix}.$$

That amidines of the above composition are formed under these conditions may be shown by heating diphenylamine, acetamide, and dry phosphoric anhydride at 150° for 10 hours, when among the products a compound occurs which melts at 64°, and has approximately the properties of Bernthsen's ethenylisodiphenylamidine (Abstr., 1878, 788). Similarly, benzenylisodiphenylamidine is formed on heating benzamide, diphenylamine, and phosphoric anhydride for 21 hours at 170—180°. It is improbable that the formation of the

carbazacridines is due to the action of carbazole on the acids liberated from amides by phosphoric anhydride, as under the circumstances mere traces of acid are formed, which would be without influence on the result. S. B. A. A.

Paradiamidodiphenylmethane. By J. Gram (*Ber.*, **25**, 302—304).—Paradiamidodiphenylmethane (m. p. 85°) is now prepared by heating anhydroformaldehydeaniline with aniline and aniline hydrochloride (D.R.-P. 53,937), and is employed in the production of pararosaniline and rosaniline, which are formed when it is heated with aniline or 1 : 2-amidotoluene in the presence of an oxidising agent. The diacetyl derivative agrees with Staedel and Haase's description (Abstr., 1883, 990); whilst the *dibenzylidene* derivative, $C_{27}H_{22}N_2$, prepared by adding benzaldehyde to an alcoholic solution of the base, melts at 125. A *dinitro*-derivative, $C_{17}H_{16}N_4O_6$, is obtained when the acetyl derivative is dropped into nitric acid, sp. gr. 1·48 (5 parts); it forms lemon-yellow needles, melts above 300°, and is sparingly soluble in alcohol and benzene, less so in ether and water, readily soluble in phenol, and somewhat sparingly in glacial acetic acid. It is hydrolysed when heated with aqueous potassium hydroxide and a little alcohol, with the formation of *metadinitroparadiamidodiphenylmethane*, which crystallises from a mixture of phenol and alcohol in small, red needles, and melts at 224°; its reduction product yields azines with orthodiketones. *Orthodinitroparadiamidodiphenylmethane* is produced by nitrating paradiamidodiphenylmethane, dissolved in a large quantity of concentrated sulphuric acid, with potassium nitrate (2 mols.); the compound is precipitated by ammonia, dissolved in boiling dilute hydrochloric acid, reprecipitated by ammonia, and crystallised from dilute alcohol, being thereby obtained in lustrous, golden leaflets, melting at 202°; the *hydrochloride* crystallises in colourless needles, and is partially dissociated on heating at 100°, and also by the presence of a large excess of water. The research is being continued.

A. R. L.

Dicyanostilbene. By L. Chalanay and E. Knoevenagel (*Ber.*, **25**, 285—288).—In view of the fact that bidesyl and isobidesyl can be obtained from deoxybenzoïn (Knoevenagel, Abstr., 1888, 706), it seemed of interest to ascertain whether benzyl cyanide could in an analogous manner be converted into diphenylsuccinonitrile.

When benzyl cyanide (1 mol.) is added to a solution of sodium (1 equivalent) in alcohol (10 parts), the whole diluted with an equal volume of ether, and iodine (1 equivalent) dissolved in ether slowly dropped into the cooled liquid with shaking, a small quantity of dicyanostilbene, melting at 158° (Reimer, *Ber.*, **14**, 1797), is obtained from the resinous product, together with unaltered benzyl cyanide amounting to about half that employed. The mechanism of this reaction appears to be that a small quantity of diphenylsuccinonitrile is initially produced, and this, reacting with the sodium ethoxide, is converted into the sodium derivative, CN·CNaPh·CNaPh·CN, which is then converted into dicyanostilbene by the action of the iodine, with the elimination of 2 atoms of sodium (compare next abstract). It has, indeed, been experimentally proved that diphenylsuccino-

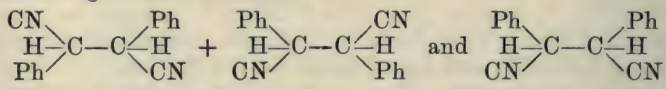
nitrile yields a small quantity of dicyanostilbene when it is suspended in sodium ethoxide and an ethereal solution of iodine added. The yield is augmented by increasing the quantity of sodium ethoxide and iodine, but is at most only 10—20 per cent. of the theoretical. When an ethereal solution of iodine (2 equivalents) is added to benzyl cyanide (1 mol.) in alcohol, and a solution of sodium (2 equivalents) slowly dropped in with cooling and shaking, 70—90 per cent. of the theoretical quantity of dicyanostilbene is produced with scarcely any resinous products. Dicyanostilbene is also readily formed from diphenylsuccinonitrile when the reagents are added in the last-mentioned order. It exhibits all the reactions and properties described by Reimer (*loc. cit.*), and when heated with a solution of potassium hydroxide in dilute alcohol, yields diphenylmaleïc anhydride (m. p. 150) on acidification.

A. R. L.

Stereoisomeric Diphenylsuccinonitriles. By L. Chalanay and E. Knoevenagel (*Ber.*, **25**, 289—301).—*Symmetrical dimethyldiphenylsuccinonitrile*, CN·CMePh·CMePh·CN, is obtained when methylbenzyl cyanide (hydratroponitrile) (1 mol.), prepared by V. Meyer's method (Abstr., 1889, 596), is added to a solution of sodium (1 equivalent) in methyl alcohol (10 parts), and iodine (1 equivalent) in ethereal solution slowly dropped in with agitation. The mixture is poured into water, and the precipitated compound crystallised from boiling alcohol; it is insoluble in benzene, only sparingly soluble in cold glacial acetic acid or alcohol, and melts at 227°. As the yield is small, the existence of isomerides could not be determined.

Symmetrical dibenzyldiphenylsuccinonitrile,

$$CN\cdot CPh(CH_2Ph)\cdot CPh(CH_2Ph)\cdot CN,$$



is prepared from benzylbenzyl cyanide in a manner similar to the last-described nitrile; it forms a white, crystalline powder, is insoluble in ether and benzene, sparingly soluble in alcohol, and melts at 235°. The compound is still under investigation.

Diphenylsuccinonitrile, CN·CHPh·CHPh·CN (dibenzylene dicyanide; Reimer, Abstr., 1882, 170), is obtained in considerable quantity when benzyl chloride and benzal chloride (1 mol. of each) are heated with potassium cyanide (3 mols.); also in yield amounting to 50—60 per cent. of the theoretical, when benzyl cyanide and benzal chloride (1 mol. of each) are heated in aqueous alcoholic solution in a reflux apparatus with potassium cyanide (2 mols.). By the action of benzaldehyde and potassium cyanide in alcoholic solution on benzyl chloride, the authors obtained a certain quantity of diphenylsuccinonitrile, together with benzoïn, α-phenylcinnamonitrile, and a nitrogenous compound melting at 180—181°, and after a study of the reaction, from a theoretical aspect, they discovered that diphenylsuccinonitrile is obtained in about 50 per cent. yield when mandelonitrile and benzyl cyanide (equal molecules) are heated with alcoholic potassium cyanide at 50—60° for 12—18 hours. The product crystallised from glacial acetic acid generally melts at 220—221°, but its melting point is very variable; it gives the dicarboxylic acid (β-dibenzyldicarboxylic acid, m. p. 229—230°; Reimer, Abstr., 1882, 200) when heated with concentrated hydrochloric acid at 150—160°.

When the nitrile as thus obtained is boiled with absolute alcohol for 12—18 hours in a reflux apparatus, the greater portion remains undissolved, and melts at 239—240° (*β*-modification); whilst a lower melting product separates from the alcoholic solution, and still lower ones on concentrating it; on evaporating the last alcoholic mother liquors to a small volume, a compound melting at 160° (*α*-modification) is obtained.

β-Diphenylsuccinonitrile, which represents the chief portion of the last-described crude product, is obtained as above mentioned; or the crude product (m. p. 220—221°) is boiled for several hours with glacial acetic acid, whereby the *α*-modification, which it contains, is converted into the *β*-modification; it crystallises from glacial acetic acid in colourless needles, melts at 239—240°, and is soluble in hot alcohol, and almost insoluble in the cold liquid, as also in ether, benzene, and chloroform. When heated with concentrated hydrochloric acid at 150—160° for 2—3 hours, it gives *β*-diphenylsuccinic acid (m. p. 229—230°; *loc. cit.*); on heating with alcohol at 180°, it decomposes into *α*-phenylcinnamonitrile (m. p. 84°) and hydrogen cyanide; whilst when heated with acetic acid and water at 160°, a compound, $C_{16}H_{13}NO_2$, having basic properties, is obtained.

α-Diphenylsuccinonitrile is obtained from the crude product as above described, but its isolation presents some difficulty; it melts at 160°, but agrees in other respects with the *β*-modification. When heated with concentrated hydrochloric acid at 150—160°, it yields the same diphenylsuccinic acid (m. p. 229—230°) as the *β*-modification, a result which is not surprising, in view of Reimer's observation that *α*-dibenzyldicarboxylic acid (m. p. 183°) is converted by heating it with concentrated hydrochloric acid into the *β*-modification (m. p. 229°). Both the diphenylsuccinonitriles are optically inactive, and the authors, regarding the *α*- and *β*-modifications as the analogues of racemic and mesotartaric acids respectively, propose the following spacial configurations for them:—

α-Diphenylsuccinonitrile. *β*-Diphenylsuccinonitrile.

A. R. L.

Metanitro- and Paranitro-diparadihydroxytriphenylmethane. By G. Bertoni and M. Zenoni (*Gazzetta*, **21**, ii, 331—336).—The authors have continued their experiments on the formation of nitrohydroxy-derivatives of triphenylmethane by Baeyer's reaction (compare Abstr., 1891, 1378, and *Rend. R. Ist. Lomb.*, **23**).

Metanitrodiparadihydroxytriphenylmethane,

$$NO_2{\cdot}C_6H_4{\cdot}CH[C_6H_3(OH)_2]_2,$$

is prepared by melting quinol (4·4 grams) with metanitrobenzaldehyde (3 grams) and treating the mixture with a little dilute sulphuric acid. The product, when pure, is a light, amorphous substance of a pink colour; it darkens at 250°, and begins to alter at 264°. It dissolves freely in alcohol, but is insoluble in cold water. In other

respects it resembles the nitrohydroxy-compounds previously described by the authors.

The *paranitro*-derivative is formed in a manner analogous to the preceding compound. It is a dull-white, uncrystallisable powder, insoluble in water, chloroform, or light petroleum, but very readily soluble in alcohol and ether. It turns brown at 260°, intumesces at 274°, and decomposes. When rapidly heated on platinum-foil or in a test tube, it evolves violet vapours. S. B. A. A.

Condensation Products of Nitrobenzaldehydes with Hydroxybenzenes. By G. Siboni (*Gazzetta*, **21**, ii, 340—345).—*Paranitrophenyldimetadihydroxyphenylmethane*,

$$NO_2{\cdot}C_6H_4{\cdot}CH[C_6H_3(OH)_2]_2.$$

—Resorcinol (7 grams) and paranitrobenzaldehyde (4 grams) are melted together and treated with dilute sulphuric acid; the product, after purification, is a clear, brick-red, uncrystallisable compound, soluble in ether, alkalis, &c., but not in water.

Orthonitrophenyldiparadihydroxyphenylmethane is prepared, like the preceding compound, from quinol (3·3 grams) and orthonitrobenzaldehyde (2·2 grams). It is a brown powder, resembling in properties the other nitrohydroxy-derivatives.

Metanitrophenyldiorthocresolmethane, $NO_2{\cdot}C_6H_4{\cdot}CH(C_6H_3Me{\cdot}OH)_2$, prepared by the action of dilute sulphuric acid on orthocresol and metanitrobenzaldehyde, is a cinnamon-coloured powder. It dissolves in alcohol, forming brown solutions, which are turned violet by alkalis; acids precipitate it as a purplish-red, flocculent powder. S. B. A. A.

Condensation of Nitrobenzaldehydes with Salicylic Acid. By G. de Varda (*Gazzetta*, **21**, ii, 345—350; compare Abstr., 1891, 1346).—*Metanitrophenyldihydroxyphenylmethanedicarboxylic acid*,

$$NO_2{\cdot}C_6H_4{\cdot}CH[C_6H_3(OH){\cdot}COOH]_2,$$

is prepared by the action of concentrated sulphuric acid on a mixture of metanitrobenzaldehyde and salicylic acid. The pure product is a yellowish, amorphous substance, almost without odour or taste; it turns brown at about 200°, and partially fuses and turns black at 210—220°. It is moderately soluble in ether, alcohol, and acetic acid, and sparingly in benzene, chloroform, or boiling water; in the latter it becomes emulsified, and is slowly deposited as a pale-yellowish powder. It forms salts with the hydroxides of potassium, sodium, and barium, and is reprecipitated unchanged by acids from aqueous solutions of these salts. It is slightly soluble in hot concentrated sulphuric acid, which colours it reddish-brown.

The corresponding *ortho*-compound, formed from orthonitrobenzaldehyde, salicylic acid, and sulphuric acid, is a coffee-coloured, amorphous substance, without taste or odour; it darkens at 214—216°, swells up, and fuses. It is sparingly soluble in hot water, and becomes emulsified on cooling the solution; it is soluble in acetic acid, and partially in alcohol and ether. With alkalis, sulphuric acid, &c., it behaves like the meta-derivative. The *para*-compound is

an amorphous, dark-red substance, which turns brown at 200°, and softens at 215°. Its properties are in general very similar to those of the preceding compounds. None of these derivatives can be distilled or volatilised, and they only burn with difficulty.

S. B. A. A.

Metanitrophenylsantoninmethane. By G. Bertoni (*Gazzetta*, **21**, ii, 336—340).—*Metanitrophenylsantoninmethane*,

$$NO_2{\cdot}C_6H_4{\cdot}CH{:}C_{15}H_{16}O_3,$$

is prepared by melting metanitrobenzaldehyde (3 grams) with santonin (9·84 grams) and adding a few drops of hot dilute sulphuric acid to the molten mass. When pure, the product is a flocculent, uncrystallisable, orange-coloured substance, soluble in alcohol, acetic acid, &c., but almost insoluble in water. It softens at 107°, becomes transparent at 120°, and melts at 138°, simultaneously turning brown.

S. B. A. A.

Decomposition of Diazo-compounds of Nitronaphthalenes with Alcohol. By W. R. Orndorff and M. Cauffmann (*Amer. Chem. J.*, **14**, 45—57).—It was shown previously, that when a diazonaphthalene sulphate is decomposed by alcohol, two reactions occur, resulting respectively in the formation of naphthalene and of a naphthyl ethyl ether (Abstr., 1891, 1073); it is now found that in the case of the three diazonitronaphthalene sulphates, $NO_2{\cdot}C_{10}H_6{\cdot}N_2HSO_4$ [$NO_2 : N_2HSO_4 = 3:4$, $= 4:3$, and $= 1:4$, respectively; in the last case the nitrate was actually used], only the first reaction takes place, no ether being formed; the yield of nitronaphthalene is, respectively, 84, 52, and 57 per cent. of the theoretical.

3 : 4-*Nitrodiazonaphthalene sulphate* was obtained by dissolving the corresponding nitronaphthylamine in a little ordinary alcohol, adding gradually excess of concentrated sulphuric acid, cooling, adding rather more than the theoretical quantity of amyl nitrite, then adding ether, and again cooling. It forms yellow, monoclinic (?) prisms with a hexagonal section, and dissolves in water and dilute alcohol, but not in ether and absolute alcohol. It explodes when heated, but not on percussion. It decomposes when exposed to air and light, becoming red, and when boiled with water yields nitrogen and 3 : 4-nitronaphthol.

4 : 3-*Nitrodiazonaphthalene sulphate* was prepared in the same way as the 3 : 4-isomeride. It forms orange-yellow needles, which dissolve readily in water and dilute alcohol, sparingly in absolute alcohol, and not all in ether. It explodes feebly at 167°, but not when struck. It decomposes when exposed to air and light, turning brown; and when boiled with water yields nitrogen and 4 : 3-nitronaphthol. 4 : 3-*Nitrodiazonaphthalene nitrate* was prepared in the same way as the sulphate, concentrated nitric acid being used instead of sulphuric acid. It forms pale yellow needles, soluble in water and alcohol, insoluble in dry ether. It explodes when heated, but not when struck. It decomposes when exposed to light, turning dark-brown; and when boiled with water yields the same products as the sulphate.

1 : 4-*Nitrodiazonaphthalene nitrate* was prepared in a similar manner to the last-mentioned nitrate. It forms pale yellow needles, which

dissolve readily in water, moderately in alcohol, not at all in dry ether. It explodes feebly when heated, but not when struck. It decomposes when exposed to light, turning greenish-yellow.

In conclusion, the author advances the view that the formation of an ether by the action of alcohol on a diazo-compound never takes place when a nitro-group is present. The only exception, and that but a partial one, is the diazo-derivative of nitrotoluylenediamine.

C. F. B.

Tautomerism of Sulphinic Acids. By R. Otto and A. Rössing (*Ber.*, **25**, 230—233).—*Methyl β-naphthylsulphinate*, $C_{10}H_7 \cdot SOOMe$, can be easily prepared by treating sodium β-naphthalenesulphinate with methyl chlorocarbonate in ice-cold alcoholic solution; after adding water, the solution is extracted with water, and the extract evaporated, when there remains a mixture of methyl β-naphthylsulphinate and a substance melting at 92—93°, probably methyl naphthylsulphone formate, $C_{10}H_7 \cdot SO_2 \cdot COOMe$, which can be separated by treatment with light petroleum, in which the former alone is soluble. On evaporating the light petroleum solution at the ordinary temperature, methyl β-naphthylsulphinate is deposited in prismatic crystals melting at 44°, and readily soluble in ether, chloroform, alcohol, and ethyl acetate, but insoluble in water. It is readily hydrolysed by warm concentrated potash, and is also decomposed by boiling water; on oxidation with potassium permanganate, it gives a crystalline compound melting at 53—54°, which is probably methyl β-naphthylsulphonate.

β-Naphthylmethylsulphone, prepared from sodium β-naphthylsulphinate and methyl iodide, crystallises in lustrous, rectangular plates, melts at 139—140°, and is insoluble in water, but readily soluble in hot alcohol and benzene; it is not acted on by potash or by potassium permanganate.

In the first part of the paper, the authors reply to some criticisms of Baumann, who has questioned the existence of tautomeric sulphinic acids.

F. S. K.

Picene. By R. Lespieau (*Bull. Soc. Chim.* [3], **6**, 238—239).—Among the products of the action of ethylene bromide on naphthalene in presence of aluminium chloride, Roux noticed a hydrocarbon boiling above 450°, and crystallising as scales which melt about 300°. The author finds it very difficult to free this product from dinaphthyl and naphthalene hydrides, but finally obtained it in a state of sufficient purity to identify it with the picene, $C_{22}H_{14}$, described by Burg. The author failed to obtain the hydrocarbon by substituting acetylene bromide for ethylene bromide in the generating reactions.

T. G. N.

Terpenes and their Derivatives. By J. W. Brühl, H. Biltz, A. Cantzler, and L. Reuter (*Ber.*, **25**, 142—151; see also this vol., pp. 200, 347).—Menthene, which stands in the same relation to menthone as camphene to camphor, may be readily obtained by the action of dehydrating agents on menthol, phosphoric anhydride acting at the ordinary temperature, and zinc chloride at the boiling point. Concentrated sulphuric acid, on the other hand, even in the cold,

gives very little menthene, the chief product having a much higher boiling point. Anhydrous copper sulphate may also be employed with good results. To purify the menthene, it is heated with sodium on an oil-bath, and distilled over the metal in a vacuum; it boils at 167·1° under a pressure of 768·6 mm., and when heated with anhydrous copper sulphate at 250°, is converted into cymene. As menthol so readily loses water, the reaction probably takes place between the hydroxyl group and the hydrogen atom in the ortho-position, the constitution of menthol and menthene being represented by the following formulæ:—

$$CHPr^{\beta}<\begin{matrix}CH_2\cdot CH(OH)\\ CH_2\text{——}CH_2\end{matrix}>CHMe \text{ and } CHPr^{\beta}<\begin{matrix}CH:CH\\ CH_2\cdot CH_2\end{matrix}>CHMe.$$

Terebenthene was prepared from French oil of turpentine by shaking it with soda solution, drying over solid soda, and heating in an oil-bath with sodium until the surface of the latter remained bright. The product was then distilled, and two fractions collected boiling at 155·4—155·8° and 155·8—156·1°, under a pressure of 748·9 mm. The purified terebenthene was converted into the monohydrochloride by saturating it with hydrogen chloride at −20°, filtering off the mother liquor at the same temperature, and washing with alcohol; the product may be purified by dissolving in light petroleum, filtering from separated water drops, and allowing to crystallise; it melts at 125°. Terecamphene was first prepared from this hydrochloride by Berthelot, by heating it with sodium stearate; if benzoate or acetate is employed instead of the stearate, inactive camphene is obtained. Alcoholic ammonia is without action on the hydrochloride, and aniline, contrary to the statement of Lauth and Oppenheim (*Bull. Soc. Chim.* [2], **8**, 6), has very little action. The hydrocarbon may be obtained by heating the hydrochloride with an equivalent quantity of sodium acetate and a slight excess of soda in alcoholic solution at 180—200° for 6—8 hours. The corresponding potassium salts have the same effect, but the action is much slower and less complete. When the product is distilled in a current of steam, camphene passes over, and solidifies on cooling. After treatment with soda, distilling over sodium, and repeated crystallisation, it melts at 51—52°, and boils at 158·5—159·5°.

Borneocamphene was prepared from bornyl chloride by Wallach's method, which does not, according to the author, proceed so readily as stated by the former. The product always contains chlorine, and must be purified by treatment with soda and distillation over sodium. It then melts at 53·5—54°, instead of 48—49°, as given by Wallach.

In order to redetermine the physical properties of cymene for comparison with those of the terpenes, this substance was also prepared in quantity from camphor and from cumin oil. From the first source a fraction was obtained boiling at 175—176°, and from the second two fractions boiling at 174·5—175·2° and 175·2—175·9°, under a pressure of 752 mm. H. G. C.

Terpenes and their Derivatives. By J. W. Brühl (*Ber.*, **25**, 151—174).—This paper contains an account of the results of the

spectroscopic examination of the hydrocarbons described in the previous abstract. The results obtained with menthene agree with the supposition that it contains one ethylene linkage, as shown in the constitutional formula given above. In the case of terebenthene (lævopinene), the figures are in agreement with the presence of one para-linkage and one ethylene linkage, thus confirming Wallach's formula. For terecamphene and borneocamphene, the author finds numbers which also agree with the existence of one para-linkage and one ethylene linkage; his previous prediction that camphene would be found to have no ethylene linkage was arrived at from Gladstone's measurements, which differ from those now made. The formula usually accepted for camphene, namely, $CPr^{\beta}\begin{matrix}CH:CH\\CH_2\cdot CH_2\end{matrix}CMe$, is thus confirmed; but whether terecamphene and borneocamphene are isomeric or identical is at present doubtful. The determination of the heat of combustion of the two substances by Stohmann gave 1466·7 cal. for terecamphene, and 1470·3 cal. for borneocamphene, their manner of burning being also different. It appears, therefore, probable that they are isomeric, but the isomerism is most likely due to differences of position, and not of structure.

The examination of cymene gave results which agree well with those obtained in the case of other benzene derivatives. With methylindene, the figures agree approximately with the formula

$$\begin{matrix}CH:C\\CH:CH\end{matrix}\!\!>\!\!\begin{matrix}H\cdot C\cdot CMe\\H\cdot C\cdot CH_2\end{matrix}\!\!>CH.$$

H. G. C.

German and Turkish Rose Oils. By C. U. Eckart (*Ber.*, **25**, 311).—In his paper on this subject (this vol., p. 203), the author erroneously gave the old formula for dipentene, whereas, according to Wallach's recent investigations, the latter is a compound of the two optically active limonenes of opposite sign, analogous to racemic acid; accordingly both limonenes must be simultaneously produced from the elæoptene, rhodinol (*loc. cit.*). A. R. L.

Terpenes from the Resin of Pinus abies. By B. Kuriloff (*J. pr. Chem.* [2], **45**, 123—133).—A large quantity of the resin was subjected to steam distillation, and the oil obtained carefully fractionated and freed from products containing oxygen by distillation over sodium. It was separated into two portions boiling at temperatures corresponding with terpene and isoterpene.

The terpene, after careful purification, was quite inactive, and showed no rotatory power when examined in a tube 200 mm. long. It boils at 157° (corr.) under 760 mm. The density is 0·8750 at 0°/4°, and 0·8588 at 20°/4°; coefficient of dilation = 0·00093; molecular refractive power $P\frac{A-1}{d} = 71{\cdot}48$. When treated with hydrogen chloride, it yields a monohydrochloride melting at 126·5°.

The fraction containing the isoterpene, after careful purification, yielded an isoterpene boiling at 176·7° under 772 mm. pressure, and having a specific rotatory power $[\alpha]_D = -47{\cdot}5$. The density is 0·8627 at

0°/4°, and 0·8529 at 20°/4°; coefficient of dilation = 0·00087; molecular refractive power $P\frac{A-1}{d} = 73{\cdot}28$. When treated with hydrogen chloride, it yields a dihydrochloride melting at 48·5°. The quantity of lævorotatory isoterpene obtained only amounted to 2 per cent. of the oil. It corresponds with the dextrorotatory isoterpene obtained by Flawitzky in all particulars, except in the specific rotatation, which is −47·5, whereas dextroisoterpene gives +57·6.

From the above results it is concluded that the oil from *Pinus abies* contains inactive terpene and lævorotatory isoterpene, together with substances containing oxygen which were not examined.

E. C. R.

Camphorone. By W. Koenigs and A. Eppens (*Ber.*, **25**, 260—269).—Gerhardt and Liès Bodart (*Annalen*, **72**, 293) obtained, by distilling calcium camphorate, an oily compound, $C_9H_{14}O$, having a peppermint-like odour, and boiling at 208°, which they named camphorone. Fittig (*Annalen*, **110**, 32; **112**, 311) regarded it as identical with the acetophorone obtained by treating acetone with calcium oxide, as both compounds gave cumene on heating with phosphorus pentoxide. Kachler (this Journal, 1872, 1011), by boiling camphorone with nitric acid, obtained, besides oxalic acid, a crystalline, bibasic acid, $C_6H_{10}O_4$, which he at first believed to be adipic acid, but subsequently stated (*Annalen*, **166**, 320) that it was not.

Camphorone is obtained by distilling dry calcium camphorate, driving over the product in a current of steam, and repeatedly rectifying it, when the chief portion passes over at 195—200° (715 mm.); its composition, $C_9H_{14}O$, was established. The oxime was obtained in a crystalline, but not entirely pure condition. The *bromodibromide*, $C_9H_{11}Br_3O$, is formed when camphorone (2 grams) is dissolved in carbon bisulphide (10 grams) and treated at 0° with a solution of bromine (5 grams) in carbon bisulphide (5 parts); the liquid is washed successively with solutions of sodium hydrogen sulphite and sodium carbonate, and finally with water, the solvent evaporated, and the product allowed to remain in a desiccator under diminished pressure for a while. The yellowish oil, which has a penetrating odour, is then dissolved in alcohol, and water added until the liquid becomes turbid, when colourless needles separate after a time; these are collected and purified by repeated dissolution in alcohol and precipitation with water. The pure compound is odourless, and scarcely soluble in cold water, although readily so in ordinary organic solvents; it commences to sinter at 49°, and melts at 52°, decomposing with the evolution of hydrogen bromide when strongly heated. It will be seen therefore that camphorone behaves towards bromine differently from the crystalline acetophorone (compare Claisen, this Journal, 1876, i, 896). When camphorone (10 grams) is suspended in water, and treated at 0° with potassium permanganate (29 grams) in 4 per cent. aqueous solution, after decolorising the liquid with sodium hydrogen sulphite, driving over any unattacked substance with a current of steam, boiling the filtrate with

animal charcoal, acidifying with dilute sulphuric acid, and distilling, formic and acetic acids pass over, whilst ether extracts a bibasic acid, $C_6H_{10}O_4$, from the residue; this when repeatedly crystallised from benzene melts at 77·5°, and is identical with α-methylglutaric acid (Wislicenus and Limpach, Abstr., 1878, 783; Kiliani, *ibid.*, 1883, 962). It is probable that the acid obtained by Kachler (*loc. cit.*) was also α-methylglutaric acid, but it is not sufficiently characterised by him to decide this question.

The authors adopt the following formulæ for camphoric acid and camphorone respectively (compare Brühl, this vol., p. 202), $\begin{matrix}CH_2\cdot CPr^{\beta}\cdot COOH\\ CH_2\cdot CMe\cdot COOH\end{matrix}$ and $\begin{matrix}CH_2\cdot CPr^{\beta}\\ CH_2\cdot CMe\end{matrix}>CO$, and they interpret the above described oxidation of the latter as follows:—$\begin{matrix}CH_2\cdot CPr^{\beta}\\ CH_2\cdot CMe\end{matrix}>CO + H_2O + 3O_2 = CH_3\cdot COOH + H\cdot COOH + COOH\cdot CH_2\cdot CH_2\cdot CHMe\cdot COOH.$

In conclusion, the authors draw attention to the remarkable resemblance of camphorone to ditetramethylene ketone (Colman and Perkin, Trans., 1887, 236). Both compounds have the same composition, boiling point, and characteristic odour; it is, however, scarcely conceivable, in light of the above formula for camphoric acid, that the two compounds can be identical, and it is difficult to explain the formation of α-methylglutaric acid from ditetramethylene ketone; furthermore, Colman and Perkin obtained a compound of their ketone with sodium hydrogen sulphite, whereas the authors' observations confirm those of Limpricht, that camphorone does not combine with that salt. A. R. L.

Note.—Armstrong and Kipping (Proc., 1891, 188; 1892, 54) have recently separated the ketone 1 : 2 : 4-dimethylacetylbenzene from the product of the action of concentrated sulphuric acid, or of zinc chloride, on camphor. A. R. L.

Puleone, an Isomeride of Camphor. By P. Barbier (*Compt. rend.*, **114**, 126—128).—*Puleone*, $C_{10}H_{16}O$, is the chief constituent of commercial oil of pennyroyal (*Mentha pulegium*, Labiées), from which it may be isolated by repeated fractionations. It is a colourless, mobile liquid which smells strongly of mint, dissolves in alcohol, ether, and benzene, but not in water, boils at 222—223°, and has a sp. gr. of 0·9482 at 0°, and 0·9293 at 23°. It is dextrogyrate, the rotatory power being $[\alpha]_D = +25·25°$. Its index of refraction at 14·9° is 1·4833 and 1·4997, for the tin lines λ 645 and 452·6 respectively. A liquid of the same composition which Kane obtained from the same source (*Phil. Mag.*, **13**, 442) does not appear to be identical, as it boiled at 182—183°.

Puleone, like camphor, contains a carbonyl group, as it combines with hydroxylamine to form an oxime, *puleonoxime*, $C_{10}H_{16}{:}NOH$, which is a colourless liquid having a powerful odour, and boiling at about 170° under a pressure of 48 mm. The oxime is soluble in dilute sulphuric acid, but by boiling this solution is transformed into a very unstable oil of the composition $C_{10}H_{15}N$.

Puleone is oxidised by chromic acid mixture to acetic and carbonic acids, and an acid, $C_7H_{12}O_4$, which crystallises in slender, silky needles, melts at 89—91°, is very soluble in water, alcohol, and ether, and appears to be identical with the propylsuccinic acid obtained by Wurtz from propylethenyltricarboxylic acid (Abstr., 1882, 948). Bromine acts energetically on puleone, hydrogen bromide being evolved, but an additive product is not formed, even at low temperatures and on dilution, so that ethylene linkages do not occur in the molecule. When puleone is treated with phosphoric chloride, hydrogen chloride is evolved, and a liquid derivative, $C_{10}H_{15}Cl$, is formed, and this in turn, when boiled for a long time, loses the elements of hydrogen chloride, and is transformed into a hydrocarbon, $C_{10}H_{14}$, which boils at 177—179°, and appears to be identical with the cymene yielded by camphor under similar treatment.

The formation of propylsuccinic acid from puleone may be held to establish the presence of the group $-C\cdot CHPr^{a}\cdot CH_2\cdot C-$ in the molecule of the latter, and the author thinks, therefore, that it may have the constitution $\begin{matrix} CHPr^{a}\cdot CH\cdot CO \\ | \quad\quad | \quad\quad | \\ CH_2 — CH\cdot CHMe \end{matrix}$. Jn. W.

Fraxin and Fraxetin. By G. Koerner and P. Biginelli (*Gazzetta*, **21**, ii, 452—454).—The authors confirm the previous observations on the properties of fraxetin. It melts at 227°, and is found by Zeisel's method to contain one methoxy-group.

Dimethylfraxetin is formed on boiling a solution of fraxetin (2 grams), caustic potash (1·1 gram), and methyl iodide (3 grams) in methyl alcohol for six hours. The alcohol is distilled off, and the solution extracted with ether. On evaporating the ethereal solution, a crystalline product is obtained which separates from dilute alcohol in small, yellowish rhombs, $a : b : c = 0{\cdot}7045 : 1 : 0{\cdot}4096$. It melts at 103—104°. When heated at 100° in a closed tube with potash and methyl iodide, methyl tetramethoxycinnamate is obtained. This substance, on hydrolysis in a closed tube at 100°, yields an acid which is extremely soluble in alcohol, ether, and benzene, sparingly so in cold water. It decomposes carbonates, and gives a barium salt soluble in water. The acid could not be analysed owing to the small quantity obtained.

Fraxetin most probably has the constitution represented by the formula $OMe\cdot C_6H(OH)_2<\begin{matrix} CH:CH \\ | \quad | \\ O — CO \end{matrix}$, and its glucoside fraxin is therefore $OMe\cdot C_6H(OH)(O\cdot C_6H_{11}O_5)<\begin{matrix} CH:CH \\ | \quad | \\ O — CO \end{matrix}$. W. J. P.

Pyridine and Piperidine Bases of the β-Series. By C. Stoehr (*J. pr. Chem.* [2], **45**, 20—47; compare Abstr., 1891, 219, 579).—This paper is a summary of the author's work on the β-pyridine bases, and has nearly all appeared before.

The *platinum compound*, $(C_6H_7N)_2,HCl,PtCl_4$, is obtained when β-methylpyridine platinochloride is repeatedly recrystallised; it forms pale-yellow laminæ, and is sparingly soluble in cold water; it begins to melt at 210—212°, but is not fully melted until 220—224°, when it

decomposes. The *zincochloride*, $(C_6H_7N)_2,ZnCl_2$, crystallises in needles, melts at 158°, and dissolves easily in alcohol and water (compare Hesekiel, Abstr., 1886, 256). The *argentonitrate*, $(C_6H_7N)_3,AgNO_3$, crystallises in lustrous prisms which very easily lose some of the base when heated.

β-Methylpiperidine was obtained by the reduction of β-methylpyridine with sodium and alcohol on the water-bath; it boils at 125—126° (mercury column in vapour; 763 mm.), and its sp. gr. at 0°/4° = 0·8635. The *nitrate* crystallises in colourless, hygroscopic laminæ; the hydriodide melts at 158—159° (not 131°, Ladenburg, *Annalen*, **247**, 67); the hydrochloride crystallises from absolute alcohol in thick, colourless aggregates of needles, melts at 171—172°, and is hygroscopic in air (compare Ladenburg, *loc. cit.*).

The platinum compound of ethylpyridine, $(C_7H_9N)_2,HCl,PtCl_4$, melts with decomposition at 240°, not 204—205° (de Coninck, Abstr., 1883, 740). The normal aurochloride, $C_7H_9N,HAuCl_4$, melts at 130°, and the modified aurochloride, $C_7H_9N,AuCl_3$, at 172—174° with decomposition. The picrate melts at 128—130°. The foregoing constants are identical for β-ethylpyridine from brucine and for synthetical β-ethylpyridine, with the exception that the modified platinochloride of the latter melts at 243°. The *cadmioiodide* of *β-ethylpyridine methiodide*, $C_7H_9N_3MeI,CdI_2$, from the synthetical base melts at 125°; the *platinochloride* of the *methochloride* melts, with decomposition, at 210°; the *mercurochloride* of the *methochloride*, $C_7H_9N,MeCl,2HgCl_2$, melts at 85—86°.

In a table, the author compares the melting points and boiling points of β-ethylpyridine from brucine and its derivatives with those of synthetical β-ethylpyridine and its derivatives, and concludes that the two bases are identical.

β-Ethylpiperidine boils at 154—155° (mercury column in vapour); it fumes in the air, and is only slightly soluble in water; its sp. gr. at 0°/4° is 0·8711; it combines readily with carbon bisulphide. The *hydrochloride* forms hygroscopic needles, and melts at 141—142°; the *hydriodide* crystallises in hygroscopic needles, and melts at 123°; the *picrate* forms prismatic needles and prisms melting at 63°; the *platinochloride* forms prismatic crystals (with $\frac{1}{2}$ mol. H_2O), and melts, with decomposition, at 180°; the *aurochloride* forms prismatic needles, and melts at 112°, with decomposition; the *nitrate*, *mercurochloride*, and *cadmioiodide* were obtained. A. G. B.

ββ-Dimethyldipyridyl. By C. Stoehr and M. Wagner (*Ber.*, **24**, 4231—4233).—*ββ-Dimethyldipyridyl* is obtained from β-methylpyridine by a process similar to that employed for the preparation of the αα-derivative (Abstr., 1890, 80; this vol., p. 75); the reaction proceeds in the cold and is complete in about eight days. The product is a dark-coloured liquid mass containing unattacked sodium, and may, without danger of explosion, be added to water; the oily layer is separated, dissolved in ether, the ethereal solution dried over solid potash, and distilled, when about half the β-methylpyridine employed passes over at 170°, the thermometer quickly rising to 250°, and between this temperature and 300° a pale-yellow oil passes over

which quickly solidifies, and is freed from the liquid portion by treatment with a little alcohol and anhydrous ether. The pure compound crystallises from dilute alcohol in large, lustrous, four-sided, anhydrous tables, melts at 125°, sublimes easily, and is only slightly volatile with steam; it is sparingly soluble in hot water, less so in cold, but readily in alcohol and benzene. The *hydrochloride*, $C_{12}H_{12}N_2,2HCl$, separates in small, lustrous crystals, when dry hydrogen chloride is passed into a solution of the base in absolute alcohol; it sublimes without melting, and is very easily soluble in water, its aqueous solutions giving a sparingly soluble bromide on the addition of bromine. The *platinochloride* is very sparingly soluble in water; the *mercurochloride* crystallises from dilute hydrochloric acid in thick, lustrous needles, and melts at 221—222°; whilst the *picrate* separates from its hot aqueous solution in long, lustrous, yellow needles, and melts at 230° with decomposition. The base gives a compound with silver nitrate, sparingly soluble in cold water, readily so in hot, and combines with 2 molecular portions of alkyl halides. The *methiodide*, $C_{12}H_{12}N_2(MeI)_2$, formed by treating the base with methyl iodide at the ordinary temperature, crystallises from boiling alcohol in lustrous, yellowish needles, carbonises at a high temperature without melting, is readily soluble in water, and gives a sparingly soluble *cadmioiodide*. A. R. L.

So-called γ-Bromoquinoline. By H. Decker (*J. pr. Chem.*, [2], **45**, 47—55).—The orientation of the γ′-bromoquinoline of La Coste (Abstr., 1881, 741) and Claus and Collischonn (Abstr., 1887, 159) would be settled if the bromoquinoline could be converted into Baeyer and Bloem's 4′-bromocarbostyril (Abstr., 1883, 196).

For this purpose, 10 grams of the bromoquinoline were dissolved in sulphuric acid, and the solution poured into 5 litres of water; after neutralisation with sodium hydroxide, boric acid, and solution of bleaching powder were added. After one night, *bromopseudochlorocarbostyril*, $C_9H_5BrONCl$, crystallised out. This compound melts about 170° when quickly heated, solidifies again as the heat is continued, and melts finally at 222°; when slowly heated, it melts at 222° only. When it is dissolved in hot concentrated sodium hydroxide solution, sodium bromocarbostyril crystallises on cooling; this is decomposed by water with the formation of bromocarbostyril.

The bromocarbostyril thus obtained crystallises from alcohol in small prisms which melt, at first, at 248°, but at 253° after several recrystallisations. It dissolves in hot alcohol, benzene, hot water, cold concentrated acids, and dilute alkalis. It sublimes unchanged. Baeyer and Bloem's 4′-bromocarbostyril melts at 266°, and is, therefore, not identical with the bromocarbostyril in question, for which the only remaining orientation is 3′-bromo-2′-hydroxyquinoline. The so-called γ-bromoquinoline is thus shown to be 3′-bromoquinoline, and all the compounds which Claus and his co-workers have described as 4′-derivatives are really 3′-derivatives. In support of his position the author compares the behaviour of this bromoquinoline with that of 3-pyridine derivatives, and points out that this bromoquinoline is as stable when heated with water and alkalis or acids as β-bromo-

pyridine; he also points out that Skraup's derivative of kynurin (Abstr., 1890, 174) should be 4′-chloroquinoline. Srpek's orientation of the compound obtained by fusing the bromonicotinic acid derived from this bromoquinoline with potassium hydroxide, as 4′-hydroxypyridine, is pronounced to be rash in the absence of knowledge as to how fusion with potassium hydroxide may alter orientation.

A dibromoquinoline melting at 97°, a tribromoquinoline melting at 174°, and a nitrobromocarbostyril melting, with decomposition, at 308—310°, were prepared in connection with this investigation.

A. G. B.

Benzimidazoles. By E. Bamberger and J. Lorenzen (*Ber.*, **25**, 269—273).—The analogy which might be expected to exist between quinoline and benzimidazole bases is not apparent in so far as the capability of the two for taking up additional hydrogen atoms is concerned, for whereas the former are readily hydrogenised, the latter withstand even the action of concentrated hydriodic acid and phosphorus at a high temperature. It was decided from experiments carried out in the manner given by Niementowski (Abstr., 1886, 544) that the formation of the anhydro-base (methylbenzimidazole) takes place as follows:—$C_6H_4<^{NH_2}_{NH\cdot COMe} = H_2O + C_6H_4<^{NH}_{\ \ N}>CMe$. This and the two following papers deal with 2 : 2′-dimethylbenzimidazole, a compound obtained by reducing 3 : 4 : 1-nitracetamidomethylbenzene, and with other compounds of the same series, principally to ascertain to what extent the analogy subsists between them and the corresponding quinoline derivatives. Experimental details are reserved for a paper to be published in the *Annalen*. The group NH in benzimidazoles exhibits acidic properties, the hydrogen atom being displaceable by sodium and silver, and when the adjacent group is CH or CPh, the compound even dissolves in aqueous alkalis, and its acidic properties may be still further enhanced by displacing an atom of hydrogen in the benzene nucleus by NO_2. The hydrogen of the NH group may be displaced, through the medium of the silver derivative, by acetyl, but the resulting compound is hydrolysed on boiling it with water; it may also, contrary to Hübner's statement, be displaced by benzoyl, but all attempts have failed to displace it by NO, or the residues –COOEt and –CHMe·COOEt. By the action of bleaching powder on benzimidazoles, chlorimides are produced from which chlorine is evolved at the ordinary temperature on treatment with concentrated hydrochloric acid, and when these are boiled with benzene the chlorine atom is exchanged for an atom of hydrogen in the benzene nucleus; thus the compound $C_6H_3Me<^{NCl}_{\ \ N}>CMe$ yields $C_6H_2ClMe<^{NH}_{\ \ N}>CMe$; the latter compound forms a chlorimide, in a similar manner to the original benzimidazole, which undergoes intramolecular change on boiling with benzene, and in this way all the hydrogen of the benzene nucleus may be displaced by chlorine; the ultimate compound, $C_6Cl_3Me<^{NCl}_{\ \ N}>CMe$, being unattacked by boiling benzene.

A. R. L.

Benzimidazoles. By E. Bamberger and B. Berlé (*Ber.*, **25**, 274—278; 278—281).—2 : 2′-Dimethylbenzimidazole, like 2 : 2′-dimethylquinoline, yields crystalline compounds with phthalic anhydride, benzaldehyde, and chloral, of the formulæ :—

$$C_6H_3Me<^{NH}_{\ N}>C\cdot CH{:}C_2O_2{:}C_6H_4, \quad C_6H_3Me<^{NH}_{\ N}>C\cdot CH\cdot CHPh,$$

and $C_6H_3Me<^{NH}_{\ N}>C\cdot CH{:}CH\cdot CCl_3$ respectively. The two phthalones agree in chemical, physical, and also in tinctorial properties, but the compound of chloral with 2 : 2′-dimethylbenzimidazole is hydrolysed by boiling with water, whereas the corresponding quinoline derivative is not. 2-Methylbenzimidazole yields a coloured condensation product with phthalic anhydride, $C_6H_4{:}C_2O_2{:}CH\cdot C_6H_3<^{NH}_{\ N}>CH$, but it differs in its properties from the phthalones. 3-Methylquinoline yields a crystalline derivative with chloral, which is being investigated, but does not condense with phthalic anhydride. The primary oxidation product of 2 : 2′-dimethylbenzimidazole is the acid $COOH\cdot C_6H_3<^{NH}_{\ N}>CMe$, which corresponds in its behaviour with 2′ : 2-methylquinolinecarboxylic acid, yields a phthalone, and when passed over heated lime, gives the base $C_6H_4<^{NH}_{\ N}>CMe$, identical with the anhydro-base obtained from orthonitracetanilide or orthoacetylphenylenediamine; whilst, by more energetic oxidation, the bibasic acid, $COOH\cdot C_6H_3<^{NH}_{\ N}>C\cdot COOH$, is produced. The acid $C_6H_3Me<^{NH}_{\ N}>C\cdot COOH$, obtained by carefully oxidising benzylidenimidazole, decomposes by heating into the base $C_6H_3Me<^{NH}_{\ N}>CH$, which is identical with that obtained from 2 : 3 : 5-diamidotoluene. The authors draw attention to the ease with which the last-mentioned acid, which contains its carboxyl in position 2′, is decomposed, the corresponding quinolinecarboxylic acid exhibiting a similar behaviour. The methylbenzimidazoles containing the methyl group in the benzene nucleus are very readily oxidised; for example, the 2-methyl-derivative is easily converted into the carboxylic acid, which behaves in every respect as the homologue of 2′ : 2-methylbenzimidazolecarboxylic acid (see above). When benzimidazole is oxidised with potassium permanganate, it yields Maquenne's glyoxalinedicarboxylic acid, $CH<^{NH\cdot C\cdot COOH}_{N\text{—}C\cdot COOH}$, which, when heated, decomposes into Debus' glyoxaline, the constitution of which may therefore be regarded as $CH<^{NH\cdot CH}_{N\text{—}CH}$.

The authors failed to obtain a benzoyl derivative from 2 : 2′-dimethylbenzimidazole. When, however, benzimidazole is treated by the Baumann-Schotten method, it yields a compound, $C_6H_4(NH\cdot CBz)$,

together with formic acid, and this is convertible into Hübner's 2′-phenylbenzimidazole, $C_6H_4<^{NH}_{N}>CPh$, and benzoic acid. A similar benzoyl derivative is obtained from 2-methylbenzimidazole, which gives Hübner's 2 : 2′-methylphenylbenzimidazole and benzoic acid, and also from nitrobenzimidazole. These reactions are the more remarkable when the stability of the reacting compounds is considered, thus :—bases which withstand the action of alkalis, acids, and reducing agents, and may be heated at a high temperature without alteration, are decomposed as above described by treatment with benzoic chloride and alkali at 0°. A similar case in the quinoline series will be published later, by Bamberger and Williamson. When glyoxaline is treated with benzoic chloride and alkali at 0°, it yields, besides formic acid, dibenzoyldiamidoethylene, $C_2H_2(NHBz)_2$, a compound which crystallises well. These decompositions appear to be dependent on the presence of the group –N·C·N–; pyrroline and pyrazole do not behave in an analogous way. A. R. L.

Etard's Glycoline and Stoehr's Dimethyldiazine. By M. Dennstedt (*Ber.*, **25**, 259—260).—The base obtained by Etard (*Jahresb.*, 1881, 509 and 970) by distilling glycerol with ammonium chloride, to which he gave the name glycoline, is, doubtless, identical with Stoehr's dimethyldiazine (this vol., p. 507); it has, most probably, the composition $C_6H_{10}N_2$, and, when treated with nitrous acid, it yields an oil which gives Liebermann's reaction. F. S. K.

Tetrahydropyrazine. By L. Garzino (*Gazzetta*, **21**, ii, 497—504).—A mixture of ethylenediphenyldiamine (10 grams), bromacetophenone (18·7 grams), and anhydrous sodium acetate (7·5 grams) is gradually heated to 100° for half an hour. After cooling, the mass is powdered and extracted with water to remove sodium bromide. The residue is now digested with boiling alcohol (9—10 parts) for 24 hours, washed with alcohol, suspended in water, heated on the water-bath until no further odour of bromacetophenone is observed, and finally evaporated to dryness. On treatment with ether, the greater portion, consisting of a pyrazine derivative, dissolves, whilst a smaller portion (2 grams) remains undissolved, and is purified by digesting for a day with cold alcohol. It is now collected and recrystallised several times from a mixture of alcohol and benzene. In this way *diacetophenonethylenediphenyldiamine*, $C_2H_4(NPh·CH_2·COPh)_2$, is obtained, crystallising in yellow, prismatic needles, and melting at 170—172°. It is very soluble in acetic acid, less so in benzene and chloroform, and only sparingly in alcohol, ether, and carbon bisulphide. It is not decomposed by aqueous potash, but alcoholic potash decomposes it, with formation of a red substance soluble in ether. Its solution in acetic acid turns emerald-green when heated with phenylhydrazine.

The ethereal solution filtered from the crude diacetophenoneethylenediphenyldiamine is evaporated to dryness, dissolved in cold ether, filtered, again evaporated to dryness, and the residue repeatedly crystallised from a mixture of alcohol (9 parts) and

benzene (1 part). Splendid hexagonal scales of *triphenyltetrahydropyrazine*, $PhN<^{CH_2\cdot CH_2}_{CH:PhC}>NPh$, are thus obtained. It melts at 129—131°, and is very soluble in benzene, chloroform, and ether, less so in alcohol. It dissolves to a green solution in acetic acid, and is precipitated unaltered by water from its solutions in hydrochloric and concentrated sulphuric acid. Mercuric chloride, silver nitrate, and auric chloride are reduced by its alcoholic solution; with ferric chloride solution, a green colour, soon turning to intense yellow, is obtained.

If bromacetophenone and ethylenediphenyldiamine are heated together at 100° without sodium acetate, much hydrogen bromide is evolved, but nothing but the unaltered diamine could be separated from the product. Sodium carbonate may be substituted for the sodium acetate without affecting the result. W. J. P.

Synthesis of Pyrazolone Derivatives. By L. Lederer (*J. pr. Chem.* [2], **45**, 83—94).—By the condensation of ethyl acetoacetate and phenylhydrazine, Knorr obtained a phenylmethylpyrazolone which yields antipyrine hydriodide when treated with methyl iodide. He gives to antipyrine the formula $NPh<^{CO—CH}_{NMe\cdot CMe}$. He considers ethyl acetoacetate as a ketone, and hence the phenylmethylpyrazolone has the formula $NPh<^{CO\cdot CH_2}_{N:\ CMe}$, and then he explains the conversion of this compound into antipyrine as due to the formation of an additive compound which undergoes spontaneous molecular change. Nef considers that ethyl acetoacetate behaves as ethyl hydroxycrotonate, and hence arrives at the formula $NPh<^{CO\cdot CH}_{NH\cdot CMe}$ for the pyrazolone derivative, and this formula clearly explains the formation of antipyrine. The author has attempted to settle the question by a synthesis of the pyrazolone from phenylhydrazine and β-halogenbutyric acid. This synthesis requires the formation of symmetrical phenylhydrazinebutyric acid, $NHPh\cdot NH\cdot CHMe\cdot CH_2\cdot COOH$, as primary product, whereas the results show that the asymmetrical compound, $NH_2\cdot NPh\cdot CHMe\cdot CH_2\cdot COOH$, is formed. The latter yields a pyrazolone derivative of the formula $NPh<^{CMe:CH}_{NH\cdot CO}$, and, finally, a compound having a very great resemblance to antipyrine, but not identical with it. The author proposes to call the pyrazolone, $NH<^{CH\cdot CH}_{NH:CO}$, isopyrazolone, and the antipyrine-like compound, isoantipyrine.

Potassium β-bromobutyrate is dissolved in $2\frac{1}{2}$ times the quantity of water, mixed with sodium acetate and the calculated quantity of phenylhydrazine, and allowed to remain in a vacuum at the ordinary temperature for 24 hours. The reaction is completed by warming on the water-bath, the mixture being frequently shaken; after cooling, it

is extracted with ether. The aqueous solution retains most of the phenylhydrazinebutyric acid, which can be extracted with chloroform; whilst phenylmethylhydroisopyrazolone is found in the ethereal solution, and is purified by crystallisation from benzene.

Asymmetrical phenylhydrazinebutyric acid,

$$NH_2{\cdot}NPh{\cdot}CHMe{\cdot}CH_2{\cdot}COOH,$$

crystallises from alcohol in silvery leaflets, melts at 111°, and is easily soluble in hot water, alcohol, and chloroform, but only sparingly in cold water and ether; it quickly reduces silver nitrate and Fehling's solution in the cold, and is stable in the presence of alkalis, less so in the presence of acids.

Phenylmethylhydroisopyrazolone, $NPh<^{CHMe\cdot CH_2}_{NH---CO}$, is obtained by heating the preceding compound (0·5 gram) with concentrated sulphuric acid (2 grams) for ¾ hour at 100°. The mixture is diluted with water, neutralised with ammonia, and extracted with chloroform. It crystallises from benzene in two modifications, the stable modification separating in transparent, pale-red, short prisms, whilst the labile forms colourless tablets which become opaque when separated from the solvent. It dissolves easily in chloroform, hot alcohol, and hot benzene, more sparingly in hot water, separates from alcohol in colourless crystals, melts at 127°, dissolves easily in sodium hydroxide, and is reprecipitated by carbonic anhydride. Its solutions turn rose-red on exposure to air. It reduces silver nitrate solution with the production of a blue dye, and gives a carmine-red coloration with sodium nitrite in dilute acetic acid. When methylated, it yields a derivative which melts at 160°, and tastes like antipyrine. The *acetyl* derivative, $NPh<^{CHMe\cdot CH_2}_{NAc---CO}$, is obtained by heating it with acetic anhydride for some hours in a reflux apparatus. It crystallises from ether in colourless, rhomboidal crystals, melts at 79°, is easily hydrolysed by warming with dilute acids and alkalis, and is easily soluble in ether, chloroform, and benzene, sparingly so in water. In neutral solutions, it is stable towards oxidising agents; in alkaline or acid solutions, it is converted into phenylmethylisopyrazolone.

Phenylmethylisopyrazolone, $NPh<^{CMe:CH}_{NH\cdot CO}$, is obtained by adding the calculated quantity of ferric chloride to a warm alcoholic solution of the above hydroisopyrazolone. The mixture is poured into water and extracted with chloroform. On distilling off the chloroform, the isopyrazolone is obtained pure. It crystallises in colourless needles, melts at 167°, and also occurs in another modification which melts at 157° and is easily converted into the first modification. It dissolves in dilute alkalis, is reprecipitated by carbonic anhydride, is easily soluble in benzene, chloroform, and alcohol, sparingly so in water.

Phenyldimethylisopyrazolone (*Isoantipyrine*), $NPh<^{CMe:CH}_{NMe\cdot CO}$, is obtained by heating phenylmethylisopyrazolone with methyl alcohol and a slight excess of methyl iodide in a sealed tube for some hours

at 100°. The alcohol is then distilled off, the residue extracted with water, the solution decolorised with sulphurous acid, precipitated with potassium carbonate, and the isoantipyrine extracted with chloroform. It crystallises in large, yellowish tablets, melts at 113°, is very easily soluble in water and alcohol, easily in chloroform, hot benzene, and hot toluene, but only sparingly in ether, and is a strong base. The *platinochloride* forms dark-yellow crystals, melts at 192°, and is more soluble in water than the corresponding antipyrine derivative. The *picrate* is obtained in bright-yellow needles by mixing aqueous solutions of isoantipyrine and picric acid, and melts about 168°. The *ferrocyanide* is obtained as a white, crystalline precipitate on adding potassium ferrocyanide to a faintly acid solution of isoantipyrine. The *salicylate* is sparingly soluble in water. Isoantipyrine also resembles antipyrine in its behaviour towards ferric chloride, sodium nitrite, nitric acid, and bromine. With ferric chloride, it gives a dark-red coloration. Sodium nitrite colours the faintly acid solution emerald-green; the colour remains unaltered for many hours in dilute solutions; in more concentrated solutions, yellowish-green, oily drops are soon deposited, and by strongly cooling the solution, the *nitroso*-compound can be obtained in moss-green needles which explode at 155°. *Nitroisoantipyrine* is obtained as a crystalline precipitate by dissolving isoantipyrine in cold nitric acid, cautiously warming the solution until it begins to turn red, and then pouring it into water; it melts at 210°. The *bromide* crystallises out on allowing an acetic acid solution of isoantipyrine and bromine to remain for a time. Isoantipyrine does not yield a crystalline compound with benzaldehyde. E. C. R.

Synthesis of 1:3-Phenylpyrrodiazolecarboxylic Acid, 3-Methylpyrrodiazole, 3-Pyrrodiazolecarboxylic Acid, and Pyrrodiazole. By A. Andreocci (*Ber.*, **25**, 225—230).—When 1:3-phenylmethylpyrrodiazole, $\begin{matrix}\mathrm{NPh{\cdot}CH}\\ \|\\ \mathrm{N{=}CMe}\end{matrix}\!\!>\!\mathrm{N}$, is oxidised with potassium permanganate in alkaline solution, it is converted into 1:3-phenylpyrrodiazolecarboxylic acid, which is identical with Bladin's phenyltriazolecarboxylic acid (compare Abstr., 1891, 472). This acid is decomposed on heating, yielding 1-phenylpyrrodiazole, which is, doubtless, identical with Bladin's phenyltriazole; phenylpyrrodiazole melts at 47°, and boils at 266° under a pressure of 760 mm.

Methylpyrrodiazole, $\begin{matrix}\mathrm{NH{\cdot}CH}\\ \|\\ \mathrm{N:CMe}\end{matrix}\!\!>\!\mathrm{N}$, is obtained when 1:3-phenylmethylpyrrodiazole is oxidised with potassium permanganate in acid solution; it is a colourless, crystalline, deliquescent compound, melts at about 93—94°, boils at 265° under a pressure of 760 mm., and is very readily soluble in water and alcohol, but more sparingly in light petroleum; it gives with an ammoniacal solution of silver nitrate an amorphous precipitate, and forms a crystalline platinochloride which is soluble in water.

Pyrrodiazolecarboxylic acid, $\begin{matrix}\mathrm{NH{\cdot}N}\\ \|\\ \mathrm{CH:N}\end{matrix}\!\!>\!\mathrm{C{\cdot}COOH}$, prepared by oxidis-

ing the preceding compound with an alkaline solution of potassium permanganate, is a colourless, crystalline powder, almost insoluble in water, ether, and alcohol, but soluble in alkali carbonates.

Pyrrodiazole, $\begin{matrix}NH\cdot CH\\ \|\\ N{=}CH\end{matrix}\!\!>\!N$, is formed when the carboxylic acid is heated alone at 120°, or boiled with water; it melts at 120—121°, boils at 260°, sublimes in needles, and is very readily soluble in water and alcohol, but only moderately easily in ether; it forms compounds with copper, mercury, and silver, and with hydrogen chloride, it yields a crystalline hydrochloride. F. S. K.

Triazole Derivatives. By J. A. Bladin (*Ber.*, **25**, 174—183).—In his previous communications, the author has shown that phenylmethyltriazole derivatives are readily obtained by the action of acetic acid on dicyanophenylhydrazine (Abstr., 1885, 980; 1887, 138). Other acid anhydrides may be substituted for acetic anhydride. From the nitriles, $CN\cdot C\!<\!\begin{matrix}NPh\cdot N\\ \|\\ N{-}{-}CR\end{matrix}$, thus obtained the other derivatives may be prepared in the usual manner.

Phenylethyltriazolecarboxylic acid, $C_2N_3PhEt\cdot COOH$, is obtained from the corresponding nitrile (Abstr., 1885, 980) by boiling it with an excess of potash until no more ammonia is evolved, and carefully adding hydrochloric acid. It crystallises from benzene in small, colourless crystals melting at 144—145°, and from alcohol in large, well-developed crystals melting at 122—123°, the lower melting point being probably due to the presence of water of crystallisation, which is not evolved over sulphuric acid in a vacuum. The *methyl* ether melts at 41°; the *ethyl* ether is a colourless oil; the *alkali* salts are readily soluble in water; the *silver* salt is a white, microcrystalline precipitate; and the *copper* salt, $(C_2N_3PhEt\cdot COO)_2Cu + 3\frac{1}{2}H_2O$, crystallises in lustrous, bluish-green plates, which lose their water of crystallisation at 120°. The *hydrochloride*,

$$C_2N_3PhEt\cdot COOH,HCl,$$

crystallises from boiling hydrochloric acid in small, colourless plates which are decomposed by water.

When the alcoholic solution of the crude nitrile is treated with a few drops of aqueous potash, then with 3 per cent. hydrogen peroxide, warmed, and mixed with hydrochloric acid, it is converted into the corresponding *amide*, $C_2N_3PhEt\cdot CO\cdot NH_2$, which crystallises from alcohol in colourless groups of small prisms, melts at 152—152·5°, and is sparingly soluble in water and ether. The corresponding *thiamide*, $C_2N_3PhEt\cdot CS\cdot NH_2$, is prepared by passing hydrogen sulphide into the alcoholic solution of the crude nitrile, to which a little ammonia has been added; it crystallises in hard, sulphur-yellow prisms, and melts at 149·5—150°.

The nitrile of phenylpropyltriazolecarboxylic acid is readily obtained by heating dicyanophenylhydrazine with butyric anhydride; but as it does not crystallise it was converted at once into the

acid in the manner described under the ethyl derivative. *Phenylpropyltriazolecarboxylic acid*, $C_2N_3PhPr^{\alpha}\cdot COOH$, crystallises from dilute alcohol in colourless, almost cubic crystals, and melts at 160·5—161° with evolution of gas and formation of a colourless oil, which is probably phenylpropyltriazole. It yields a readily soluble *hydrochloride* which is decomposed by water; the *methyl* and *ethyl* salts are colourless oils; the *potassium* and *ammonium* salts are very readily soluble; the *silver* salt forms a voluminous, white precipitate, which readily becomes granular; and the *copper* salt, with $\frac{1}{2}$ mol. H_2O, which is evolved at 170°, forms pale-blue, microscopic needles, the crystals retaining their colour, on further heating, until decomposition commences. The *amide*, $C_2N_3PhPr^{\alpha}\cdot CO\cdot NH_2$, obtained by allowing the methyl or ethyl salts to remain with concentrated ammonia, crystallises from benzene in colourless, spherical groups of prisms, and melts at 122—122·5°; the *thiamide*, $C_2N_3PhPr^{\alpha}\cdot CS\cdot NH_2$, prepared by the action of hydrogen sulphide on an alcoholic solution of the crude nitrile, crystallises from benzene in spherical aggregates of lustrous prisms, and melts at 130—130·5°.

Phenylisopropyltriazolecarboxylic acid, $C_2N_3PhPr^{\beta}\cdot COOH$, is obtained in a manner similar to its lower homologues, and crystallises from benzene in small, colourless prisms containing benzene of crystallisation, which is evolved at 100°, the acid then melting at 135°, with evolution of gas and formation of a colourless oil, apparently phenylisopropyltriazole. The *hydrochloride* forms colourless crystals, and is decomposed by water; the *methyl* salt forms colourless druses of crystals, and melts at 75—76°; the *ethyl* salt is a colourless oil. The *alkali* salts are readily soluble in water; the *silver* salt forms microscopic plates; and the *copper* salt, with $2\frac{1}{2}$ mols. H_2O, forms sky-blue needles which lose their water of crystallisation at 170°, and become emerald-green at 185°. The *amide* crystallises from dilute alcohol in colourless needles, and melts at 127·5—128°; the *thiamide* crystallises from benzene in sulphur-yellow prisms, and melts at 147—148°.

The following substances, analogous to some of those described above, have also been prepared: *the methyl salt of phenylmethyltriazolecarboxylic acid*, which crystallises from dilute alcohol in spherical groups of hard, colourless needles, and melts at 101—105·5°; the *thiamide* of the same acid, which forms sulphur-yellow prisms, and melts at 182°; the *thiamide* of *diphenylthiazolecarboxylic acid*, $C_2N_3Ph_2\cdot CS\cdot NH_2$, which crystallises from benzene in sulphur-yellow needles containing benzene of crystallisation, and loses the latter at 110°, the substance then melting at 170·5—171·5°; and the *thiamide* of *phenylteterazolcarboxylic acid*, $CN_4Ph\cdot CS\cdot NH_2$, which crystallises from alcohol in arge, sulphur-yellow plates, and melts at 168—169°. H. G. C.

Ethyl and Methyl Morphine Carbonates. By R. Otto and A. Holst (*Arch. Pharm.*, **229**, 618—628).—With the potassium derivative of morphine, ethyl and methyl chlorocarbonates react very readily and perfectly. 10 grams of morphine is dissolved in sufficient potassium hydroxide solution (10 per cent.) to allow of a

slight excess of potash being present. Solution of ethyl or methyl chlorocarbonate (10 per cent.) in benzene is added in such quantity that a slight excess of the chlorocarbonate is also present. The two solutions are then agitated together, and the reaction takes place almost instantly, with formation of ethyl or methyl morphine carbonate. The carbonates remain dissolved in the benzene, and, after distilling off the solvent, they are left as yellowish, amorphous, brittle masses, similar to varnish, and become strongly electrical when rubbed. The *methyl* salt, $C_{17}H_{18}NO_2{\cdot}O{\cdot}COOMe$, melts at 116—120°; the *ethyl* compound, $C_{17}H_{18}NO_2{\cdot}O{\cdot}COOEt$, at 113°. In this form they seem to contain benzene. They are readily soluble in benzene, alcohol, ether, chloroform, ethyl acetate, and carbon bisulphide; water dissolves but small quantities, the solutions being strongly alkaline. They react with most of the alkaloïd reagents, but not with tannin. With acids, they react as monacid bases, and form well-defined salts. Those of the *methyl* compound which are described are the *normal sulphate*, a white, crystalline powder, soluble in water and alcohol, and melting at 225°; the *hydrochloride*, very soluble in water; the *platinochloride*, a yellow, crystalline precipitate. The salts of the *ethyl* compound are the *normal sulphate*, the *hydrochloride*, and *platinochloride*, which are similar to the corresponding salts of the methyl compound, and the neutral *oxalate*, a white, crystalline substance, which crystallises with 2 mols. H_2O.

Ethyl and methyl morphine carbonates are decomposed by the alkalis and by ammonia, morphine being set free. The same change occurs by simply boiling the solutions in water, and slowly, by contact with the atmosphere at the ordinary temperature.

The behaviour of these carbonates at a high temperature was examined. It appeared possible that carbonic anhydride might be liberated, with formation of codeïne. Both the compounds yielded carbonic anhydride at 110—120°, in almost exactly the theoretical amount required for the loss of 1 mol. CO_2 from 1 mol. of the base; but no codeïne could be detected in the residue. The residue reacted with the usual alkaloïd reagents. The physiological action of the two double carbonates was somewhat similar to that of codeïne, and dissimilar from that of morphine. J. W. L.

Action of Hydriodic Acid on Cinchonine. By E. Lippmann and F. Fleissner (*Monatsh.*, **12**, 661—666; compare Abstr., 1891, 1517, and Pum, this vol., p. 514).—The authors have repeated some of their experiments on the formation of hydriodocinchonine, $C_{19}H_{23}N_2OI$, with the result that they confirm the statements made in their former communication (this vol., p. 83). Hydriodocinchonine may also be obtained by decomposing in the cold with aqueous ammonia the dihydriodocinchonine, which the authors have prepared by a method similar to that described by Pum (*loc. cit.*). The authors have obtained a compound melting at 187—190°, and apparently indentical with Pum's dihydriodocinchonine, by dissolving in hot alcohol molecular proportions of hydriodocinchonine and dihydriodocinchonine hydriodide (compare Pum, *loc. cit.*). On cooling, a mass of

white needles separated, which, on analysis, gave numbers closely corresponding with those required by the formula $C_{38}H_{48}N_4O_2I_4$.

G. T. M.

Action of Hydriodic Acid on Quinine and on Quinidine. By A. Schubert and Z. H. Skraup (*Monatsh.*, **12**, 669—690; compare Abstr., 1891, 1517; Skraup, this vol., p. 83; and Lippmann and Fleissner, this vol., p. 81).—When anhydrous quinidine is warmed with colourless hydriodic acid of sp. gr. 1·7, and the resulting dark-yellow solution is allowed to remain in the cold for some days, a crystalline mass of reddish-yellow plates is formed which, on treatment with potash, is resolved into the two substances *dihydriodoquinidine hydriodide*, $C_{20}H_{26}N_2O_2I_2,HI$, and *dihydriodoapoquinidine hydriodide*, $C_{19}H_{24}N_2O_2I_2,HI$. If the alkaloïd is heated for three hours at 100° with a more concentrated acid (sp. gr. 1·96), the sole product is dihydriodoapoquinidine hydriodide, whereas if the action takes place at the ordinary temperature, and in absence of light, dihydriodoquinidine hydriodide alone is formed.

Dihydriodoquinidine hydriodide crystallises from alcohol in large, yellow plates, melts at 230°, is insoluble in potash, and, on the addition of alcoholic ammonia at the ordinary temperature, is converted into *dihydriodoquinidine*, $C_{20}H_{26}N_2O_2I_2$. This compound is only slightly soluble in alcohol, and is almost insoluble in water. It melts at 218—220°, decomposes at 228°, and forms an *oxalate*,

$$C_{20}H_{26}N_2O_2I_2,C_2H_2O_4,$$

which crystallises in yellow, microscopic needles, and a *hydrochloride*, $C_{20}H_{26}N_2O_2I_2,HCl$, which crystallises in small grains.

Dihydriodoapoquinidine hydriodide melts at 252°, is soluble in potash, and, on addition of alcoholic ammonia, furnishes the base $C_{19}H_{24}N_2O_2I_2$, which forms a crystalline *hydrochloride*,

$$C_{19}H_{24}N_2O_2I_2,HCl,$$

and *nitrate*, $C_{19}H_{24}N_2O_2I_2,HNO_3$.

A *base* of the composition $C_{20}H_{24}N_2O_2$, and therefore isomeric with quinidine, is obtained on warming an alcoholic solution of dihydriodoquinidine hydriodide with silver nitrate. It melts at 78—79°, and is dissolved by acids, yielding solutions which have a blue fluorescence and are turned green on the addition of chlorine and ammonia. Dihydriodoapoquinidine, when similarly warmed with silver nitrate, gives the base $C_{19}H_{22}N_2O_2$, which melts at 157°, and forms, with acids, solutions having a slight green fluorescence, and yielding a green coloration with chlorine and ammonia. This base appears also to be formed on long-continued heating of dihydriodoapoquinidine (1 mol.) with aniline (3 mols.) at 100°.

When anhydrous quinine is heated at 100° with hydriodic acid of sp. gr. 1·7, a substance which melts at 228—230°, and gives numbers corresponding with the formula $C_{20}H_{24}N_2O_2,3HI$ (compare Lippmann and Fleissner, *loc. cit.*), is obtained. It appears to be a mixture, since, on treatment with cold alcoholic ammonia, it yields two distinct bases having the composition $C_{20}H_{25}N_2O_2I$ and $C_{20}H_{26}N_2O_2I_2$, respectively. The former, *hydriodoquinine*, the chief product, is

soluble in alcohol, but almost insoluble in ether, and melts at 155—160°, with decomposition; its solution in dilute acids shows a blue fluorescence, and gives a brownish-yellow precipitate with chlorine and ammonia.

If quinine is treated with a stronger acid (sp. gr. 1·96), methyl iodide is evolved, and a substance of the composition $C_{19}H_{22}N_2O_2,3HI$ obtained. It melts at 236—238°, is insoluble in potash, and is most probably a mixture of $C_{19}H_{23}N_2O_2I,2HI$ and $C_{19}H_{24}N_2O_2I_2,HI$, since it gives with alcoholic ammonia in the cold the two bases $C_{19}H_{24}N_2O_2I_2$ and $C_{19}H_{23}N_2O_2I$ respectively. The former is the chief product; the latter gives a bright yellow *oxalate*, $C_{19}H_{23}N_2O_2I,C_2H_2O_4$, which melts at about 187°. G. T. M.

Alkaloïds of Berberis aquifolium and B. vulgaris. By C. Rüdel (*Arch. Pharm.*, **229**, 631—666).—The publications of Wacker, of Hesse, and of Stubbe, on the alkaloïds of the roots of *Berberis vulgaris*, and those of Parsons (Abstr., 1882, 1140), of Jungk, and of Stubbe on the alkaloïds of the roots of *Berberis aquifolium* show that each contains three alkaloïds, and that they are in all probability the same. The chemical formula and the exact description of the salts were not, however, very perfectly defined, and the author has endeavoured to complete this part of the work.

The ground-up roots were in each case extracted with very dilute acetic acid, and the extract was then concentrated to a syrup. Oxyacanthine was precipitated by sodium sulphate, berberine as acetone-berberine (Gaze's method) and berbamine by the addition of sodium nitrate.

Oxyacanthine, $C_{19}H_{21}NO_3$.—The elementary analyses of the specimens of this alkaloïd, as obtained from the two different sources, agreed closely with the above formula. The melting point lay between 174° and 185°; the base appears to exist in an amorphous and in a crystalline modification. It reacts with the usual alkaloïd reagents. The salts prepared were the normal *sulphate*,

$$(C_{19}H_{21}NO_3)_2,H_2SO_4 + 4H_2O,$$

white and crystalline; the hydrochloride, $C_{19}H_{21}NO_3,HCl + 2H_2O$, prepared from the platinochloride by precipitating the platinum with hydrogen sulphide, white and crystalline; the platinochloride, $(C_{19}H_{21}NO_3)_2,H_2PtCl_6 + 5H_2O$, a yellow, amorphous salt which could not be obtained crystalline; and the aurochloride, $C_{19}H_{21}NO_3,HAuCl_4 + 4H_2O$, a golden-yellow, amorphous substance, which likewise could not be obtained crystalline. These salts of oxyacanthine from different sources were alike in all respects.

Berbamine, $C_{18}H_{19}NO_3$, separated from the solution of the alkaloïds by the addition of sodium nitrate, was purified by precipitating the solution of the sulphate with ammonia and recrystallising from anhydrous ether. Thus obtained, it forms a fine, white, crystalline mass. The specimens from both sources proved to be identical. The following salts were prepared; the normal sulphate,

$$(C_{18}H_{19}NO_3)_2,H_2SO_4 + 4H_2O,$$

crystalline; the platinochloride, $(C_{18}H_{19}NO_3)_2,H_2PtCl_6 + 5H_2O$, a light-

yellow, amorphous powder; and the aurochloride, $C_{18}H_{19}NO_3,HAuCl_4 + 5H_2O$, a golden-yellow, amorphous powder.

Berberine, $C_{20}H_{17}NO_4$, was most readily separated by Gaze's acetone method. Acetoneberberine, $C_{20}H_{17}NO_4,C_3H_6O$, was obtained as a lemon-yellow, crystalline powder; acid berberine sulphate, $C_{20}H_{17}NO_4,H_2SO_4$, prepared by treating acetoneberberine with dilute sulphuric acid, is a pale-yellow, crystalline salt; the nitrate, $C_{20}H_{17}NO_4,HNO_3$, prepared by treating the acetone compound with the exact quantity of nitric acid, is a crystalline, yellowish-red salt; the platinochloride,

$$(C_{20}H_{17}NO_4)_2,H_2PtCl_6 + H_2O,$$

prepared by precipitating the hot solution of the hydrochloride with platinum chloride, is obtained as a yellow, crystalline precipitate; the hydrochloride, $C_{20}H_{17}NO_4,HCl + 4H_2O$, obtained by decomposing the acetone compound with hydrochloric acid, is a light orange-yellow-coloured salt.

Since Gaze found a "methylberberine" accompanying the berberine which he obtained from hydrastis berberine, the author converted a considerable quantity of his berberine specimen into hydroberberine, by reduction with zinc and sulphuric acid, and searched very carefully among the crystals of hydroberberine which were obtained for any second substance. No such other alkaloïd could, however, be found. J. W. L.

Constituents of Angostura Bark. By H. Beckurts and P. Nehring (*Arch. Pharm.*, **229**, 591—617).—The bark of the Columbian rutacea, *Cusparia trifoliata*, Engler (*Galipea officinalis*, Hancock), has been examined by the authors.

30 kilos. of the coarsely-powdered bark was extracted with 75 kilos. of ether; most of the ether was then distilled off, and the brown residue extracted with dilute sulphuric acid. Wax and essential oils were thus separated from the alkaloïds, and, in addition, a greenish-yellow, crystalline substance was precipitated; it is the salt of a base or bases, but it could not be obtained pure.

From the acid solution, four alkaloïds, *cusparine*, *cusparidine*, *galipine*, and *galipidine* were separated. The separation of these was, however, exceptionally difficult, since their solubilities are very similar, and they were obtained pure only by means of (1) repeated fractional crystallisation from their solutions in light petroleum; (2) fractional crystallisation of the respective sulphates from hot aqueous solution.

The residual bark, after extraction with ether, was extracted with 60 kilos. of alcohol, and the alkaloïds, wax, and oils separated from each other as from the ether extract. The same four alkaloïds were again obtained. The total quantity of impure bases which was thus separated amounted to 595 grams, or 2·0 per cent.

Galipine, $C_{20}H_{21}NO_3$, crystallises from light petroleum in slender, lustrous, soft needles which are pure white. It melts at 115·5°. It dissolves very readily in alcohol, chloroform, acetone, benzene, and ether, but is only sparingly soluble in light petroleum. Its salts are yellow, and crystallise like the base. The *hydrochloride*,

$$C_{20}H_{21}NO_3,HCl,4H_2O,$$

forms lustrous, yellow plates, very soluble in warm water. The *hydrobromide*, $C_{20}H_{21}NO_3,HBr$, crystallises in deep-yellow needles, and is very soluble in water and alcohol. The *hydrogen sulphate*, $C_{20}H_{21}NO_3,H_2SO_4$, forms lustrous, yellow needles. The *platinochloride*, $(C_{19}H_{21}NO_3)_2,H_2PtCl_6$, melts at 174—175°, crystallises in very small, yellow needles, and is almost insoluble in alcohol and in water. The *aurochloride*, $C_{20}H_{21}NO_3,HAuCl_4$, melts at 175—176°, and crystallises in very small, brownish-red needles. The *methiodide*, $C_{20}H_{21}NO_3,MeI$, forms small, lemon-yellow needles which melt at 146°; it is soluble in alcohol and in hot water, insoluble in ether.

Galipidine, $C_{19}H_{19}NO_3$, crystallises from light petroleum in very light, silky, lustrous plates which are pure white. It is readily soluble in alcohol, ether, benzene, ethyl acetate, and chloroform, less soluble in light petroleum; it melts at 111°. The salts are pale yellow, are readily soluble in hot water, and the solutions have a bitter taste. The *hydrochloride*, $C_{19}H_{19}NO_3,HCl + 3H_2O$, forms pale-yellow needles, soluble in warm water, but only sparingly soluble in cold water; the *hydrobromide*, $C_{19}H_{19}NO_3,HBr$, crystallises in minute, pale-yellow needles, readily soluble in water and alcohol; the *aurochloride*, $C_{19}H_{19}NO_3,HAuCl_4$, is precipitated as a mass of minute, chocolate-brown needles; it melts at 167°, and is almost insoluble in water and alcohol; the *platinochloride*, $(C_{19}H_{19}NO_3)_2,H_2PtCl_6$, separates as a voluminous, yellow, crystalline precipitate, very sparingly soluble in water; it melts at 182°. The *methiodide*, $C_{19}H_{19}NO_3,MeI$, forms a fine, yellow, crystalline powder, readily soluble in hot water and alcohol; it melts at 142°, and has an intensely bitter taste.

Cusparine, $C_{20}H_{19}NO_3$, is comparatively easily separated from the other bases, owing to the sparing solubility of its salts. It melts at 89°, and is readily soluble in alcohol, ether, choloroform, acetone, and benzene, more sparingly in light petroleum. Its salts are white and sparingly soluble in water, more readily in alcohol. The *hydrochloride*, $C_{20}H_{19}NO_3,HCl + 3H_2O$, crystallises in long, white needles, very slightly soluble in water, readily in alcohol, and of a bitter taste; the *hydrobromide*, $C_{20}H_{19}NO_3,HBr$, forms long, pale-yellow needles, of bitter taste; it is very sparingly soluble in water; the *sulphate*, $(C_{20}H_{19}NO_3)_2,H_2SO_4 + 7H_2O$, crystallises in white prisms of a bitter taste; it is only sparingly soluble in water, more readily in alcohol; the *aurochloride*, $C_{20}H_{19}NO_3,HAuCl_4$, forms a light-brown, voluminous mass of minute crystals, melts at 165°, and it is almost insoluble in water; the *platinochloride*, $(C_{20}H_{19}NO_3)_2,H_2PtCl_6$, forms minute, yellow needles, which may be recrystallised from hot water. It melts at 179°. The *methiodide*, $C_{20}H_{19}NO_3MeI$, forms lustrous, yellow needles, of intensely bitter taste, melting at 186°.

Cusparidine, $C_{19}H_{17}NO_3$, crystallises from light petroleum in minute, slender, white needles. It melts at 78°, and dissolves readily in chloroform, alcohol, ether, and ethyl acetate, less readily in light petroleum. The salts are white and of bitter taste; they are less soluble than those of galipine and galipidine, but more readily than those of cusparine. The *hydrochloride*, $C_{19}H_{17}NO_3,HCl + 3H_2O$, is precipitated as a white, voluminous mass of crystals, which melt very readily; it is sparingly soluble in water, more readily in alcohol,

and has a bitter taste. The *hydrobromide*, $C_{19}H_{17}NO_3,HBr$, crystallises from water in well-formed prisms, which are anhydrous; it is sparingly soluble in hot water, almost insoluble in cold water, more readily soluble in alcohol. The *sulphate*, $(C_{19}H_{17}NO_3)_2,H_2SO_4 + 3H_2O$, separates as a crystalline precipitate when cusparidine is exactly neutralised with sulphuric acid; it is moderately soluble in water, still more readily in alcohol, and has a very bitter taste. The *aurochloride*, $C_{19}H_{17}NO_3,HAuCl_4$, separates as a voluminous, brown mass of minute crystals; it is anhydrous, and melts at 167°. The platinochloride, $(C_{19}H_{17}NO_3)_2,H_2PtCl_6$, forms a pale-yellow, crystalline precipitate, which is insoluble in water and alcohol; it melts at 182°. The *methiodide*, $C_{19}H_{17}NO_3MeI$, is prepared by heating cusparidine with excess of methyl iodide for three hours at 100° in a sealed tube; after recrystallising from water, it forms a pale-yellow, crystalline powder, soluble in water and alcohol, insoluble in ether. It has a very bitter taste; its colour changes to brown on exposure to the air or light, and it melts at 149°.

The four alkaloïds are tertiary bases; their reactions with the various alkaloïdal reagents are described.

The *essential oil* of angostura bark, which was extracted by means of ether, was freed from alkaloïds by dilute sulphuric acid, and then remained as a dark-coloured liquid. From 100 kilos. of the bark, 1·5 kilos. of the oil was obtained. It has an aromatic odour: the sp. gr. at 15° is 0·956, and it dissolves in ether, alcohol, chloroform, light petroleum, and glacial acetic acid; it reddens litmus. It is free from sulphur and nitrogen, and does not react either as a phenol, a ketone, or an aldehyde. Distilled under a pressure of 35 mm., it commences to boil at 153°; the greater part distilled between 200° and 220°; the last portions became solid when cooled with a mixture of sodium sulphate and hydrochloric acid.

The *bitter principle, angosturin*, is insoluble in ether, but soluble in alcohol, and is found therefore in the alcoholic extract of the bark; it is obtained free from alkaloïds after the alcoholic extract has been rendered alkaline with sodium carbonate and extracted with ether. The bitter principle is difficult to obtain pure. The residue, after separating the alkaloïds, was dissolved in water, and an excess of tannin added; the precipitate was washed with water, and dissolved in alcohol; lead acetate was added, and the precipitate first washed with alcohol and then with boiling water. The angosturin was further purified by dissolving it in water, precipitating with charcoal, extracting with alcohol, and finally evaporating the latter. It remained as a transparent, pale-yellow mass, which is soluble in water, alcohol, and glacial acetic acid. The addition of ether to the solution in acetic acid precipitated the angosturin quite white; it melts at 58°.

The angostura bark contains a *glucoside*, which may be separated from the bark, after exhausting it first with ether, and then with alcohol, by extraction with water. The solution fluoresces and reduces Fehling's and other metallic solutions. The glucoside was not however obtained pure. J. W. L.

Ash-free Albumin. By E. Harnack (*Ber.*, **25**, 204—209; compare Abstr., 1891, 476; also Werigo, Abstr., 1891, 1268, and Stohmann and Langbein, this vol., p. 4).—The author points out that the ash-free albumin prepared by his method has none of the characteristic properties of an acid albumin in spite of the fact that it contains hydrochloric acid; he considers that his ash-free albumin may be ordinary albumin freed from inorganic bases, &c., and combined with hydrochloric acid without any alteration of the molecule, just as in the case of the hydrochlorides of amido-acids.

Preparations of ash-free albumin which have been repeatedly dissolved and reprecipitated and then well washed contain 1·4 per cent. of chlorine, which corresponds with 2 mols. of hydrogen chloride to 3 atoms of sulphur in the albumin molecule. When the ash-free albumin is submitted to dialysis, the hydrochloric acid passes away, and the albumin gradually separates from the solution in the form of a transparent jelly; if the water containing the jelly is heated to boiling, the albumin becomes white, compact, and crystalline in appearance, especially after drying; the same effect is produced when the jelly is treated with alcohol. The crystalline powder obtained in this way is insoluble in water, but dissolves at once on the addition of a trace of hydrochloric acid, the solution having the properties of a solution of the original ash-free albumin. F. S. K.

Rotatory Power of Various Silks. By L. Vignon (*Compt. rend.*, **114**, 129—131).—The specimens were dissolved in the manner previously described (this vol., p. 254), with the exception that in one case sulphuric acid was substituted for hydrochloric acid.

The solutions were lævogyrate in all cases, the values of $[\alpha]_j$ at 15° varying from −9° to −43·6° for the alkaline solutions, the mean being −29·6°, and from −39·4° to −50° for the acid solutions, the mean being −44°. Jn. W.

Physiological Chemistry.

Digestibility of Pentose Carbohydrates. By W. E. Stone (*Amer. Chem. J.*, **14**, 9—14).—Rabbits were fed during the first period with a mixture of bran and meal; during the second, with bran only. A complete analysis was made in each case of the food and of the dung, the pentosans or pentose carbohydrates being estimated in the "nitrogen-free extract" by converting them into furfuraldehyde and titrating this with a standard solution of phenylhydrazine (pentosans = furfuraldehyde × 1·38). The pentosans are much less digestible than the true carbohydrates. In the first period, about 60 per cent. was digested; but in the second period, when the proportion of nitrogenous to carbonaceous matter was considerably increased, the pentosans did not seem able to supply

the lack of carbohydrates, and were themselves digested to a less extent than 40 per cent. The proportion of pentosans in the nitrogen-free extract of the dung is much higher than in that of the food; thus the digestive action has been selective, and only certain constituents of the nitrogen-free extract of the food have been removed, whilst others remain wholly or in part unchanged. C. F. B.

Absorption without Osmosis. By E. W. Reid (*Brit. Med. J.*, i, 1892, 323—326).—In a previous paper (Abstr., 1890, 277), it was shown that in the skin of the living frog, the osmotic transfer of liquid occurred in one direction, namely, from without inwards, that whatever raised its vitality increased the flow, and whatever depressed it diminished the flow. The evidence of the existence of vital absorptive force would be stronger if one could put osmosis entirely on one side and actually observe the passage of liquid across the living skin by virtue of its own unaided activity. This can be effected by an apparatus which is figured and described in the present communication. Briefly, it consists of a cylinder placed horizontally, across the middle of which a diaphragm of live skin is placed; both sides are filled with salt solution, and the transfer of liquid watched in fine manometers, also running horizontally, one on each side of the membrane. The liquid falls in one, that facing the outer surface of the skin, as it rises in the other. This is not osmosis, filtration, or electro-osmosis, but a special non-osmotic vital absorptive power. W. D. H.

Tissue-Fibrinogens. By A. E. Wright (*Proc. Roy. Irish Acad.* [3], **2**, No. 2).—In a previous communication, Wooldridge's "tissue-fibrinogens" were stated to consist chiefly of nucleo-albumin. These substances were said to give the biuret reaction characteristic of proteoses and peptones, and the theory advanced that in the body a peptone-like substance is split off from the proteïd. This is now supported by experiments which show that in animals, after the intravenous injection of tissue-fibrinogens, there is at a certain stage not only the increased coagulability of the blood noted by Wooldridge, but also a diminished coagulability, such as is produced by peptone. Moreover, "peptonuria" also occurs. W. D. H.

Formation of Uric Acid from Nucleïn. By J. Horbaczewski (*Sitz. k.k. Akad. d. Wiss. Wien. Mathem.-naturw. Cl.*, 1891, Abth. 3).—By treating splenic pulp with blood, uric acid is formed. If fresh pulp is allowed to digest with water for 8—10 hours until an odour of putrefaction is just observable, and then lead acetate added, and the mixture filtered, the filtrate when mixed with blood leads to the formation of uric acid. If, however, the filtrate is boiled first, no uric acid, but an equivalent of xanthine and hypoxanthine, is formed.

Recent researches having shown that nitrogenous bases are obtained from nucleïn, the idea arose that the nucleïn of the splenic cells might be the source of the uric acid, and, in fact, nucleïn (prepared as an insoluble residue after the gastric digestion of splenic

pulp) yielded uric acid just as splenic pulp does. Uric acid was also found to be obtainable from any organ rich in nuclei.

The next step in the investigation showed that uric acid was increased in the urine of animals after food, and especially by food which, like meat, causes an increase of leucocytes in the blood. Subcutaneous injection of nucleïn led to a great increase in the uric acid excreted. This occurs both in animals and in men. In certain cases of disease in man in which no increase of leucocytes occurred, there was also no rise in the uric acid eliminated.

The influence of drugs was also investigated. Quinine produces a fall in the number of leucocytes, and a fall also in the excretion of uric acid. Atropine acts in the same way. Pilocarpine produces the opposite effect. Antipyrin and antifebrin produce an increase of leucocytes, but a fall in the uric acid; this is explained by the hypothesis that although the leucocytes are more numerous, they are not destroyed so rapidly. Microscopic examination of the spleen and blood showed the leucocytes in an atrophic condition after quinine and atropine, whilst after pilocarpine they are undergoing karyokinetic changes.

Lastly, the condition of things in various pathological conditions showed that wherever there is leucocytosis or leucocythæmia there also is an increase in the output of uric acid; and the theory that it originates from nucleïn is considered to be borne out very fully.

W. D. H.

Influence of Various Salts on Live Weight and on the Composition of Bones and Teeth. By H. Weiske (*Landw. Versuchs-Stat.*, **40**, 81—108; compare Abstr., 1891, 848 and 1525). —The experiments now described were made in order to ascertain whether calcium carbonate, or salts having an alkaline reaction, or organic salts, have the same effect as hay (or other foods which give alkaline ashes) in hindering the extraction of minerals observed with foods which yield acid ashes. As in the earlier experiments, rabbits were used; they were fed on oats alone, and on oats with the addition of one of the following salts:—calcium carbonate, tricalcium phosphate, sodium phosphate, sodium dihydrogen phosphate, sodium citrate. With regard to increase in weight, it was found that oats alone is unsuitable; oats with hay, with calcium carbonate (and possibly calcium phosphate), and in one case with sodium phosphate, gave satisfactory results, whilst the other salts were more or less injurious. With the addition of hay or calcium carbonate to oats, the rabbits remained healthy and increased in weight, and the bones increased both in weight and strength. Both the calcium carbonate and the minerals of the hay tend to neutralise the acids of oats, and both contribute to increase the lime in the bones. The fact that one of the rabbits which had calcium phosphate lost weight makes it probable that want of lime was not the only cause of the unsatisfactory results obtained by the exclusive use of oats. Sodium dihydrogen phosphate produced loss of weight, and the bones became poorer in minerals, thin-walled, and weaker. Sodium citrate gave rise to a greater loss of total weight, and of the weight of the bones, than was

the case with oats alone; the bones were also poorer in minerals. The composition of the teeth varied only slightly in all the experiments.

Tables are given showing the weights of the rabbits during the experiments, the amount of flesh found after they were killed, the composition of the ash of the flesh, and the weight and composition (organic matter and ash constituents) of the bones. N. H. M.

Blood of Invertebrata. By A. B. Griffiths (*Proc. Roy. Soc. Edin.*, **18**, 288—294).—The gases of the blood of various invertebrates investigated by the use of the mercurial air-pump, gave the following results:—

Animal.	Oxygen.	Carbonic anhydride.	Nitrogen.
Sepia officinalis	12·9—13·6	29·1—32·1	1·2—2·0
Cancer pagurus	14·7—14·9	27·1—28·6	1·0—1·3
Palinurus vulgaris	14·2—14·7	28·9—30·0	1·2—1·8
Homarus vulgaris	14·8—14·9	28·8—31·1	1·7—1·8
Octopus vulgaris	13·2—13·6	30·2—31·2	1·3—1·4
Acherontia atropos	16·2—16·7	32·9—34·2	1·1—1·9

The oxygen and carbonic anhydride, as in vertebrates, thus do not obey Dalton's law, but are in part in chemical combination; the oxygen being held by hæmocyanin, a copper-containing proteïd, which takes the place of hæmoglobin in these animals.

The mineral matter of the blood was examined in a number of invertebrates; in gastropods, its amount was 1·1 to 1·8 per cent.; in *Sepia* the percentage was 2·8; in *Octopus* 3.

The following table gives a few results, selected from the fuller tables in the paper:—

	Cancer pagurus.	*Astacus fluvatilis.*	*Homarus vulgaris.*	*Anodonta cygnea.*	*Octopus vulgaris.*
CuO	0·22	0·2	0·18	0·23	0·21
Fe_2O_3	trace	0	trace	0	0
CaO	3·55	3·58	3·54	3·61	2·40
MgO	1·91	1·88	1·89	1·82	1·55
K_2O	4·97	4·82	4·77	4·90	4·90
Na_2O	43·9	44·96	44·99	44·18	45·31
P_2O_5	4·9	4·81	4·84	4·89	4·88
SO_3	2·9	2·75	2·81	2·80	2·83
Cl	37·65	37·0	36·96	37·55	37·92

In addition, it may be mentioned that in the blood of *Anodon* a trace of lithium was detected by the spectroscope; that in *Mytilus edulis* a trace of manganese was found, in addition to the usual (0·22)

percentage of copper, while in *Pinna squamosa* the percentage of manganese was 0·19, and only a trace of copper was found.

W. D. H.

Carbonic Anhydride in the Urine. By T. C. Van Nüys and R. E. Lyons (*Amer. Chem. J.*, **14**, 14—19).—The normal urates of sodium and potassium ($C_5H_2N_4K_2O_3$, $C_5H_2N_4Na_2O_3$) are strongly alkaline; they are decomposed by carbonic anhydride or acid calcium phosphate, $CaH_4(PO_4)_2$, with formation of the acid urates, which are themselves further decomposed, uric acid being deposited. Carbonates are decomposed by acid sodium or calcium phosphate; hence carbonic anhydride can hardly exist combined in urine, unless the latter is strongly alkaline.

The carbonic anhydride in the urine was estimated after employing (1) a mixed diet, (2) a vegetable diet, (3) after ingesting large doses of normal sodium tartrate, $C_4H_4Na_2O_6$. With (1) the urine was acid in reaction, and contained a relatively small quantity of carbonic anhydride; with (2) it was strongly alkaline, and contained more carbonic anhydride; with (3) it was strongly alkaline, owing partly to alkali carbonates, for it effervesced with acids.

The following conclusions are drawn:—(1) Combined carbonic anhydride is not ordinarily a constituent of normal urine. (2) When carbonic anhydride does appear in the urine combined, it is owing to excessive alkalinity of the blood, when it is induced to combine with the hydroxides of potassium and sodium which would otherwise appear in the urine. (3) The alkalinity of normal urine, unless excessive in degree, is caused by di- or tri-basic potassium or sodium phosphates, and by normal urates of potassium and sodium.

C. F. B.

Hæmatoporphyrin in Urine. By O. Hammarsten (*Skand. Arch. f. Physiol.*, **3**, 319—343).—This is a very thorough investigation of the urine in four cases of hæmatoporphyrinuria, in which the pigments were all separated, and the hæmatoporphyrin crystallised as a hydrochloride.

The cases were all women suffering from melancholia or mania, and were all treated with sulphonal. More observations are, however, necessary before it can be absolutely proved that the drug is the cause of the pigment in the urine.

Urine No. 1.—The pigments found were:—(1) Urobilin. (2) A yellow pigment, probably identical with that in normal urine. (3) Hæmatoporphyrin. (4) A red-brown pigment which gives no fluorescence with zinc chloride and ammonia, and so does not belong to the urobilin group.

Urine No. 2.—The pigments (1), (2), and (3) were the same as in urine No. 1. (4) A red-brown pigment similar to Le Nobel's hexahydrohæmatoporphyrin (*Pflüger's Archiv*, **11**). (5) A chromogen of a pigment of the urobilin group. (6) A chromogen which, on the addition of acid, yields a rose-red pigment which, however, is not identical with indigo-red or uroseïn.

Urines Nos. 3 *and* 4.—In the main the same as urine No. 1.

W. D. H.

The Urine in a Case of Phosphorus Poisoning. By E. H. Starling and F. G. Hopkins (*Guy's Hosp. Rep.*, 1890, 275—278).—In a case of phosphorus poisoning, which proved fatal in a few days, the urine gave the following analytical results:—

Urea	2·5	per cent.	
Ammonia	0·18	„	
Total nitrogen	1·344	„	
Nitrogen as urea	1·17	„	ratio 7·9 : 1.
„ ammonia	0·148	„	
Leucine and tyrosine	none		
Total sulphur	0·24	„	
Oxidised sulphur	0·122	„	0·116 as sulphates. 0·006 as ethereal sulphates.
Ratio of unoxidised to oxidised sulphur			0·97 : 1.
Total amount of urine in 12 hours			528 c.c.

The urine is thus nearly normal; the deviations from the normal being the large amount of nitrogen as ammonia and of sulphur in the unoxidised condition. The former is probably due to diminished alkalescence of the blood, as evidenced by the decrease of carbonic anhydride there (Meyer, *Arch. exp. Path. Pharm.*, **14**, 313).

Chemistry of Vegetable Physiology and Agriculture.

Ferments in Pineapple Juice. By R. H. Chittenden, E. P. Joslin, and F. S. Meara (*Trans. Connecticut Acad.*, **8**, 1—28).—Papaïn is the best known instance of a proteolytic ferment in the vegetable kingdom; recent research shows that such ferments are almost universally distributed, and that that in pineapple juice is very remarkable in its powers. The juice itself is acid, and contains a small amount of proteïd matter (less than 0·025 per cent.) which consists of three proteïds, one coagulated at 75°, another at 100°, and a small amount of non-coagulable proteose.

The proteolytic action of the juice tested on flesh, fibrin, white of egg, &c., takes place in an acid, alkaline, or best in a neutral medium, and at a temperature of 40°. The juice has also the power of curdling milk like rennet.

Saturation with ammonium sulphate precipitates all the proteïds in the juice, and with them the ferment or ferments. The proteïd precipitate, freed from excess of salt by dialysis, acts on proteïds like the original juice. Sodium chloride also precipitates a proteïd having characters akin to globulin and to heteroproteose; this is either the ferment or closely associated with it.

W. D. H.

Action of Boric Acid on Germination. By J. Morel (*Compt. rend.*, **114**, 131—133).—The rate of germination of beans and wheat which have been soaked in aqueous solutions of boric acid or borax (0·01—0·1 per cent. of acid) is considerably less than the normal, the amount of retardation increasing with the strength of the solution. The plants which subsequently develop from the seedings are weakly, and etiolated in the same proportion. Jn. W.

Sodium Chloride in Plants. By P. Lesage (*Compt. rend.*, **114**, 143—145).—By watering certain plants, such as *Lepidium sativum* and *Raphanus sativus*, with sea-water or salt solution the author recently succeeded in producing modifications in them identical with those which they undergo naturally when they are allowed to grow near the sea-coast. He now finds that sodium chloride is actually absorbed by the plants thus artificially modified, an excessive amount of sodium, for instance, being found in the stems of the first-named plant, and in the tubers of the other. Jn. W.

Absence of Oxalates in Young Leaves, as in the case of some Phanerogam Parasites. By C. Wehmer (*Land. Versuchs-Stat.*, **40**, 109—159).—Crystals of calcium oxalate occur in nearly all the cells of quite young leaves developed at the beginning of summer; in the case of leaves which develop in the early spring, the same leaf in its first and last stages is free from them. This is readily seen in the case of *Symphoricarpus racemosa*, and has been observed by the author in the case of many woody plants. The present investigation was undertaken with a view to ascertain whether in the absence of microscopically visible calcium oxalate, the salt (or oxalic acid) is really absent, or whether it is present in another form. Young leaves of the following species were examined:—*Symphoricarpus racemosa*, *Cratægus oxyacantha*, *Æsculus hippocastanum*, *Sambucus nigra*, *Prunus Padus*, *Juglans regia*, and *Aspidium filix mas*. The methods employed for the identification of lime and oxalic acid are fully described.

Æsculus hippocastanum.—The leaves of the 5th May were 2—6 cm. long. The sap contained no oxalic acid or oxalate, but lime was readily detected; nitrates were absent. The ash contained carbonate, indicating the pre-existence of an organic acid.

Symphoricarpus.—The leaves (2nd May) were 6 cm. or less long. The sap gave an indistinct and doubtful reaction for nitrate with diphenylamine. Some leaves of the 6th May gave a deep-blue colour, whilst others of the same date gave a slight reaction. The sap contained no alkaline oxalate, whilst it is uncertain whether calcium oxalate was present or not. The analytical results are given in the table below, together with those obtained with *Cuscuta* and *Lathræa*.

Lathræa squamaria.—The sap gave no nitrate reaction, but reddened litmus. The ash of the stalk, treated with sulphuric acid, gave off much carbonic anhydride, and crystals of gypsum separated; no oxalate crystals could be detected. It is probable that the leaves contain traces of calcium oxalate, too minute to be weighed.

Cratægus oxyacantha.—The sap reddened litmus slightly. No

oxalic acid could be detected, but lime was found in considerable amount.

Juglans regia.—The sap reddened litmus. Calcium was found, but no oxalic acid.

Sambucus nigra.—All the leaves (5th May) gave blue coloration with diphenylamine sulphate. The ash contained calcium.

Aspidium filix mas.—A piece of a leaf stalk (0·5 cm.) gave only a trace of ash, which melted when heated on platinum. It contained only a trace of calcium, if any. Oxalic acid was absent, but it is probable that an alkaline organic salt was present.

Cuscuta europæa.—The sap reddened litmus; it contains no oxalic acid, but probably another organic acid and a trace of calcium. A large amount of substance was extracted, the solution evaporated, and the syrup treated with animal charcoal; after some weeks, crystals of oxalate could be detected with a microscope.

The following table gives the percentage amounts of soluble, insoluble, and total dry matter, the amounts of ash in the soluble and insoluble portions, and in total dry matter, and the percentage of lime in the ashes:—

	Dry matter.			Ash.			Lime in pure ash.		
	Soluble in water.	Insoluble in water.	Total.	In the soluble substance.	In the insoluble substance.	In total dry substance.	Of soluble substance.	Of insoluble substance.	Total ash.
Cuscuta europ...	4·4	6·43	—	11·0	3·31	5·07	2·7	6·01	2·94
Symphoricarpus racemosa	6·1	10·6	16·61	4·22	2·65	—	21·05	20·0	20·25
Lathræa squamaria	3·72	6·82	10·54	21·9	3·11	—	0·476	25·16	6·85
Do.	5·04	5·17	11·11	20·0	—	—	1·61	—	—
Do.	—	—	—	—	—	—	—	—	5·1
Do.	—	—	10·71	—	—	—	—	—	11·3

The results of the experiments show that calcium compounds are universally present in young spring leaves, so that the absence of oxalic acid is not due to absence of lime. The amount of lime varies considerably, and is partly in a soluble and partly in an insoluble form; the dissolved lime is perhaps in combination with an organic acid. Oxalic acid and alkaline oxalates could never be detected with certainty, and if present at all occur only in traces. Calcium oxalate could not be found in the cells, and only traces could be obtained by using large amounts of substance. It is thus seen that the change of substance of the cells does not necessarily yield oxalic acid even in presence of calcium salts; in the case of *Cuscuta* it was seen that the greater part of the bases existed as organic salts (not oxalates).

The Latex of Ficus carica. By U. Mussi (*L'Orosi*, **14**, 297—304).—The latex of the common fig, *Ficus carica*, is a white, mobile liquid with a disagreeable odour, a bitter taste, and an acid reaction; its specific gravity is 1·05. If left in the dark without access of air, it slowly deposits small, white, amorphous masses of an elastic substance. When exposed to air and light, it darkens, and sometimes putrefies. It is composed of an enormous number of microscopic granules resembling in structure those of potato starch, but containing neither starch, inulin, nor nitrogenous compounds.

By filtration, the latex may be divided into a liquid and a solid portion. The former contains vegetable albumin, traces of mineral salts, substances of a gummy and pectic nature, among which occurs a new digestive ferment, termed by the author, *cradin*, and described in a previous paper (*L'Orosi*, **13**, 364), glucose, and malic acid. The solid portion consists of cerotic acid, caoutchouc, a white substance insoluble in water, but soluble in cold alcohol, ether, and chloroform, and a substance occurring in thin scales, insoluble in water and all ordinary solvents. The percentage composition of the latex is as follows:—

Cradin.	Albumin.	Gummy and peptic substances.	Resinous matters.	Extractive matters.	Insoluble organic compound.
6·89	3·51	0·07	1·53	1·23	2·43

Glucose.	Malic acid.	Cerotic acid.	Caoutchouc.	Water.	Ash.
1·29	0·47	2·79	12·86	66·19	0·76

Cause of Acidity in Green Grapes. By C. Ordonneau (*Bull. Soc. Chim.* [3], **6**, 261—264).—See this vol., p. 589.

Constituents of the Nitrogen-free Extract. By W. E. Stone (*Chem. News*, **65**, 39—40).—The author has shown by means of the furfuraldehyde reaction, that many of our feeding-stuffs such as hay, straw, bran, maize, brewers' grains, &c., contain very appreciable quantities of gum-like carbohydrates which on hydrolysis yield pentoglucoses, or pentoses, arabinose, or xylose, as the case may be. These substances are practically insoluble in water, but may be extracted from tissues by heating with weak alkalis, and in the course of an ordinary fodder analysis they would count as carbohydrates. Their value as a food is, however, very doubtful, as the author has tested the excreta of animals for substances of this class with positive results. The manure of steers fed on a diet composed largely of maize ensilage yielded an amount of furfuraldehyde equivalent to more than 5 per cent. of these compounds. Owing to the incompleteness of the method by which they were obtained, the percentage found was no doubt considerably below the truth.

The author hopes to gain some light as to the absolute digestibility of these substances, and promises further experiments on the subject (compare this vol., p. 645). L. de K.

Truffles: Relation between the Terfâs or Kamés of Africa and Western Asia and the Truffles of Europe. By A. CHATIN (*Compt. rend.*, **114**, 46—53).—The terfâs or kamés belong to the genus *Terfezia*, with the exception of one, *Tirmania Africana*. The soils in which they grow may be termed terfasseries.

Soils of the Terfasseries.

	I.	II.	IV.
Nitrogen	0·140	0·145	0·16
Phosphoric acid	0·151	0·170	0·20

Water	—	—	86·10	—
	100·00	100·000	100·00	100·00

I, II, and IV were analysed after drying; No. III was analysed in the natural moist state. In some cases the proportion of ash is increased by the earthy matter that adheres tenaciously to the tubercle.

In the ash of No. I (see table on next page) the proportion of potash, phosphoric acid, &c., is reduced in consequence of the considerable admixture of earthy matter. I is the terfâs of Barika (*Terfezia Boudieri*). The soil is an ochre-coloured, pulverulent clay, containing numerous small fragments of calcium carbonate; II is the terfâs of Briska (*Tirmania Africana*); III is the kamé of Damas (*Terfezia Claveryi*); IV is the kamé of Bagdad (*Terfezia Hafazi*). The soil is a very fine clay, which effervesces strongly with acids.

The earth of the terfasseries is much more friable, and much lighter

Composition of the Ash of the Tubercles.

	I.	II.	III.	IV.
Phosphoric acid	5·390	12·330	13·40	15·60
Sulphuric acid	3·360	3·660	4·50	3·70

	100·000	100·000	100·00	100·00

than the earth of the truffle beds; it contains a considerable quantity of fragments of calcium carbonate. Iron, nitrogen, and phosphoric acid are present in both cases. Potash is present in considerably lower proportion in the earth of the terfasseries than in the earth of the truffle beds.

In general composition the terfâs are similar to truffles. The proportion of phosphoric acid, however, is only half as great in the former as in the latter. This is true also of potassium. Chlorine, iodine, sodium, calcium, magnesium, iron, and manganese are present in practically the same proportions in both cases.

Judging from their composition, the terfâs or kamés should constitute a valuable food. C. H. B.

Spontaneous Oxidation of Humic Acid and Vegetable Soil. By Berthelot and G. André (*Compt. rend.*, **114**, 41—43).—Humic acid from sugar and starch, when exposed to light in presence of air and moisture, changes to a yellow substance. A very small quantity of a soluble substance is formed at the same time. The humic acid is oxidised, and carbonic anhydride is evolved, but no nitrogen is oxidised during the change, and the alteration does not extend beyond the superficial layer. Humic acid extracted from soils by potash and precipitated by hydrochloric acid behaves in a similar manner, although the change takes place less rapidly, probably because the humic acid has previously been partially oxidised.

The change takes place in complete absence of bacteria, and hence the latter are not essential to the oxidation of the vegetable matter in soils, although they do in nature play an important part. The observation that humic acid is oxidised under the influence of light in presence of air and moisture explains why earth that is continually exposed gradually loses its organic matter. Since also it seems that the product of oxidation is more readily assimilated than the original

humic acid, the observation also explains why, within certain limits, free exposure of a vegetable soil to air and light increases its fertility. C. H. B.

Estimation of Sulphur in Vegetable Soils, and the Forms in which it is Present. By BERTHELOT and ANDRÉ (*Compt. rend.*, **114**, 43—46).—The ratio of total sulphur to sulphur present as sulphates varies considerably in different soils, the organic sulphur being sometimes equal to, and sometimes much greater than, the sulphur as sulphates.

The total sulphur can only be estimated by complete destruction of the soil. Even chlorine in presence of hot aqueous potash is unable to effect complete oxidation. It is noteworthy, too, that 10 per cent. aqueous potash seems to be incapable of completely decomposing the calcium sulphate.

A point of great importance is the ratio of organic sulphur to organic nitrogen. In one case the sulphur was 8·7 per cent. of the nitrogen; in another it was 36·5 per cent. It would seem that in cases like the first the sulphur is present in a form similar to the proteïds, whilst in the others it is present in the form of carbon compounds of a very different character. C. H. B.

Influence of the Proportion of Clay and Organic Nitrogen in Fallow Soils on the Absorption of Atmospheric Nitrogen, the Retention of Nitrogen, and Nitrification. By P. PICHARD (*Compt. rend.*, **114**, 81—84).—In soils growing no crops, the absorption of atmospheric nitrogen is greatly accelerated by the presence of clay, and within certain limits the increase in nitrogen is proportional to the quantity of clay present. About 10 per cent. of the absorbed nitrogen is found in the form of nitrates, and 8 to 10 per cent. in the form of ammonium salts. The addition of calcium sulphate increases the quantity of nitrogen fixed, probably by preventing loss in the form of ammonium carbonate. The beneficial influence of clay is also observed in mixtures of clay, sand, and seed cake; addition of calcium sulphate reduces the loss of nitrogen in this case also, but addition of calcium carbonate increases it.

When soils contain 2—3 grams of organic nitrogen per kilo., the presence of clay prevents loss of nitrogen, but does not seem to facilitate its absorption.

For a given quantity of organic nitrogen, the presence of clay sometimes facilitates, and sometimes impedes, nitrification. With 1 gram of organic nitrogen per kilo., the presence of clay seems to be beneficial. Increase of organic nitrogen from 1 gram to 3 grams per kilo. is unfavourable to nitrification, seemingly because ammonium carbonate is formed more rapidly than it can be nitrified.

If it is desired to prepare a compost so that the nitrogen shall all be converted into nitrates, the quantity of organic nitrogen should not exceed 1 gram per kilo., and about 30 per cent. of clay and 0·5 per cent. of calcium sulphate should be added. For an ammoniacal compost, the proportion of organic nitrogen should be increased to 2 or 3 grams per kilo., and clay and calcium sulphate may be added with advantage. In soils where cessation of nitrification seems to be

due to the formation of too much ammonia, calcium carbonate should be added. C. H. B.

Analytical Chemistry.

New Drying Apparatus for Elementary Analysis. By E. Sauer (*Ber.*, **25**, 258).—The author describes a form of drying apparatus for use in elementary analysis; it consists of two wash-bottles, made entirely of glass, and containing concentrated potash; two others, containing concentrated sulphuric acid; and two large U-tubes, provided with lateral tubulures, and partly filled with granulated calcium chloride, and partly with soda-lime. The air or oxygen is passed through one-half of the apparatus in the usual way, and, as only four corks are used in the construction of the apparatus, it is easily kept air-tight if the india-rubber tubing which forms the connections is occasionally renewed. F. S. K.

Estimation of Iodates in Potassium Iodide. By T. Gigli (*L'Orosi*, **14**, 229—232).—4 to 5 grams of potassium iodide is dissolved in 300 c.c. of distilled water, 20 c.c. of dilute sulphuric acid (2 per cent.) added, and the iodine liberated ($5HI + HIO_3 = 3H_2O + 3I_2$) titrated with decinormal sodium thiosulphate and starch. 1 molecule of sodium thiosulphate corresponds with 1 atom of iodine, and hence with $\frac{1}{6}$ mol. KIO_3. The reaction which occurs is represented by the equation $2Na_2S_2O_3,5H_2O + I_2 = 2NaI + Na_2S_4O_6 + 10H_2O$, no secondary reactions being introduced by the presence of sulphuric acid in the solution. S. B. A. A.

Influence of Temperature on Griess' Reaction for Nitrites in Water. By G. Bosio (*L'Orosi*, **14**, 416—418).—The temperature at which Griess' test for nitrites is carried out has a considerable influence on the time required for the appearance of the coloration, and on the depth of the tint. When, for instance, it is applied to water at a low temperature (0° to 10°) the product is insoluble, and separates as a reddish-white, gelatinous precipitate, which, on raising the temperature to 40—50°, redissolves instantaneously, giving the characteristic crimson coloration. To obtain accurate and comparable results when the reaction is used for colorimetric determinations, it is advisable to uniformly heat the water to the boiling point, or to 50—60°, after adding the reagents. S. B. A. A.

Estimation of Sulphur in Inorganic Sulphides. Analysis of Molybdenite, Realgar, and Orpiment. By P. Jannasch and V. Wasowicz (*J. pr. Chem.* [2], **45**, 94—102).—The method is based on the volatilisation of the sulphur as oxides into a solution of hydrogen peroxide, when it is completely converted into sulphuric acid. The finely powdered mineral, contained in a platinum boat, is heated

at a red heat in a stream of oxygen, and the gaseous products passed into three cylinders containing 3 per cent. hydrogen peroxide free from sulphuric acid. About 150 c.c. of hydrogen peroxide is required, and the heating takes about 1½ hours, and must not be too strong, or molybdic anhydride is sublimed. When the heating is ended, the boat with its contents is drawn out of the tube with a wire and weighed. The residue is then heated in a covered porcelain dish with ammonia on the water-bath for an hour, and the insoluble residue collected and washed with ammonia, and then with ammonia and water. The filtrate is heated on the water-bath to get rid of ammonia, and precipitated with mercuric nitrate. After 24 hours, the mercury molybdate is collected, washed with dilute mercuric nitrate, dried at 110°, separated from the filter-paper, the latter carefully washed with dilute nitric acid, the washings evaporated in a weighed Rose's crucible, the precipitate then added, and the whole reduced to metallic molybdenum in a stream of hydrogen.

The residue insoluble in ammonia is extracted with hydrochloric acid, and the iron determined in the solution by precipitation with ammonia. In the sample employed, the insoluble gangue still remaining was chiefly quartz, and amounted to 3·38 per cent.

To determine the sulphur, the hydrogen peroxide solution and the combustion tube are rinsed into a porcelain dish, the liquid evaporated to about 100 c.c., mixed with 2 c.c. of dilute hydrochloric acid, and precipitated boiling with barium chloride. The water in the mineral was determined by drying it over phosphoric anhydride for 48 hours. The results obtained are good.

Realgar and orpiment are both easily decomposed by heating in a current of oxygen. The residue in the boat amounted to 0·2—0·3 per cent. in the case of the realgar, and 0·5—0·6 per cent. in the case of the orpiment employed. The hydrogen peroxide solution is evaporated on the water-bath to 140 c.c., mixed with excess of ammonia, and the cold solution precipitated with magnesia mixture. After 24 hours, the precipitate is collected, washed with ammonia, dissolved in hydrochloric acid, and reprecipitated with ammonia, with the addition of a few drops of magnesia mixture. The precipitate dried at 100° is separated from the filter, the latter extracted with dilute nitric acid, the solution evaporated in a weighed Rose's crucible, then the precipitate added, and gradually heated in a current of oxygen, and weighed.

The sulphuric acid is determined in the filtrate, after evaporating off the ammonia in the usual way.

The author also discusses the question of priority as regards the above method. E. C. R.

Estimation of Sulphur in Galena and Minerals containing Lead. By P. Jannasch and K. Aschoff (*J. pr. Chem.* [2], **45**, 103—109).—The method depends on oxidising the mineral at a red heat by means of a current of oxygen saturated with vapours of nitric acid, and then volatilising the sulphuric acid so formed, with the aid of ammonium carbonate, into receivers containing hydrogen peroxide.

About 0·4 gram of galena in very fine powder is weighed into a porcelain boat, and heated at a dull red heat in a somewhat brisk current of oxygen and nitric acid vapour. After 20 minutes, the heat is raised and maintained for an hour; the oxygen is then replaced by air, and finally a current of air saturated with ammonium carbonate is passed through the tube; in about half an hour, the contents of the boat begin to melt and froth slightly, and the substance then becomes bright yellow, which is a sign that the reaction is finished. The boat is then drawn out of the tube, and the contents of the receivers and the tube washed into a porcelain dish, evaporated to about 100 c.c., and the sulphuric acid precipitated with barium chloride. The method gives accurate results.

The details of an analysis of bournonite by this method are also given. E. C. R.

Estimation of Sulphur in Vegetable Soils. By Berthelot and André (*Compt. rend.*, **114**, 43—46; compare this vol., p. 656).

Rapid Estimation of Sulphuric Acid. By P. Cazeneuve and Nicolle (*J. Pharm.* [5], **25**, 51—53).—Artificial seltzer water may contain occasionally as much as 0·50 gram of free sulphuric acid per litre, due to the method of manufacture. This may be approximately estimated, without titrated solutions, by the use of saturated lime-water charged with excess of carbonic anhydride. In preparing this solution, the first and second portions of water are rejected as possibly containing potash. Such a solution contains about 1·29 grams of CaO per litre, and 1 c.c. represents 0·0022 gram of sulphuric acid. To apply the process, 1 c.c. of the solution is placed in each of five test-tubes, then 4 c.c. of the mineral water to be examined is placed in the first one, 8 c.c. in the second, 12 c.c. in the third, &c. The five tubes are boiled, and if all become turbid, the amount of sulphuric acid may be neglected. If, for example, the second tube becomes turbid but the third one is clear, this serves as a first approximation, and four more tubes are charged with 8 c.c., 9 c.c., &c., and boiled. If now the tube containing 9 c.c. of mineral water becomes turbid, but the one containing 10 c.c. is clear, the latter tube then contains approximately 0·0022 gram of sulphuric acid, and a litre contains 0·22 gram. The process is only good in certain cases, but it frequently affords useful information. J. T.

Analysis of "Karlsbad Salts." By W. Kubel (*Arch. Pharm.*, **229**, 588—590).—In order to test the quality of "Karlsbad salts," which is now a recognised medicine in Germany, the author recommends that the specific gravity of a solution of 25 grams of the anhydrous salt, or 45 grams of the hydrated salt in 200 c.c., and the percentages of chlorine and alkali, the latter calculated as sodium hydrogen carbonate, should be determined. The salt should consist of crystallised sodium sulphate, 55·55 per cent.; potassium sulphate, 1·11; sodium chloride, 10; sodium hydrogen carbonate, 33·33 per cent. The specific gravity of the solution of 25 or 45 grams respectively in 200 c.c. of water should be 1·1037 at 15°. J. W. L.

Analysis of the Barium Group. By W. Fileti (*Gazzetta*, **21**, ii, 365—378).—In view of the recent work of Schweitzer, Fresenius, and Lüdeking (Abstr., 1890, 826, 924; and 1891, 110, 364), &c., the author has re-examined the behaviour of the metals of the barium group with especial reference to their qualitative separation.

Hydrofluosilicic Acid.—With this reagent, a 0·05 per cent. solution of barium chloride becomes turbid in 15 minutes, and a precipitate is gradually formed; a 0·025 per cent. solution is precipitated on the addition of half its volume of alcohol. A 3 per cent. strontium chloride solution is precipitated in 15 minutes on the addition of an equal volume of alcohol; a 6 per cent. solution is similarly precipitated on adding half its volume of alcohol. Calcium salts give precipitates with hydrofluosilicic acid and alcohol, which redissolve in excess of the acid. A 0·05 per cent. solution of barium chloride, containing 30 times as much strontium chloride, is readily precipitated by hydrofluosilicic acid on adding half its volume of alcohol; a 0·1 per cent. solution of barium chloride, containing 30 times as much strontium chloride and no alcohol, only gives a slight precipitate after long standing, and the amount of precipitate diminishes as the proportion of strontium chloride is increased. A 0·1 per cent. solution of barium chloride, containing 40 times as much calcium chloride, is barely precipitated by hydrofluosilicic acid after the addition of half its volume of alcohol. It thus appears that salts of strontium or calcium prevent or retard the precipitation of small quantities of barium by hydrofluosilicic acid.

Chromic Acid.—Neutral or ammoniacal 6 per cent. solutions of strontium chloride are immediately precipitated by potassium chromate in the cold; the precipitation is more complete on heating, and, contrary to Lüdeking's statement, there is also a precipitate in acetic acid solutions in presence of sodium acetate, especially on heating. A 2 per cent. neutral or ammoniacal solution of strontium chloride is slowly precipitated by potassium chromate in the cold; in presence of sodium acetate and acetic acid there is an immediate turbidity if there is an excess of chromate; 1 per cent. solutions are more slowly precipitated in the cold, but even solutions strongly acidified with acetic acid are at once precipitated in presence of an excess of potassium chromate. 0·002 per cent. solutions of barium chloride become turbid on the addition of potassium chromate, an excess of which must be added if an ammoniacal salt or acetic acid is present. Solutions of strontium chromate precipitate 0·004 per cent. solutions of barium chloride, but ammonium salts and free acetic acid prevent the precipitation of small quantities of barium. The presence of strontium and calcium chlorides interferes very little with the precipitation of barium by potassium chromate, but prevents its precipitation in small quantities by strontium chromate. A 0·004 per cent. solution of barium chloride, containing 300 times as much strontium chloride or 2000 to 4000 times as much calcium chloride, is readily precipitated by potassium chromate. With strontium chromate, a clear reaction cannot be obtained with a solution of barium chloride more dilute than 0·02 per cent. in presence of

60 times as much strontium chloride, or 100 parts of calcium chloride. The barium reaction with potassium or strontium chromate is thus more sensitive than that with hydrofluosilicic acid; the reaction with potassium chromate is not affected by the presence of acetic acid or ammoniacal salts, provided the reagent is added in excess, whereas the action of strontium chromate is impeded. In testing for barium, potassium chromate should therefore be added in the cold, the solution being made so dilute as to contain less than 0·5 per cent. of strontium salts. If strontium chromate is used, the solution should be made neutral or ammoniacal, or, if possible, entirely freed from ammonium salts.

The presence of calcium renders the detection of small quantities of strontium difficult. Lüdeking has shown that in presence of much calcium considerable quantities of strontium may be present without any precipitate being given by calcium sulphate. Sidersky's methods (Abstr., 1883, 508) of precipitating an ammoniacal solution of calcium and strontium with a mixture of ammonium sulphate and oxalate, and dissolving out the calcium oxalate from the precipitate with hydrochloric acid, or of directly precipitating the strontium by the same reagents in an hydrochloric acid solution, have been shown by Russmann (Abstr., 1891, 111) and by the author's experiments to be useless for the detection of small quantities of strontium.

Potassium Ferrocyanide.—On adding a large excess of a saturated solution of this reagent to a solution of calcium chloride made alkaline with ammonia, and boiling for a few minutes, the solution only retains traces of calcium. The precipitation is more complete in presence of ammonium chloride, but this acts on the ferrocyanide, forming an insoluble compound, which passes through the filter paper. To obtain a complete precipitation of the calcium, the solution is treated with excess of ammonium chloride and much ammonia, heated to boiling, an equal volume of a saturated solution of potassium ferrocyanide added, the whole boiled for a short time, allowed to remain for 15 minutes, and filtered; the filtrate is again tested in the same way.

A boiling 5 per cent. solution of barium chloride is incompletely precipitated by potassium ferrocyanide; a 2 per cent. solution only after some time; more dilute solutions are not precipitated at all. Solutions of strontium chloride are not precipitated at all by potassium ferrocyanide. The presence of several metals of the group together in solution does not sensibly affect their reactions; thus 0·0003 gram of barium chloride may be detected in presence of 0·10 gram of calcium chloride, and 0·003 gram of strontium chloride may be detected in presence of 0·20 gram of calcium chloride.

From the above experiments, the following method for the qualitative analysis of the group is deduced. The mixed carbonates, after washing, are suspended in water, heated to boiling, dissolved in dilute acetic acid, the carbonic anhydride boiled off, one portion tested for barium with strontium or potassium chromate, another portion is freed from barium and strontium by sulphuric acid and tested for calcium with ammonium oxalate and ammonia.

Calcium Absent.—Barium, if present, is removed with potassium

chromate in alkaline solution, and strontium is precipitated by adding sulphuric acid to the filtrate.

Calcium Present.—The solution is made alkaline with ammonia, heated, an equal volume of a saturated solution of potassium ferrocyanide added, and the whole boiled for a few minutes and filtered. The filtrate, after being tested for calcium, may be examined in two ways: 1st. Barium is precipitated by potassium chromate in the cold, and the filtrate tested for strontium by boiling with potassium sulphate. 2nd. Barium and strontium are precipitated together in the cold with dilute sulphuric acid, and the mixed sulphates boiled with potassium carbonate and sulphate, &c. S. B. A. A.

Estimation of Silver and Gold by means of Hydroxylamine Hydrochloride. By A. Lainer (*Monatsh.*, **12**, 639—641).—Hydroxylamine hydrochloride, in presence of potassium or sodium hydroxide, may be conveniently used for the estimation of silver in silver nitrate, silver sodium thiosulphate, and potassium silver cyanide, as well as for the complete reduction of silver chloride, silver bromide, and silver iodide. The presence of organic acids, such as citric acid, in no way interferes with the estimation of silver by this method.

In the estimation of silver, in solutions containing other metals, for example, copper, it is first precipitated as chloride, and the washed precipitate then reduced by boiling it with an aqueous solution of hydroxylamine hydrochloride and potassium hydroxide.

When hydroxylamine hydrochloride is added to a cold solution of auric chloride, the metal is only slowly precipitated, but on warming, the reduction soon becomes complete. This reaction may with advantage be employed in separating gold from solutions containing the chlorides of the alkalis and alkaline earths, as it gives accurate results. Gold is not precipitated by hydroxylamine hydrochloride when the solution contains an alkaline cyanide; the presence of sodium thiosulphate does not, however, prevent the reduction. In conclusion, the author suggests that hydroxylamine hydrochloride may be usefully employed in recovering gold and silver from photographic residues. G. T. M.

Analysis of Galena. By P. Jannasch and K. Aschoff (*J. pr. Chem.* [2], **45**, 110—111).—The galena is decomposed with strong nitric acid in a large porcelain crucible, the precipitated sulphur oxidised with bromine, and the mixture evaporated to dryness. The residue is then mixed with water, the lead sulphate brought into solution with excess of pure sodium hydroxide, diluted with water, filtered from gangue, and the solution mixed in a deep porcelain dish with bromine, and, after some time, heated on the water-bath until all the bromine has passed off. The precipitated lead oxide is filtered and washed with a very dilute solution of sodium chloride (if pure water be used for washing, the precipitate goes through the filter). The filtrate is acidified with hydrochloric acid, evaporated to dryness, taken up with water and 2 c.c. hydrochloric acid, and the sulphuric acid precipitated with barium chloride.

The lead is determined by dissolving it in nitric acid, and precipitating as sulphate. E. C. R.

Analysis of Galena by Precipitation of the Lead with Hydrogen Peroxide in Ammoniacal Solution. By P. JANNASCH and T. BICKES (*J. pr Chem.* [2], **45**, 111—113).—0·5 gram of the finely-powdered mineral is decomposed with fuming nitric acid, the precipitated sulphur oxidised with bromine, and the mixture evaporated to dryness three or four times with concentrated hydrochloric acid. The lead sulphate is then dissolved in 10 c.c. of ammonia, 10 c.c. of acetic acid, and water, and the solution warmed on the water-bath and filtered from a small quantity of gangue. The cold filtrate is mixed with 60 c.c. of a mixture of equal volumes of concentrated ammonia and hydrogen peroxide, 60 c.c. more of hydrogen peroxide added, and then small quantities of the precipitant until the settled mixture gives no turbidity on a further addition. The mixture is allowed to remain an hour with frequent shaking, and the precipitate collected and washed with cold water. The lead and sulphuric acid are then determined in the usual way.

It is necessary that the precipitation of the lead by hydrogen peroxide be conducted in the cold, since the action of hydrogen peroxide goes further when warmed, and the reddish-yellow precipitate is converted into a white compound. The latter is partially soluble in hot water, and crystallises in lustrous leaflets. E. C. R.

Analysis of Galena by Heating it in a Stream of Air saturated with Bromine. By P. JANNASCH and T. BICKES (*J. pr. Chem.* [2], **45**, 113—114).—The authors find that a mixture of oxygen and bromine vapour acts very readily on natural lead sulphide. The sulphur is carried over as sulphur bromide, and lead bromide remains behind. The sulphur is determined as described in the preceding abstracts. The lead bromide is treated with chlorine-water, dissolved in nitric acid, the solution filtered from gangue, and the lead precipitated as sulphate. E. C. R.

Volumetric Estimation of Mercury. By R. NAMIAS (*Gazzetta*, **21**, ii, 361—364).—This method is based on the action of stannous chloride on an acid solution of mercuric chloride, which takes place, as is well known, in two stages, in which mercurous chloride and mercury are respectively obtained. Whilst, however, the first reaction occurs instantaneously, the second only takes place after an interval, the length of which depends on the excess of stannous chloride present. On placing a drop of the solution on filter paper moistened with sodium molybdate, a slight excess of stannous chloride gives a bluish stain.

In practice, compounds of mercury are first converted into mercuric chloride, and the solution of stannous chloride standardised, first approximately with iodine and then with pure sublimed mercuric chloride; the sample is then titrated under the same conditions as the standard. S. B. A. A.

Analysis of Chrome Yellows. By LACHAUD and LEPIERRE (*Bull. Soc. Chim.* [3], **6**, 235—237).—The authors make use of the

fact that dilute potassium hydroxide solution dissolves lead chromate with formation of a basic lead chromate and of potassium chromate according to the equation

$$2PbCrO_4 + 2KHO = PbCrO_4,PbO + K_2CrO_4 + H_2O.$$

Under definite conditions, the potassium hydroxide which does not enter into the reaction may be determined, and the lead chromate present is deducible from this. The method of operation is as follows:—2 grams of the lead chromate are well shaken with binormal potassium hydroxide solution (20 c.c.) until the lead chromate is decomposed; after dilution with distilled water, the alkaline solution is decanted from the basic chromate and titrated with normal sulphuric acid, using phenolphthaleïn as an indicator. T. G. N.

Decomposition of Minerals containing Titanium. By J. Jones (*Chem. News*, **65**, 8).—The author recommends the following process:—2 grams of the mineral is placed in a pressure bottle with 20 c.c. of water and 20 c.c. of sulphuric acid, and the bottle is then put for two hours in an air-bath, the temperature of which is raised to 200°. The residue will consist of practically pure silica, whilst the titanium and other refractory bases pass into solution. If a pressure bottle is not at hand, one can easily be improvised. The author found an old bromine bottle to be sufficiently strong. L. de K.

Colour Reactions of Carbohydrates. By G. Bertrand (*Bull. Soc. Chim.* [3], **6**, 259—261).—On gently warming a glucose with concentrated hydrochloric acid (sp. gr. 1·18) to which traces of phloroglucinol have been added, a yellow coloration is developed which, passing to orange, is thrown down as a dirty-red precipitate on further heating, while the supernatant liquid becomes colourless. The reaction also takes place in the cold after many hours. Orcinol may be substituted for phloroglucinol in the above experiment, and definite colours are obtained with carbohydrates as under:—

1. *Orange-red.*—Glucose (Soxhlet's), glucose (from cellulose), galactose, mannose, levulose, sorbose, saccharose, lactose, maltose, raffinose, melezitose, stachyose, trehalose, isodulcitol, glycogen, inulin, starch, dextrin, achroodextrin, amygdalin, salicin, hesperidin.

2. *Violet-blue.*—Arabinose, xylose, cherry-gum, and pine-gum, whilst gum arabic and Senegal gum afford a violet-red color.

3. No coloration is yielded by xylite, sorbitol, dulcitol, mannitol, perseïtol, inosite, pinite, bergenite, or saccharin.

The author states that this coloration is due to the generation of furfuraldehyde derivatives in the course of the reaction, since furfuraldehyde behaves like the C_5 sugars, and methylfurfuraldehyde like the C_6 sugars in respect to the coloration produced, whereas the mannitols, which are unable, under the conditions of experiment, to produce furfuraldehyde compounds, give no colour. T. G. N.

Iodine Number for Lard Oil by the Hübl Method. By R. Haines (*Chem. News.*, **65**, 39).—The author carefully prepared several samples of lard oil, and took their iodine absorption by Hübl's method. The purest medicinal chloroform was used, and the iodine

reagent was allowed to act for at least three hours. All the experiments were made under exactly the same conditions, particular attention being paid to the temperature; it was found that the iodine absorption varied from 70·01° to 75·14°.

A peculiar fact, which the author is unable to explain, is that a sample of country lard of low melting point, and also the lard oil prepared from it, gave lower iodine numbers than the more solid lards and the oils made from them. L. DE K.

Rapid Method of Determining the Composition of Lubricating Oils. By H. GRIPPER (*Chem. News*, **65**, 27—28).—The author proposes the following process, which, although it only gives results within 2 or 3 per cent. of the truth, is very useful for technical or commercial purposes on account of its simplicity and rapidity. The method is simply an extension of the well-known Koettstorfer process. 2·5 grams of the sample is saponified as usual with 25 c.c. of N/2 alcoholic potash, and the excess of this is titrated back with N/2 hydrochloric acid, using phenolphthaleïn as indicator. Assuming the fatty matter to consist of brown cotton-seed oil, brown rape-seed oil, neatsfoot oil, lard oil, tallow oil, or castor oil, or their mixture, its absorption may be taken at 20·08 per cent. The percentage of potash absorbed by the sample multiplied by 4·98 will therefore represent the percentage by weight of fatty oil in the mixture.

If the amount by volume is required, it is necessary to take the sp. gr. not only of the sample but also of the unsaponifiable oil. In order to determine this, the liquid in the oil-flask is again heated to boiling, and poured through a filter moistened with boiling water. The soap solution rapidly runs through, whilst the mineral oil remains on the filter. Its sp. gr. is then taken by Hager's spirit method. L. DE K.

Analysis of White Wax. By G. BUCHNER (*Chem. Zeit.*, **14**, 1707).—The author has, a few years ago, called attention to the fact that a genuine sample of white wax may show an abnormally high saponification or acidity number if it has been bleached by chemical means. Analysts should, therefore, well consider this before pronouncing an opinion. The author's statement has been doubted, and it has been hinted that he was not supplied with genuine samples, but experiments conducted by Buisine prove him to be in the right. The acidity and saponification numbers may, in fact, come respectively as high as 24 and 100. L. DE K.

Detection of Quinine and Phenacetin in Urine. By F. SESTINI and R. CAMPANI (*L'Orosi*, **14**, 304—306).—From medico-legal investigations conducted by the authors they have arrived at the following conclusions:—The presence of phenacetin conceals the fluorescence of sulphuric acid solutions of the cinchona alkaloïds, especially when dilute. Aqueous solutions of phenacetin are coloured violet-yellow on the addition of chlorine-water and ammonia, but mixtures of quinine and phenacetin are coloured light-blue (methylene blue). Solutions of quinine acquire the characteristic green colour on

treatment with bromine vapour and a few drops of ammonia, even in presence of phenacetin, but no reaction is obtained if the solution is strongly acid. Very dilute solutions of quinine are coloured yellow by bromine vapour alone, even in presence of phenacetin; concentrated solutions give, with excess of bromine vapour or with bromine-water, a yellow precipitate which disappears on adding ammonia, without any green coloration being produced.

To obtain the green coloration of quinine salts with bromine, it is best to agitate the solution with bromine vapour until it becomes slightly turbid, and then add ammonia drop by drop; if there is much phenacetin present, the green coloration will be darker and have a violet tinge. On shaking it with ether, and allowing it to remain for a time, the lower layer assumes the emerald-green colour due to quinine, and the upper layer the violet-yellow of the phenacetin.

To detect quinine in the ethereal residues from urine or viscera examined by the Stas-Otto method, they are treated with ether, and the solution divided into two parts; to one of these, bromine vapour is added until a yellow precipitate begins to form, and then, on adding ammonia, the green colour slowly appears at the bottom of the tube. To the other portion, a saturated solution of bromine-water is added until the yellow precipitate of bromoquinine is thrown down, and this should be readily redissolved by ammonia. S. B. A. A.

Detection and Estimation of Santonine. By M. H. Manseau (*Chem. Centr.*, 1891, ii, 733—734; from *Rep. de Pharm.*, 1891, Nos. 1 and 2).—In cases of poisoning with santonine, the urine is evaporated to a syrup, treated with chloroform, the extract filtered, concentrated at a low temperature, and to the residue is added four or five drops of soda solution, together with a little alcohol. In the presence of santonine, a brick-red or blood-red coloration is formed when this solution is evaporated.

For the estimation of the alkaloïd in the seeds of *Artemisia santonica*, the drug is finely ground, mixed with calcium hydroxide, the mass extracted with alcohol, the latter distilled off, and the residue neutralised with hydrochloric acid. The tarry mass is then dissolved in 300 c.c. of alcohol (sp. gr. 0·935), treated with an excess of lead acetate, and the mixture heated for one hour at 60—70°. The precipitate is filtered off, washed with warm alcohol (in which the lead santonate is soluble), the lead precipitated as carbonate by the addition of sodium carbonate, the solution filtered, neutralised with hydrochloric acid, and the santonine weighed on a tared filter.

From pills, the alkaloïd may be extracted by chloroform, and weighed after distilling off the solvent. The author's results are, however, not quite exact. J. W. L.

Estimation of Free Alkaloïds and their Molecular Weight. By A. Christensen (*Chem. Zeit.*, **14**, 1346—1352).—Since Kjeldahl has called attention to the iodometric estimation of acids and alkalis as being particularly suitable for the determination of ammonia, the author has successfully applied the process to alkaloïds. The alkaloïd

is dissolved in a known excess of N/10 sulphuric acid, diluted with water up to 50 c.c., and, to prevent precipitation of iodised products, further mixed with 50 c.c. of spirit. An excess of potassium iodide (1—15), and then an excess of potassium iodate (1—25), is now added, and the liberated iodine just bleached by careful addition of N/10 sodium thiosulphate. If the amount of alkaloïd is unknown, it may be calculated by using the equation—

$$x = \frac{V(A - a)}{10{,}000}.$$

A = c.c. of sulphuric acid added; a = c.c. of thiosulphate; V = molecular weight of the alkaloïd.

If, on the other hand, the amount of alkaloïd taken is exactly known, but its molecular weight is required, the equation will be—

$$V = \frac{x.\ 100000}{(A - a)}.$$

The author strongly advises, if possible, not to work on too small quantities of the alkaloïd. The process is successful with all natural alkaloïds, with the exception of pilocarpine and narcotine, but altogether useless with theobromine and caffeïne, which substances can, however, scarcely be classed among the true alkaloïds. The process is no doubt of great interest to those engaged in the assay of opium. It is well known that the percentage of morphine in Persian opium is generally found somewhat too high, on account of co-precipitated foreign matters. If, however, the crude morphine is dissolved in sulphuric acid and then treated as described, very accurate results will be obtained. L. DE K.

Löwenthal's Method of Tannin Analysis. By R. L. WHITELEY and J. T. WOOD (*J. Soc. Chem. Ind.*, **10**, 523).—The authors find that in estimating small quantities of tannin matters, Löwenthal's method gives defective results. D. B.

Detection of Albumin in Urine. By P. CROCCO (*L'Orosi*, **14**, 372—379).—The author has found that the urine excreted in certain forms of liver disease, when tested by ordinary methods, gives precipitates which may be mistaken for albumin, but in reality consist of bile pigments, more particularly biliverdin. On treating such urine with acetic acid, a turbidity or precipitate either forms in the cold or on gently warming at a temperature insufficient to precipitate albumin. The precipitate is likewise thrown down by quantities of mineral acids too small to affect albumin; it is soluble in alcohol, and does not give the biuret reaction. To avoid error, it is sufficient to treat the urine with 2 to 3 per cent. of concentrated acetic acid, leave it in the cold for a few hours, and filter before applying the ordinary tests. S. B. A. A.

Detection of Vegetable Fibre in Silk or Woollen Tissue. By S. FURBINO (*L'Orosi*, **14**, 234—235; from *Il Selmi*).—This method

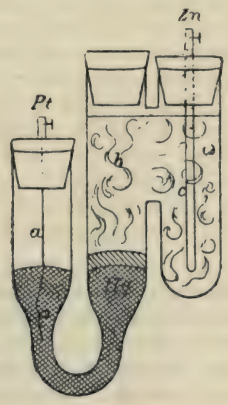
depends on the conversion of cellulose by concentrated sulphuric acid into dextrin and glucose, and on the reduction and decolorisation of colouring matters derived from archil in presence of glucose and alkalis, the original colour being restored by exposure to the air or by oxidation. The process is as follows:—A piece of the material about 1 sq. cm. in area is allowed to soak in a few drops of sulphuric acid (66°) for 5—10 minutes, water is added, the whole heated to boiling, the liquid decanted and made strongly alkaline with a concentrated solution of soda; a few drops of a very dilute solution of archil are then added, and the violet liquid obtained heated for a few minutes to about 90°. In presence of even small quantities of vegetable fibre (1 per cent. of cotton, flax, &c.), the colour of the solution is discharged; it may be restored by exposing the solution to the air in a shallow vessel. If the violet colour persists after heating for five minutes, the material can only contain an inappreciable amount of vegetable fibre. Before testing, care must be taken to cleanse the material from starchy matter, and other substances applied to it in the course of manufacture, by repeatedly boiling it with water, &c. S. B. A. A.

Valuation of Coal for Use in Steam Boilers. By T. T. P. B. Warren (*Chem. News*, **69**, 299).—The author suggests the estimation of the chlorine in the feed-water and in the boiler at certain intervals, as a measure of the water evaporated. During the tests any disturbing influences, such as priming, loss of chlorine, opening furnace doors, &c., must be avoided, and the boiler should be filled with fresh water to start with. The relationship of the data obtained to the result required are, $\left(\frac{C'}{C} \times G\right) - G =$ number of gallons evaporated, when C′ is the chlorine after some hours run, C the chlorine in the feed-water, and G the number of gallons in the boiler to the working level. It is suggested that a similar result may be obtained by taking the density, with a trustworthy hydrometer, instead of estimating the chlorine; then the number of gallons evaporated $= \left(\frac{D' - 1}{D - 1} \times G\right) - G$ in which 1 = specific gravity of pure water, G the same as in the above formula, whilst D, the initial density, is found by boiling some of the water, so as to throw out of solution any substances that would be precipitated in the boiler, and making up with distilled water the loss by evaporation; D′ is the density after some hours' run. D. A. L.

General and Physical Chemistry.

Relations between Compressibility and Indices of Refraction of Liquids. By G. Quincke (*Ann. Phys. Chem.* [2], **44**, 774—777).—The author has, from former experiments, deduced the relation $(n - 1)/\sigma = \text{const.}$, where n is the specific refraction, and σ the specific gravity of a liquid. The accuracy of this relation, and of the author's experimental results, has been placed in question by Röntgen. In the present paper, the author shows that his results agree better with those of other observers than do those of Röntgen.

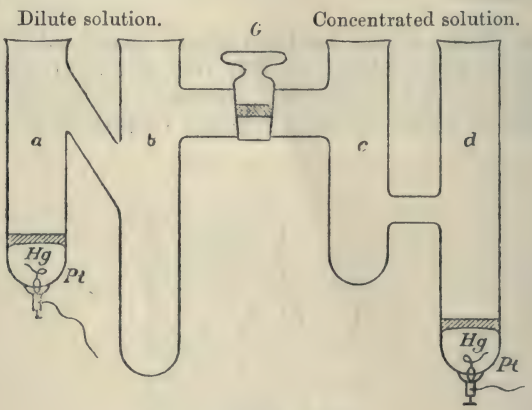
H. C.



Rotatory Power of Diacetyltartaric Derivatives. By J. A. Le Bel (*Compt. rend.*, **114**, 304—306).—A discussion with Colson. The author points out that the idea that the radicles united with an asymmetrical carbon atom have their centres of gravity situated at the solid angles of a tetrahedron, with the carbon atom at its centre, is not an essential part of his theory of optical activity. The view is quite untenable in the case of closed chain compounds.

C. H. B.

Stereochemistry of Diacetyltartaric Acid; a Reply to Le Bel. By A. Colson (*Compt. rend.*, **114**, 417—419).—A continuation of the discussion as to the exact mode of the distribution of the radicles round an asymmetrical carbon atom (preceding abstract). The author considers that unless the radicles are supposed to occupy the summits of a *regular* tetrahedron, the hypothesis no longer has a definite character.



C. H. B.

Practical Form of the Latimer-Clark Standard Cell. By W. Negbaur (*Ann. Phys. Chem.* [2], **44**, 765—766).—Objections to the ordinary form of the Latimer-Clark standard cell are the presence of a porous pot, on which the zinc sulphate frequently is deposited in

crystalline form, and the necessity for using a somewhat large quantity of mercury, in order that when the cell is disturbed the end of the platinum wire immersed in the mercury may not become coated with mercurous sulphate. These objections are avoided by making use of a cell of the form given in the accompanying diagram. The height of the cell is 6 cm. The mercury is contained in the U-tube *ab*, into the shorter limb *a* of which passes the platinum wire, the longer limb *b* containing the mercurous sulphate paste. The cylindrical side tube *c* contains the zinc rod. The opening between *b* and *c* should be as large as possible. Crystallisation of the zinc sulphate can be avoided by covering the solution with a thin layer of vaselin. The cell should be protected from the action of light by coating it with black paper. The internal resistance is somewhat larger than that of the cell in its older form. H. C.

Standard Cell for Small Differences of Potential. By W. Negbaur (*Ann. Phys. Chem.* [2], **44**, 767—770).—No standard cell for use in the measurement of small potential differences has hitherto been described. The author advocates the use of cells formed of two solutions of the same salt or acid of different concentration, between mercury electrodes coated with calomel. The substances used can be readily obtained in a pure condition, and the potential difference may be altered within wide limits by altering the concentration of the solutions; moreover, this can be calculated beforehand, if necessary. A useful form of such a cell is that given in the figure. The glass tap G serves to separate the two solutions from one another, the bore of the tap containing a plug of parchment paper. The concentrated solution is placed in the apparatus to the right of the tap. The vessels *a* and *d*

contain the mercury coated with calomel paste. As it is only necessary to retain the original concentrations at the electrodes, the vessels *b* and *c* provide for overflow of either solution: in these also may be placed the thermometer. Platinum wires are sealed into *a* and *d* communicating with the mercury. Hydrochloric acid and sodium

or lithium chlorides are suitable for establishing the concentration current, the first being the best. A potential difference of 0·1 volt may be obtained by solutions containing 4 and 0·99 grams of hydrogen chloride, or 2·5 and 0·1 grams of sodium chloride per litre. The potential difference of a cell containing such solutions of hydrochloric acid was found to remain perfectly constant for eight days.

H. C.

Potential Differences at the Surfaces of Contact of very Dilute Solutions. By W. Negbaur (*Ann. Phys. Chem.* [2], **44**, 737—758).—The main object of the present paper was to obtain experimental confirmation of the theoretical deductions of Planck with regard to the difference of potential between two dilute solutions of electrolytes (Abstr., 1890, 1355). The observed values agree generally with those calculated by means of Planck's formula. In solutions of equivalent or nearly equivalent strength, the direction of the current is always determined by the ion which has the greater velocity of the two unlike ions, this always moving with the positive current. A few experiments were made with concentrated solutions, but the observed and calculated values do not agree. H. C.

Potential Difference of Dilute Solutions. By W. Nernst (*Ann. Phys. Chem.* [2], **45**, 360—369).—This paper consists for the most part of critical observations on the work of Negbaur (preceding abstract).

The author states that the osmotic pressure of dilute salt solutions, calculated by means of his theory from the electromotive activity of the ions, agrees within 1 or 2 per cent. with the osmotic pressure as derived from the theories of Van't Hoff and Arrhenius. The measurement of electromotive forces is thus, for dilute solutions at least, by far the most exact method of indirectly measuring osmotic pressure.

J. W.

Electromotive Activity of the Ions. By W. Nernst and R. Pauli (*Ann. Phys. Chem.* [2], **45**, 353—359).—The electromotive forces developed in liquid cells made by the combination of decinormal and centinormal solutions of potassium and hydrogen chlorides have been investigated experimentally by the authors, and the results obtained are compared with the numbers deduced from the osmotic pressure and dissociation hypothesis as developed in this direction by Nernst and Planck (compare Abstr., 1890, 1355). The agreement between observation and theory is satisfactory. As solutions of zinc sulphate and of copper sulphate having equal molecular concentrations are very nearly equally dissociated into ions, it follows from the theory that there should be no considerable E.M.F. at their surface of contact. By investigating the combination

$$Hg \mid HgSO_4 \mid 1/10n CuSO_4 \mid 1/10n ZnSO_4 \mid HgSO_4 \mid Hg,$$

the authors find that in reality the E.M.F. is only 0·00024 volt. The seat of the E.M.F. in a Daniell element is consequently not to be sought for at the contact of the two liquids. J. W.

Conductivity of Lead Dioxide. By J. Shields (*Chem. News*, **65**, 87).—Both the hydrated lead dioxide, PbO_2,H_2O, prepared by electrolysing a solution of sodium lead tartrate, and lead dioxide prepared by Wöhler's method, were examined by placing a layer of the oxide between two conducting surfaces connected with the terminals of a battery and watching for polarisation currents on breaking the circuit, and also by the method employed by Streintz. The results show that both forms of oxide conduct metallically and neither of them electrolytically. The specific resistances of these two preparations are:—

	C.G.S. units.
Chemically prepared dioxide.....	$5{\cdot}59 \times 10^9$
Electrolytically prepared dioxide....	$6{\cdot}78 \times 10^9$

D. A. L.

Magnetism and Atomic Weight. By P. Bachmetéeff (*Ber.*, **25**, 566—569).—In a previous paper (*J. Russ. Chem Soc.*, 1889, 39), the author discussed the relation between the magnetic properties of the elements and their atomic weights; his conclusions have, however, been disputed by Errara (Abstr., 1891, 518), who maintains that no relationship can be traced except in so far as the elements in Mendeléeff's odd series are diamagnetic and in the even series paramagnetic.

The author in reply points out that a considerable number of the elements do not obey Errara's rule, and that many of the elements now supposed to be paramagnetic are probably in reality diamagnetic, the observed paramagnetism being due to the presence of small quantities of iron; thus, natural platinum, which contains iron, is paramagnetic, whereas the pure metal is diamagnetic. There are at least eight exceptions to Errara's rule, and no single exception to that previously given by the author; the latter, therefore, believes his system to be the more trustworthy. H. G. C.

Magnetism of Organic Compounds. By S. Henrichsen (*Ann. Phys. Chem.* [2], **45**, 38—61).—The author has investigated the magnetic constants of a considerable number of organic compounds under varying conditions. All the substances studied behaved similarly with respect to the magnetising force: as the force K increased, the quotient A/K^2, where A is the diamagnetic deflection, rose slightly and then fell off. Propyl formate, for example, gave the following numbers:—

K.	A.	A/K^2.
82·7	32·3	0·00595
116·0	65·4	0·00612
146·1	103·6	0·00613
178·6	152·4	0·00602

The function A/K^2 is considered by the author to be in reality constant.

Measurements of the temperature coefficient, between 20° and 90°, gave values of a for the different substances ranging from 0·00103 to

0·00156 in the formula $M_t = M_o\ (1 + at)$, where M is the magnetism. $a = 0{\cdot}00133$ may be adopted as the mean for all the compounds investigated.

Several measurements in absolute units are given. J. W.

Specific Heat of Aluminium. By J. W. Richards (*Chem. News*, **65**, 97—98).—Inasmuch as the recorded numbers for the specific heat of aluminium differ widely, the author has redetermined it, at temperatures between 16° and 22°, by noting the reduction in temperature produced by 100 or 200 grams of aluminium in a known weight of water at a higher temperature; at temperatures between 20° and 100°, by dropping aluminium, from suspension in steam, into water in a calorimeter; and at temperatures from 120° to 600° by heating a ball of platinum and a ball of aluminium placed together on a platinum support in the same air-bath or furnace and dropping them simultaneously into two exactly similar calorimeters; the platinum results furnished the data for calculating the values for the aluminium. The latter method gave most concordant results; selecting the best experiments and correlating the data by the method of least squares, the following formulæ are obtained, 0·2220 being the true specific heat at 0°.

$$Sm = 0{\cdot}2220 + 0{\cdot}00005(t_1 + t_2),$$
$$S = 0{\cdot}2220 + 0{\cdot}0001t,$$

making the sp. heat

At 20°	0·2240	Total caloric capacity to the melting point	158·3.
„ 100	0·2320		
„ 625 (melting point).	0·2845		

This gives 6·13 as the atomic heat, using the mean specific heat between 0° and 100°. D. A. L.

Use of Compressed Oxygen in the Calorimetric Bomb. By Berthelot (*Compt. rend.*, **114**, 318—319).—If the oxygen that is used has been kept in a gas-holder over water, it is saturated with aqueous vapour, and when compressed in the bomb sufficient water is condensed to again saturate the gas at the end of the experiment. The difference in the tension of the aqueous vapour resulting from the difference between the initial and final temperatures (usually about 3°) would introduce an error of less than half a minor calorie, which is negligible in all ordinary cases. If, on the other hand, commercial compressed oxygen is used, the gas is practically dry. It follows that in most cases some of the water produced by the combination will evaporate in order to saturate the gas in the bomb. The absorption of heat from this cause will amount to from 2 to 3·5 cal. in a bomb of about 330 c.c. capacity, and to 5 or 6 cal. in a bomb of 600 to 700 c.c. capacity. C. H. B.

Reconversion of Heat into Chemical Energy by Production of Water Generator Gas and Carbonic Anhydride Generator Gas. By A. Naumann (*Ber.*, **25**, 556—562).—The production of water

gas from carbon and liquid water, $H_2O + C = H_2 + CO$, is an endothermic reaction, and involves an absorption of 38,770 cal. Generator gas produced from air and carbon is formed with evolution of heat, the reaction $C + O = CO$ giving rise to a development of 29,690 cal. The heat evolved in the latter reaction would serve to raise the temperature of the products formed through 2169°, and if then cooled to 15° before being used, the whole of the heat of formation would be lost and the heat of combustion, 67,960 cal., of the carbonic oxide alone remain. The loss here involved is 30·4 per cent. of the heat of combustion, 97,650 cal., of the original carbon.

In order to avoid the above loss, the formation of water gas may be combined with that of generator gas, as in the Dowson process, or, in place of water, carbonic anhydride may be mixed with the air passed over the heated carbon, the reaction $CO_2 + C = 2CO$ being endothermic and involving an absorption of 38,270 cal. The mixture of water or carbonic anhydride might be made in such proportion that neither absorption nor development of heat would take place. In this case the following table gives the calculated values of the heats of combustion of 1 litre of each gas in the first column; the increase in the temperature of the flame, calculated from the heats of combustion and specific heats of the mixed gases, in the second column; and the heat obtainable from the combustible gases present in 1 litre of each gas when cooled through 1°, in the third column.

Gas.	I.	II.	III.
	cal.		cal.
Generator gas	1044	1904°	0·5487
Carbonic anhydride generator gas	1739	2449	0·7101
Water generator gas, from liquid water at 15°.	1652	2356	0·7016
Water generator gas, from gaseous water at 15°	1790	2431	0·7363
Water gas	2812	2830	0·9934

The advantage of water generator gas or carbonic anhydride generator gas above ordinary generator gas is at once apparent.

H. C.

Thermochemistry of Sodium Isopropoxide. By DE FORCRAND (*Compt. rend.*, **114**, 420—422).—In dilute solutions (1 equivalent in 4 litres) sodium hydroxide and isopropyl alcohol are without action on one another, and it follows that at this degree of dilution sodium isopropoxide is completely dissociated.

Heat of dissolution of sodium isopropoxide at +12° = +16·40 Cal.; heat of dissolution of isopropyl alcohol +3·64. It follows that—

C_3H_8O liq. + Na sol. = H + C_3H_7NaO sol. develops		+30·27 Cal.
C_3H_8O liq. + $\frac{1}{2}Na_2O$ sol. = $\frac{1}{2}H_2O$ sol. + C_3H_7NaO sol.	„	+15·405 „
C_3H_8O liq. + NaOH sol. = H_2O sol. + C_3H_7NaO sol.	„	−1·60 „
$C_3 + H_7 + Na$ (sol.) + O = C_3H_7NaO sol.	„	+108·77 „

The corresponding values with primary propyl alcohol are:— +32·52, +17·66, +0·65, and +108·65 respectively.

The compounds of sodium glycol with isopropyl alcohol recently described (this vol., p. 691) gave the following results:—

Heat of dissolution, $C_3H_7NaO,3C_3H_8O$ = 14·47 Cal.
Heat of dissolution, $C_2H_5NaO,3C_3H_8O$ = 11·81 „
C_3H_7NaO + $3C_3H_8O$ develops +0·13 Cal.
C_2H_5NaO + $3C_3H_8O$ „ −0·08 „

therefore—

C_3H_7NaO sol. + $3C_3H_8O$ liq. = $C_3H_7NaO,3C_3H_8O$ sol.	develops +12·98 Cal.
C_2H_5NaO sol. + $3C_3H_8O$ liq. = $C_2H_5NaO,3C_3H_8O$ sol.	„ + 5·04 „
$4C_3H_8O$ liq. + Na sol. = H gas + $C_3H_7NaO,3C_3H_8O$ sol.	„ +43·25 „

The last value is higher than the heat developed by the action of sodium on water. The dissolution of the compound

$$C_3H_7NaO,3C_3H_8O$$

in excess of isopropyl alcohol absorbs −2·63 Cal., and hence

$80C_3H_8O$ liq. + Na sol. = H gas + C_3H_7NaO diss. in $79C_3H_8O$ liq.	develops +40·62 Cal.

The action of sodium on isopropyl alcohol develops nearly 3 Cal. less than its action on normal propyl alcohol. Isopropyl alcohol differs from the other monhydric alcohols in that the dissolution of the solid $C_3H_7NaO,3C_3H_8O$ in excess of the alcohol is endothermic, whereas the heat of formation of the compound itself is exothermic, and amounts to +12·28 Cal. It would follow that the excess of alcohol simply dissolves the crystallisable compound without formation of polyalcoholic combinations. Similar phenomena are shown by barium hydroxide, and the hydrate $Ba(OH)_2,8H_2O$, and the corresponding strontium compounds. C. H. B.

Tartronic Acid and Alkaline Tartronates. By G. Massol (*Compt. rend.*, **114**, 422—424).—The tartronic acid used was in large, transparent, anhydrous prisms melting at 155°, with evolution of carbonic anhydride; heat of dissolution, −3·75 Cal.

$C_3H_4O_5$ + KOH.....	develops +13·77 Cal.
$C_3H_3KO_5$ + KOH.	„ +12·48 „
$C_3H_4O_5$ + 2KOH	„ +26·25 „

The potassium hydrogen tartronate forms large, very oblique prisms with a rhombic base; these contain $\frac{1}{2}$ mol. H_2O, and become anhydrous at 110°; heat of dissolution of the anhydrous salt, −7·5 Cal. The normal tartronate forms large, anhydrous crystals; heat of dissolution, −4·75 Cal.

$C_3H_4O_5 + NaOH$	develops	+13·75 Cal.
$C_3H_3O_5Na + NaOH$	,,	+13·65 ,,
$C_3H_4O_5 + 2NaOH$	,,	+27·40 ,,

The normal salt forms a very deliquescent, crystalline mass, which becomes anhydrous at 110° without further decomposition; heat of dissolution, −3·00 Cal. The acid salt, when evaporated to dryness on a water-bath, becomes partially converted into glycollate.

$C_3H_4O_5$ sol. + KOH sol. = $C_3H_3O_5K$ sol. + H_2O sol.	develops	+31·4 Cal.
$C_3H_3O_5K$ sol. + KOH sol. = $C_3H_2O_5K_2$ sol. + H_2O sol.	,,	+23·6 ,,
$C_3H_4O_5$ sol. + 2KOH sol. = $C_3H_2O_5K_2$ sol. + $2H_2O$ sol.....	,,	+55·0 ,,
$C_3H_4O_5$ sol. + 2NaOH sol. = $C_3H_2O_5Na_2$ sol. + $2H_2O$ sol.....	,,	+49·07 ,,

The corresponding values for malonic acid are about 4 Cal. per equivalent lower, a result similar to that obtained with succinic and the hydroxysuccinic acids. C. H. B.

Heat of Dissolution of Salts in Water. By R. Scholz (*Ann. Phys. Chem.* [2], **45**, 193—206).—The author has determined the heat of dissolution of various salts in water at 0° by means of Bunsen's ice calorimeter. *N* in the following table (p. 677) denotes the number of gram-equivalents of salt dissolved in a litre of water; the numbers in the other columns are the small calories evolved per gram of salt dissolved:—

These results are not in harmony with those of Staub (*Inaug. Diss., Zurich*, 1890), who employed the same method. J. W.

Theory of Heat of Dissolution and of Osmotic Pressure. By C. Dieterici (*Ann. Phys. Chem.* [2], **45**, 207—237).—Van't Hoff deduced the laws regulating the vapour pressures of solutions from the laws of osmotic pressure. The author proceeds in the reverse way from the vapour pressure of dilute aqueous salt solutions, and arrives at the following conclusions:—

1. Raoult's laws for vapour pressure are capable of explanation by adopting views borrowed from the kinetic theory of gases.

2. It then follows from the principles of thermodynamics that, when two miscible liquids with different vapour pressures are capable of interdiffusion, there must be between them a diffusion pressure which can be calculated from the difference of vapour pressure if both liquids give off the same substance as vapour.

3. The hydrostatic pressure which is equal and oppositely directed to the diffusion pressure is Van't Hoff's osmotic pressure.

4. At great dilutions this is proportional to the relative lowering of the vapour pressure, but is not so in more concentrated solutions.

5. The rule that the osmotic pressure is proportional to the absolute temperature is only valid for the temperatures at which the laws

of Boyle and Charles hold good for the vapour of the solvent, and only then so far as von Babo's law is true.

6. Whilst these principles justify the analogy of gaseous substances with substances in solution, it does not follow that substances in solution are really in the gaseous state, or that the osmotic pressure is of kinetic origin.

7. When a salt is dissolved in a solvent a certain external work, the osmotic work, can be done. If the dissolution is effected, as is usual, by mixing the salt and the solvent, this work is not done, and thus the process is irreversible.

8. Molecular forces (of kinetic nature) between the salt and the solvent perform the osmotic work. J. W.

Freezing Point of Dilute Solutions of Cane Sugar. By RAOULT (*Compt. rend.*, **114**, 268—271, and *Zeit. physikal. Chem.*, **9**, 343).—The author has modified his apparatus for determining freezing points, with a view to secure more regular cooling, and he finds it possible to obtain results accurate to 0·002 of a degree. The following results were obtained with dilute solutions of cane sugar:—

Weight of sugar in 100 grams of water.	Reduction of freezing point.	Molecular reduction of freezing point.
0·683	0·042°	20·9
1·426	0·086	20·6
2·154	0·128	20·3
2·848	0·168	20·1
4·329	0·252	19·9
5·859	0·340	19·8
7·297	0·422	19·8
11·132	0·652	20·0
16·098	0·956	20·3
39·040	2·274	21·6

If the reductions of the freezing point are taken as abscissæ, and the molecular reductions as ordinates, the latter are represented by a curve which, except in the point of origin, coincides with that previously given (*Ann. Chim. Phys.* [6], **8**). The result confirms the author's previous statement, that with cane sugar, as with other substances, the molecular reduction increases below a certain degree of dilution. The increase is, however, so small, that it seems to confirm the views of Arrhenius (compare *Zeit. physikal. Chem.*, **2**, 561). C. H. B.

The Cryoscopic Behaviour of Weak Solutions. Part I. Sulphuric Acid. By S. U. PICKERING (*Ber.*, **25**, 1099—1107).—The author gives a critical examination of his previous results (Trans., 1890, 342), using an improved method of plotting out the results, and describing a new method of estimating the experimental error, and also the error of a drawing made to represent a series of results. He finds that his original representation of his results with sulphuric acid, according to which three changes of curvature existed, attributes a mean apparent error to the points exactly equal to the ascertained

mean experimental error, 0·0008°, whereas no drawing can be made with a lath so as to obliterate any of these "breaks" without increasing the apparent error to an unwarrantable extent. A drawing obliterating all the breaks shows an error 6·3 times greater than the experimental error. The values calculated according to Van't Hoff's formula and the dissociation hypothesis do not agree within experimental error with the observed values; the total error up to a depression of 0·7° is 870 greater than it should be, and even imagining the existence of some regular but unknown source of error, this value cannot be reduced to less than 16. The best agreement extends only to 0·4°, and even here it is, with every favourable allowance, not within the experimental error, being 6—9 times greater than this error.

S. U. P.

Apparatus for the indirect Determination of Vapour Pressures. By C. A. Lobry de Bruyn (*Rec. Trav. Chim.*, **10**, 132—134; compare Abstr., 1891, 781).—This consists essentially of an inverted V-tube, to the angle of which a narrow tube furnished with an air-tight stopcock is fused, and to the free ends of the Λ-tube two small, 30—40 c.c., flasks are accurately adapted. The salt whose hygroscopicity is to be determined is placed in one flask, and sulphuric acid of known strength in the other, and a vacuum is induced in the apparatus, which is maintained for 3—4 weeks at a constant temperature. The sulphuric acid is then titrated, and the vapour pressure calculated by aid of Regnault's tables (compare also Müller-Erzbach, Abstr., 1889, 1045).

T. G. N.

Stereochemical Models of Organic Molecules. By A. Eiloart (*Amer. Chem. J.*, **13**, 559—564).—Carbon atoms are represented by tetrahedra, which may be connected either corner to corner to represent the ethane condition, or edge to edge to represent the ethylene condition; and the elements and radicles attached to the carbon atoms are represented by caps, on which their symbols and formulæ are inscribed, which fit over the corner of the tetrahedra. In this way the modern views as to the constitution of such compounds as the lactic acids, the tartaric acids, maleïc and fumaric acids, and the hydrophthalic acids may be made clear. Full details of construction, as well as numerous examples, are given.

Jn. W.

Lecture Experiment: Burning Sulphur in Oxygen. By W. A. Noyes (*Amer. Chem. J.*, **13**, 553).—A 250 c.c. flask containing a fragment of sulphur, and filled with oxygen by downward displacement, is fitted in a horizontal position to one end of the transverse and horizontal limb of a T-piece, the other end of which communicates through a stopcock with a filter-pump, whilst the vertical limb dips into mercury and serves as a pressure gauge.

The pressure in the flask having been reduced to about 450 mm., the stopcock is turned off, and the level of the mercury in the gauge marked by a strip of paper. The sulphur is then ignited by heating the flask with a small flame, and is seen to burn quietly in the rarefied oxygen. When the combustion is finished, the flask quickly cools to the original temperature, and the mercury is seen to return

to its original level, thus showing that the volume of the sulphurous anhydride is the same as that of the oxygen from which it has been formed. Jn. W.

Inorganic Chemistry.

Boiling Point of Zinc Chloride and Bromide, and Ignition Temperature of Electrolytic Gas. By F. Freyer and V. Meyer (*Ber.*, **25**, 622—635).—In a previous paper (Abstr., 1891, 1153), Krause and Meyer have shown that electrolytic gas, when slowly passing through a glass tube, does not explode at 606° (the boiling point of stannous chloride). In order to get a nearer approximation to the point of ignition of the gas, the authors have passed the gas through a tube contained in a bath of boiling zinc chloride and zinc bromide, the boiling points of which they find to be 730° and 650° respectively. With the former, explosion takes place whether the gas is wet or dry, but in the boiling bromide no appreciable combination takes place, and the temperature of ignition therefore lies between these two points.

The bath employed in the experiments consisted of a sheet-iron crucible 10 cm. in height and 6 cm. in diameter, to the lid of which was brazed a sheet-iron tube 2 cm. in diameter, and reaching to within about a short distance of the bottom of the crucible. The tube conveying the electrolytic gas is widened out at one point into a long bulb, which is wholly immersed in the inner sheet-iron tube. To ascertain the boiling point of the chloride and bromide, an air thermometer made of platinum was inserted in the iron tube, no glass being found which could withstand the temperature without partially collapsing.

The explosion in the zinc chloride only takes place with certainty if the gas is passed through the tube when the zinc chloride is already at the boiling point, and is then sufficiently violent to pass along tubes only $\frac{1}{3}$ mm. in diameter. If the gas be passed through the tube whilst the zinc chloride is being heated, the gases slowly combine, forming water without explosion. H. G. C.

Action of Nascent Hydrogen and Nascent Oxygen on Nitric Acid. By W. F. Hall (*Amer. Chem. J.*, **13**, 564—570).—A steady electrical current, averaging about 11 coulombs per day, was passed through dilute, aqueous nitric acid (sp. gr. 1·069 at 20°) for 84 days. The electrodes were arranged in separate vessels, connected by a siphon filled with the electrolyte, and the evolved gases were collected separately.

The rate of evolution of hydrogen at the cathode gradually diminished, and on the 59th day vanished; but it could always be temporarily and largely augmented by agitation. The specific gravity of the electrolyte steadily diminished (finally to 1·034 at 27°), owing to

reduction of the nitric acid to ammonium nitrate, the formation of which took place slowly at first, but afterwards with increasing rapidity.

The rate of evolution of oxygen at the anode was at first much greater in proportion than that of the hydrogen at the cathode, but it decreased after a few days to the normal amount, and continued to decrease until the end of the experiment. As in the previous case, the flow could at any time be temporarily and largely augmented by agitation. The specific gravity of the electrolyte steadily increased (finally to 1·079 at 27°), owing, probably, to the conversion of the nitric acid into orthonitric acid, H_3NO_4. Jn. W.

Decomposition of Sulphurous Anhydride by Carbon at High Temperatures. By Scheurer-Kestner (*Compt. rend.*, **114**, 296—298).—When sulphurous anhydride is passed over carbon heated to bright redness, it is decomposed in accordance with the equation $2SO_2 + 3C = 2CO + CO_2 + S_2$. It is possible that carbon bisulphide and carbon oxysulphide are formed as intermediate products.

The result confirms the author's view as to the nature of the reaction between a sulphate, silica, and carbon at a high temperature. The sulphate is converted into a silicate and sulphuric anhydride; the latter is decomposed by heat into oxygen and sulphurous anhydride, and these in presence of carbon yield carbonic anhydride, carbonic oxide, and oxygen, $3RSO_4 + 6SiO_2 + 5C = 3(RO,2SiO_2) + 3S + 4CO_2 + CO$. C. H. B.

Action of Iodine on Sodium Hydrogen Sulphite. By W. Spring and E. Bourgeois (*Arch. Pharm.*, **229**, 707—710).—Referring to the results obtained by Otto and Holst (Abstr., 1891, 978), the authors point out that their previous work on this subject showed that there was no formation of dithionic acid (Abstr., 1886, 978). In order to test the accuracy of Otto's results, each of the authors repeated his work independently of the other in different laboratories, but could detect no dithionic acid. They further determined the amounts of iodine used during the oxidation, and these in every case corresponded with the equation

$$2NaHSO_3 + 2I_2 + 2H_2O = 2NaHSO_4 + 4HI,$$

whilst only half this amount of iodine is required for the formation of dithionic acid. J. W. L.

Amorphous Boron. By H. Moissan (*Compt. rend.*, **114**, 319—324).—The author has prepared amorphous boron by the various known methods, and has analysed the products; the results are contained in the following table (p. 682):—

No. 1 was prepared by the method of Gay-Lussac and Thenard, using a copper tube. Hydrochloric acid removes part of the potassium, but, even after repeated washing with this acid and water, the residue contains about 7 per cent. of potassium. No. 2 was obtained by the action of sodium on boric anhydride in presence of sodium chloride, the product being washed with hydrochloric acid and dried

	1.	2.	3.	4.	5.
Boron	44·1	62·50	71·97	32·38	51·15

Not estimated	—	4·33	—	—	—
	99·5	100·00	99·68	99·11	92·03

in a vacuum or in an atmosphere of hydrogen. No. 3 is the same product after prolonged treatment with boiling hydrochloric acid, and No. 4 a similar product after prolonged treatment with water. No. 5 was obtained by Berzelius' method, namely, the action of potassium on excess of potassium borofluoride.

The product (No. 2), obtained by the method of Deville and Wöhler, contains a small quantity of boron hydride, gives off hydrogen at 250—275°, and yields hydrogen phosphide when heated in phosphorus trifluoride.

Iron boride is obtained as a grey mass by the action of boron chloride on iron reduced by hydrogen. C. H. B.

Preparation of Amorphous Boron. By H. Moissan (*Compt. rend.*, **114**, 392—397).—When a current of 35 ampères is passed through boric anhydride mixed with 20 per cent. of sodium borate and heated at 1200°, boron is liberated, but immediately recombines with oxygen with vivid incandescence.

It is well known that when boric anhydride is heated with the theoretical quantity or an excess of magnesium, reduction takes place with formation of magnesium borides. The author finds that if the boric anhydride is in considerable excess different results are obtained. There are two magnesium borides, one unstable and decomposed by water with liberation of hydrogen and boron hydride, the other stable and not affected by water, hydrochloric acid, or nitric acid.

70 grams of finely-powdered magnesium free from iron and silicon, was intimately mixed with 210 grams of recently fused boric anhydride. The mixture was heated to bright redness in a clay crucible, and in a few minutes an energetic reaction took place. The central part of the product was boiled with water and hydrochloric acid until the magnesium borate was removed, then treated for a long time with successive quantities of pure boiling hydrochloric acid, washed with water, treated with alcoholic potash, again washed with water, boiled for several hours with hydrofluoric acid, washed with water, and dried in a vacuum. The product is a very light maroon powder which does not alter when exposed to air; it contains 94 to

95 per cent. of boron, 2·3 to 3·75 per cent. of magnesium, and 1·2 to 1·6 per cent. of insoluble matter.

If this product is fused with 50 times its weight of boric anhydride, and the product treated in the same way as the original product, a maroon powder is obtained containing only traces of magnesium.

One product contained boron, 98·30; magnesium, 0·37; insoluble, 1·18 = 99·85.

If the boron is required perfectly free from nitride, reduction must be effected in a crucible brasqued with a mixture of finely powdered titanic oxide and carbon; the product contains from 92·6 to 99·2 per cent. of boron. Boric anhydride may also be reduced by magnesium in porcelain dishes in an atmosphere of hydrogen, and a very pure product is obtained, but the yield is small. C. H. B.

Explosion of Ammonium Nitrate. By C. A. Lobry de Bruyn (*Rec. Trav. Chim.*, **10**, 127—134).—Ammonium nitrate is a component of many explosives which are but slightly sensitive to ordinary mechanical shocks, and are difficult of ignition, although by the detonation of small quantities of mercuric fulminate they are rendered explosive. Berthelot (Abstr., 1882, 453) and Thorpe (Trans., 1889, 220) prove that endothermic combinations decompose explosively under the influence of mercuric fulminate, and it is well known that explosives require a variable initial impulse to cause their decomposition. The author describes the following experiments which were made with shells of 8 cm. calibre, weighing 7 kilos., and capable of holding about 200 grams of explosive. The force of the explosion was estimated by the number and weight of the collected pieces and the distance to which they were scattered, the difference between this weight and the original weight being reckoned as shell reduced to powder by the explosion. In the case of black gunpowder fired electrically by a platinum thread, 10 pieces were collected whose collective weight was nearly that of the original shell, but, when a fulminate cap was used, 77 pieces whose collective weight was but 3·8 kilos. were obtained. When shells filled with bellite, dynamite, and cotton-powder were exploded by means of 1 gram of mercuric fulminate, the shells were reduced to powder. 1 gram of mercuric fulminate produced no effect on a shell filled with ammonium nitrate except to evaporate a small amount in the immediate vicinity of the fuze, whilst the screw holding the shell was moved. 3 grams of fulminate caused a low, rumbling explosion, and 62 pieces of shell were collected which weighed 6 kilos. A shell containing 180 grams of ammonium nitrate and 20—30 grams of bellite (composed of dinitrobenzene 1 part and ammonium nitrate 4 parts) yielded, on explosion by 1 gram of mercuric fulminate, 230 pieces weighing 2·75 kilos. Hence it appears that ammonium nitrate requires a stronger initial impulse than either dynamite or dry cotton-powder; that its employment, unless it be mixed with charcoal or aromatic nitro-compounds, is negatived on account of its weaker action, although for coal mining purposes its employment would seem to be advantageous, as but a slight rise in temperature accompanies the explosion. T. G. N.

Silver Sulphite. By W. H. Sodeau (*Chem. News*, **65**, 102).—Silver sulphite was prepared by passing sulphurous anhydride into a solution of recrystallised silver nitrate, washing well, and drying in a vacuum over sulphuric and chromic acids mixed; when sealed up in tubes, it was blackened slowly and slightly by a fortnight's exposure to ordinary sunlight, and, in other experiments, more intensely and more readily as the temperature, at which it was exposed, was raised. The presence of water also accelerates the blackening. D. A. L.

Silver Nitrosilicate: Existence of a Nitrosilicic Acid. By G. Rousseau and G. Tite (*Compt. rend.*, **114**, 294—296).—When silver nitrate is heated with a small quantity of water and fragments of marble in sealed tubes at 180—300° for many hours, deep ruby crystals are obtained, adhering strongly to the sides of the tube. They have the composition $2AgNO_3,3Ag_4SiO_4$ or

$$7Ag_2O,3SiO_2,N_2O_5.$$

Similar results are obtained if finely-divided silica is added to the contents of the tube, and in this case the crystals do not adhere to the glass. Silver oxide may be used in place of calcium carbonate, but the excess is difficult to separate at the end of the operation. The same product is obtained in smaller crystals by heating silver nitrate with silica at 350—440°.

Silver nitrosilicate forms short, ruby prisms showing longitudinal extinction in parallel light. When heated to dull redness, the crystals intumesce with evolution of nitrogen oxides, and a residue of metallic silver and the silicate Ag_2SiO_3 is left. The nitrosilicate is easily soluble in dilute nitric acid, but after some time, and especially on heating, silica separates. Hydrochloric acid decomposes the compound immediately with separation of silver chloride. Ammonium chloride also decomposes it, and the solution smells of ammonia, but nitrosilicic acid could not be isolated. Potassium chloride solution is without action even at 100°, but potassium iodide yields silver iodide and potassium nitrosilicate, the latter separating in long needles when the filtrate from the silver iodide is concentrated in a vacuum.

Solubility of Tricalcium Phosphate and Dicalcium Phosphate in Solutions of Phosphoric Acid. By H. Causse (*Compt. rend.*, **114**, 414—417).—The author has measured the solubility of tricalcium phosphate and dicalcium phosphate respectively in 100 c.c. of solutions containing 5, 10, 15, 20, 25, 30 grams of phosphoric acid respectively. With more than 30 grams of phosphoric acid, monocalcium phosphate is precipitated.

	1.	2.	3.	4.	5.	6.
Tricalcium phosphate dissolved.....	3·85	7·28	9·45	12·50	13·79	15·10
Dicalcium phosphate dissolved.....	4·30	7·15	9·30	11·86	13·40	15·10

With tricalcium phosphate, when the solutions are heated at 100°,

there is a precipitate of dicalcium phosphate in Nos. 5 and 6; with dicalcium phosphate, under similar conditions, there is a precipitate in all six solutions.

It will be observed that the solubility of tricalcium phosphate is greater than that of dicalcium phosphate. A condition of equilibrium seems to be established between phosphoric acid, monocalcium phosphate, and water, the water playing the principal part and determining the proportion of free phosphoric acid and monocalcium phosphate. C. H. B.

Barium Carbide. By MAQUENNE (*Compt. rend.*, **114**, 361—362).—When barium amalgam is mixed with powdered charcoal and distilled in a current of pure and dry hydrogen, a somewhat energetic reaction takes place at a red heat without any absorption of gas. The product is a grey, fritted mass containing excess of carbon. It does not change at a bright red heat, but is immediately decomposed by cold water with evolution of acetylene mixed with 7 per cent. of some gas not absorbed by cuprous chloride. The formula of the carbide is BaC_2. It contains no hydrogen and its formation takes place readily in an atmosphere of nitrogen. In this case, however, barium cyanide is formed in quantity equal to about 25 per cent. of the original weight of the barium. The decomposition of the carbide by water is represented by the equation $BaC_2 + 2H_2O = C_2H_2 + Ba(OH)_2$.

If the property of forming carbides is common to other metals, this fact may throw some light on the natural formation of hydrocarbons, since Berthelot has shown that acetylene is the starting point in the synthesis of these compounds. C. H. B.

Lead Chlorosulphide and Bromosulphide. By F. PARMENTIER (*Compt. rend.*, **114**, 298—301).—Lead chloride is dissolved in hydrochloric acid, the solution diluted with water, and hydrogen sulphide is allowed to play on the surface of the liquid until yellow striæ become visible. The liquid is then rapidly agitated and poured into a large, dry vessel. A cinnabar-coloured precipitate of the chlorosulphide, $PbS,PbCl_2$, separates; it is very unstable, and is decomposed by water, acids, and alkalis. Alkalis at first blacken it, but the black substance rapidly changes to a white, flocculent mass. A similar change takes place, although slowly, when freshly precipitated lead sulphide is treated with an alkaline hydroxide.

Lead bromosulphide, $PbS,PbBr_2$, is obtained in a similar manner, but more readily; it is orange-yellow, and is unstable.

An iodosulphide also seems to exist, but its preparation is difficult on account of the slight solubility of lead iodide in hydriodic acid. C. H. B.

So-called Mercurosammonium Compounds. By L. PESCI (*Gazzetta*, **21**, ii, 569—580; compare Abstr., 1891, 268).—The author has examined most of the so-called mercurosammonium compounds, obtained by treating mercurous salts with ammonia, and finds that they consist of the corresponding mercurammonium salts mixed with metallic mercury. The mercurammonium salts being readily soluble

in a saturated solution of ammonium sulphate containing ammonia, the metallic mercury can be separated from the precipitate.

When calomel is treated with ammonia, a grey powder ordinarily known as mercurosammonium chloride, NH_2Hg_2Cl, is obtained; this, on microscopical examination, is seen to contain metallic mercury, and on treating it with ammoniacal ammonium sulphate solution, it partially dissolves, leaving a residue of mercury. Under the action of light the product rapidly changes, but when preserved from such disturbing influences, the reaction between calomel and ammonia is probably represented by the equation

$$2Hg_2Cl_2 + 4NH_3 = Hg_2NCl,NH_4Cl + 2Hg + 2NH_4Cl.$$

This is confirmed by treating the precipitate with aqueous potash until the evolution of ammonia is at an end. The mercurammonium salt is thus converted into hydrated mercurammonium chloride, Hg_2NCl,H_2O; the mixture of this salt and mercury thus obtained gives satisfactory numbers on analysis.

In a similar manner, the reaction between mercurous sulphate and ammonia, supposed to yield a compound having the composition $(NH_2Hg_4O)_2SO_4$, is shown to proceed as represented by the equation $28Hg_2SO_4 + 56NH_3 + 12H_2O = 7(Hg_2N)_2SO_4,(NH_4)_2SO_4,12H_2O + 28Hg + 20(NH_4)_2SO_4$. The double salt loses ammonia when treated with aqueous alkalis, and gives hydrated mercurammonium sulphate, $(Hg_2N)_2SO_4,2H_2O$.

When a mercurous nitrate solution is allowed to remain in a slightly ammoniacal atmosphere, basic mercurous nitrate, $Hg_{10}N_6O_{20},2H_2O$, separates.

On treating mercurous nitrate solution with aqueous ammonia, a precipitate of variable composition is obtained. This reaction has given rise to considerable discussion owing to the therapeutic value formerly attributed to the product. The author shows that the reaction may be represented by the following equation:—$6Hg_2(NO_3)_2 + 12NH_3 + 2H_2O = 3Hg_2N\cdot NO_3,NH_4\cdot NO_3,2H_2O + 6Hg + 8NH_4\cdot NO_3$.

W. J. P.

Metals of the Cerium Group. By P. Schottländer (*Ber.*, **25**, 378—394).—The author gives details respecting the separation of the metals of the cerium group by Auer v. Welsbach's methods (*Monatsh.*, **5**, 508) under the following headings:—(I.) *Preparation of cerium salts free from lanthanum and didymium.* (II.) *Preparation of lanthanum and didymium salts free from cerium.* (III.) *Separation of lanthanum and didymium by the oxide process.* (IV.) *Preparation of pure lanthanum salts and partial separation of didymium into its constituents by crystallisation of ammonium didymium nitrate* (see *Wien. Acad. Ber.*, 1885, **2**, 317).

A. R. L.

Metals of the Cerium Group. By P. Schottländer (*Ber.*, **25**, 569—599).—This paper contains an account of the spectroscopic investigation of the didymium material described in the author's previous communication. The results obtained have not led to any very positive conclusions; they show, however, that every absorption maximum is not necessarily a characteristic of one distinct element,

as has been assumed by Krüss and Nilson (Abstr., 1887, 890), and that therefore the number of elements present in the material examined by the latter investigators is probably considerably less than they were led to conclude. H. G. C.

Action of Certain Liquids on Aluminium. By G. Lunge (*Chem. News*, **65**, 110—111).—Adverse opinions having been expressed in connection with the application of aluminium to domestic, food storage, surgical and such like purposes, the author instituted the following experiments with commercial rolled sheet aluminium 1 mm. thick and containing per cent. 99·20 of aluminium, 0·55 of silicon, 0·25 of iron, and trace of copper. Suitable strips were cut from this, and after the edges and compressed rolled surface had been removed by filing, the strips were thoroughly cleaned by washing with soda, then successively with water, sulphuric acid, and again water, finally scrubbing with distilled water, rinsing with alcohol, and drying in an oven. Three strips were weighed and then suspended, without touching one another, from glass hooks, in corked flasks, containing about 400 c c. of the liquids examined, comprising:—Ordinary claret and hock, brandy, pure 50 per cent. alcohol, solutions of tartaric, acetic, citric, lactic, butyric, boric, and salicylic acids, phenol, and tea, coffee, and beer. After six days, the strips were removed, washed, and weighed, and the experiments repeated for another period of six days. The results are tabulated in the paper, but the conclusions are that tea, coffee, and beer are practically without action on aluminium, brandy nearly so, whilst the action of acids and acid liquids, although more pronounced, is far too slight to cause any alarm; in the worst case, acetic acid, only 5 milligrams were dissolved per 100 c.c. in six days; and such action in a quart canteen, supposing it always to be full, would only amount to 1 gram in 200 days. The author hence asserts that aluminium may be employed without fear for holding articles of food, at least at the ordinary temperature.

D. A. L.

The Hypothetical Manganese Tetrachloride. By S. U. Pickering (*Phil. Mag.* [5], **33**, 284).—If, when manganese dioxide is dissolved in hydrochloric acid, the sesquichloride is formed, some chlorine must be liberated at the same time; whereas, if the tetrachloride is formed, no chlorine need be liberated. Vernon's results (Abstr., 1882, 19), which tended to prove that the dissolution might be effected without evolution of chlorine, are, in the author's opinion, open to question. If the tetrachloride is formed, it would be possible to reproduce the whole of the dioxide taken by decomposing it with water; whereas, if it were the sesquichloride which were formed, only 50 per cent. of the dioxide taken could be thus recovered; yet, in spite of Vernon's experiments, which were supposed to show that the tetrachloride could be obtained almost undecomposed, he only in one case recovered a fraction more than the 50 per cent. of the dioxide, and he gives no analytical data to show what reliance can be placed on this excess (1·2 per cent.). In every other respect Vernon confirmed Pickering's conclusions (Trans., 1879, 654), and, in his (Pickering's) opinion,

adduces no evidence to disprove that the higher chloride is Mn_2Cl_6, or to prove that it is $MnCl_4$. S. U. P.

Bismuthic Acid. By G. André (*Compt. rend.*, **114**, 359—360).—Bismuthic acid combines very slowly and incompletely with potassium hydroxide, even when the latter is in excess. Prolonged boiling of the acid with an aqueous solution of ten times the quantity of potash required to saturate it yields a compound $KBiO_3,4HBiO_3$.

If, in the preparation of bismuthic acid, by the action of chlorine on bismuth oxide suspended in hot aqueous potash, the passage of chlorine is continued until the potash is completely saturated, a violet-black product is obtained that will not emulsify even after prolonged boiling with water. The product contains only a very small proportion of potassium, and sometimes it contains chlorine. After prolonged treatment with nitric acid and drying at 100°, it has the composition $Bi_2O_5,2HBiO_3$.

The emulsion obtained in the preparation of bismuthic acid (compare this vol., p. 413) is precipitated by dilute nitric acid, and the brown precipitate, when washed and dried at 100°, has the composition Bi_2O_5, or more probably $HBiO_3,Bi_2O_5$. C. H. B.

Note.—The author makes no reference to Mr. Pattison Muir's researches on this subject.–[Editors.]

Ruthenium Chloride and Hydroxychloride. By A. Joly (*Compt. rend.*, **114**, 291—293).—Chlorine attacks finely-divided ruthenium very slowly at 360° and converts it partially into the trichloride. If, however, the finely-divided metal is heated at 360° or 440° in a mixture of chlorine and carbonic oxide, care being taken that the chlorine is in excess, ruthenium trichloride is formed rapidly, and occupies many times the volume of the original metal. A small quantity of metal always remains unattacked. The chloride is a dark-brown substance, insoluble in cold water, inorganic and organic acids, carbon tetrachloride, carbon bisulphide, chloroform, phosphorus trichloride, or ether. When digested with 50 times its weight of absolute alcohol in sealed tubes for several hours, the chloride is dissolved, and the unattacked metal remains undissolved. Hot water slowly decomposes the chloride.

The solution of the chloride in absolute alcohol is purple-violet, but in presence of atmospheric moisture or if the alcohol is not quite anhydrous, the solution very slowly becomes violet-blue and afterwards deep indigo-blue. The change takes place more rapidly at 60°, and is due to the formation of a hydroxychloride, $RuCl_2{\cdot}OH$, which is obtained as a black product when the alcohol is distilled off, and is stable at 150°. It is very soluble in water, forming a deep indigo-blue solution, which gradually deposits ruthenium hydroxide, $Ru(OH)_3$.

If the hydroxychloride is dissolved in a considerable excess of hydrochloric acid, it forms a brown solution of a hydrochloride of the chloride, which is stable at about 150°, but at 200° is converted into the anhydrous chloride.

The hydroxychloride combines with ammonium and forms a compound very soluble in water; it yields an intense crimson solution, turning to yellow in presence of hydrochloric acid.

When ruthenium is subjected to the action of chlorine and carbonic oxide at 360° or 440°, a small quantity of a product containing carbonic oxide is formed. C. H. B.

Mineralogical Chemistry.

Elaterite and Dopplerite. By W. Alexéeff (*Zeit. Kryst. Min.*, **20**, 187—188; from *Mining J., St. Petersburg*, **1**, 361—375).—The author has made an examination of the elaterites and dopplerites of the Caucasus. The so-called elaterite of the government of Kutais proves, on analysis, to be dopplerite, the analytical results being as follows:—

C.	H.	O + N.	Ash.	Total.
51·17	4·60	34·57	9·66	100·00

The percentage of hygroscopic water was 7·28.

In composition, this mineral is very similar to the coal of Lepsia, in the Northern Ural. The author regards dopplerite as intermediate between bituminous coal and lignite. Pure elaterites are probably nothing more than asphalt, $n(CH_2)$, with which a small proportion of an oxygen compound is mixed. Elaterite from Sakupris Gelle, in the government of Kutais, gave, on analysis:—

C.	H.	O + N.	Ash.	Total.
84·66	8·19	4·98	2·19	100·02

B. H. B.

Manganese Hydroxide from the Euganeen, Italy. By G. di Boccard (*Zeit. Kryst. Min.*, **20**, 175—176; from *Riv. min. crist. ital.*, **4**, 55).—A black substance, consisting of manganese hydroxide, limonite, and sand, was found coating trachyte and calcite in geodes in the trachyte. It had a sp. gr. of 3·13 and a hardness of 5. Neglecting the sand, the analysis gave:—

Mn_2O_3.	Fe_2O_3.	H_2O.
75·51	6·80	17·69

An analysis of a similar substance, containing a larger proportion of limonite, yielded:—

Mn_2O_3.	Fe_2O_3.	H_2O.	Sand.
9·31	7·85	10·21	72·63

B. H. B.

Iron Ores of Central Russia. By P. A. Zemjatschensky (*Zeit. Kryst. Min.*, **20**, 184—186; from *Memoirs of the Soc. of Naturalists of St. Petersburg*, **20**, 1—300).—The author gives an exhaustive geological and chemical description of the iron ores of a portion of the Moscow coalfield. The ores are mostly brown hæmatites.

Numerous analyses are given, one of which, that of the ore from Katnoff, does not represent the composition of brown hæmatite but that of Hermann's turjite, its formula being $2Fe_2O_3,H_2O$. In physical properties, this mineral is similar to the turjite from the Turjin mine, in the Ural. In the ores of Dankoff, in some very compact brown hæmitites, crystals of a ferric hydrate occur, to which the author assigns the name of *hydrogoethite*. Its chemical formula is $3Fe_2O_3,4H_2O$, and its sp. gr. 3·556. The same mineral is also found in the ores occurring in the vicinity of Lipezk. B. H. B.

Vivianite. By W. Tjelouchin (*Zeit. Kryst. Min.*, **20**, 183; from *J. Russ. Chem. Soc.*, **21**, 129).—This mineral was found at Tamanj, on the Sea of Azov. The crystals, which occur in a fossiliferous rock, gave, on analysis, the following results:—

H_2O.	FeO.	Fe_2O_3.	P_2O_5.	CO_2.	CaO.	MgO.	Total.
29·41	37·05	3·07	28·23	0·15	0·54	2·01	100·46

B. H. B.

Natrolite from Monte Baldo. By G. Luzzatto (*Zeit. Kryst. Min.*, **20**, 175; from *Riv. min. crist. ital.*, **4**, 54).—An analysis of this mineral gave the following results:—

H_2O.	SiO_2.	Al_2O_3.	CaO.	Na_2O.	Total.
9·57	47·16	26·76	0·28	16·18	99·95

B. H. B.

Zoisite from Orenburg. By M. P. Melnikoff (*Zeit. Kryst. Min.*, **20**, 186; from *Material for Russian Geology*, **13**, 249—375).—This mineral occurs in the granite at Kulachta in fairly large crystals, and gave, on analysis, the following results:—

SiO_2.	Al_2O_3.	Fe_2O_3.	CaO.	Loss on ignition.	Total.
40·48	31·71	2·07	23·50	2·51	100·27

B. H. B.

Organic Chemistry.

Fulminuric Acid. By P. Seidel (*Ber.*, **25**, 431—432).—*Ethyl fulminurate*, $C_3H_2N_3O_2{\cdot}OEt$, is obtained when silver fulminurate is heated with ethyl iodide at about 80—90° in a closed vessel; the yield is quantitative. It separates from a mixture of chloroform and acetone in crystals, melts at 133°, and decomposes at a slightly higher temperature; it is only very sparingly soluble in ether, ethyl iodide, light petroleum, benzene, cold water, and alcohol, but moderately easily in hot water and hot alcohol, and very readily in acetone. It dissolves unchanged in concentrated mineral acids, but is reprecipitated on the addition of water. When boiled for a long time with water and alcohol, it is decomposed with formation

of aldehyde and a crystalline acid; the last-named compound separates from water in large, colourless, efflorescent needles containing 1 mol. H_2O, and is very readily soluble in water, acetone, and alcohol; the anhydrous acid melts at 184°. F. S. K.

Decylene and its Derivatives. By L. Grosjean (*Ber.*, **25**, 478—481).—When castor oil is subjected to dry distillation under diminished pressure, a mixture of œnanthaldehyde and undecylenic acid, $CH_2{:}CH{\cdot}[CH_2]_8{\cdot}COOH$, is obtained, and from the latter compound decylene is conveniently prepared by heating the barium salt (2 parts) dried at 120° with sodium ethoxide (1 part) in a retort, under a pressure of 50 mm. Decylene is a limpid, colourless liquid, insoluble in water; it boils at 61·5° under 15 mm. pressure, at 87—88° under 50 mm., at 106—107° under 100 mm., and at 172° under 760 mm., without decomposition. The sp. gr. at 0° = 0·7630, at 15° = 0·7512, and at 30° = 0·7398. The *dibromide* boils at 135° under 9 mm., and at 145° under 15 mm. pressure. The sp. gr. at 0° = 1·3841, at 15° = 1·3677, and at 30° = 1·3512. The *diacetate* was only obtained in an impure state as a colourless oil which boiled at 142° under 9 mm., at 152° under 14 mm., and at 264—272° at the ordinary pressure, with partial decomposition.

Decylene glycol is obtained by heating the diacetate with alcoholic potash in a reflux apparatus. It is a colourless, viscid liquid, boils at 145° under 15 mm., and at 255° under the ordinary pressure, without decomposition. The sp. gr. at 0° = 0·9226, at 15° = 0·9115, and at 30° = 0·9011.

Chlorodecyl benzoate, $C_{10}H_{20}Cl{\cdot}OBz$, is obtained by heating the above glycol (1 part) with benzoic chloride (0·807 part) for five hours at 120°, and then for one hour at 160°, and distilling the product under diminished pressure. It is a colourless oil, and boils at 201° under 12 mm.

Bromodecyl acetate, $C_{10}H_{20}Br{\cdot}OAc$, is obtained mixed with a small quantity of decylene dibromide by the action of silver acetate (1 mol.) on decylene dibromide. It boils at 146—147° under 15 mm. pressure, is a colourless oil, and, when boiled with alcoholic potash, is converted into a mixture of decylene glycol and decylene oxide, $C_{10}H_{20}O$. The latter boils at 85—86° under 10—11 mm. pressure, is very limpid, and has a penetrating odour. E. C. R.

Sodium Isopropoxide. By De Forcrand (*Compt. rend.*, **114**, 301—303).—When isopropyl alcohol is dehydrated by baryta and then twice distilled over sodium, the proportion of water is reduced to 0·5 per cent., and it boils at 82·2—82·8° (corr.); sp. gr. at 15° = 0·789.

When sodium is dissolved with the aid of heat in at least five equivalents of the alcohol, and the solution is allowed to cool, acicular crystals separate, which have the composition $C_3H_7NaO,3C_3H_8O$. If a solution of this compound is heated for some time with glycol, the compound $C_2H_5NaO_2,3C_3H_8O$ is obtained, and it also forms acicular crystals. Attempts to isolate the isopropoxide from the crystals were unsuccessful.

If 23 parts of sodium are dissolved at 100° in a mixture of 300 parts of isopropyl alcohol and 500 parts of crystallisable benzene, and the liquid is heated at 130—135° in a current of hydrogen, the alcohol is removed with the benzene, and sodium isopropoxide remains as a white powder, which is very hygroscopic. C. H. B.

Decomposition of Ethereal Nitrates by Alkaline Solutions. By W. G. Mixter (*Amer. Chem. J.*, **13**, 507—514).—In attempting to extract the cellulose in guncotton by converting it into substances capable of reducing alkaline copper tartrate, it was found that guncotton and similar ethereal nitrates themselves exert a direct reducing action on this solution. In order to trace the course of this reaction, experiments were instituted on the nitrates of ethyl, ethylene, glycerol, mannitol, and cellulose.

Ethyl nitrate is completely hydrolysed by alcoholic potash, as was observed by Millon (*Ann. Chim. Phys.* [3], **8**, 236), no other products being formed, and it does not reduce alkaline copper tartrate.

Ethylene nitrate is not merely hydrolysed by potash, as stated by Champion (*Compt. rend.*, **73**, 571), but is oxidised to carbonic anhydride at the expense of the nitric acid, both in aqueous and alcoholic solutions. It is oxidised to oxalic acid by boiling aqueous barium hydroxide, and does not reduce alkaline copper tartrate.

Glyceryl trinitrate is decomposed by hot aqueous potash into oxalic acid, carbonic anhydride, nitrous acid, ammonia, and traces of cyanogen and glycerol. Other organic substances appear to be formed, but could not be isolated. Glycerose is not formed. Glyceryl trinitrate reduces alkaline copper tartrate, but the products of decomposition to which the reduction is due are themselves decomposed by the further action of the alkali, since a solution of the nitrate in potash has no reducing power. On boiling glyceryl trinitrate with baryta-water, however, ammonia is expelled, and a reddish precipitate thrown down, which reduces alkaline copper tartrate, gives off ammonia when heated with lime, and consists of a mixture of barium oxalate with other unspecified substances. Nitrous acid is also formed in the reaction.

When mannitol nitrate is boiled with baryta-water, it yields a red, granular precipitate, which contains barium oxalate, and reduces alkaline copper tartrate. The nature of the reducing substance was not ascertained. The filtrate from the precipitate contains nitrites and organic matter, but does not reduce alkaline copper tartrate. Mannitol nitrate is decomposed by hot concentrated aqueous potash into oxalic acid and carbonic anhydride, and the solution has no reducing power. With dilute alkalis, however, oxalic acid is not formed, and the solution reduces alkaline copper tartrate, as the nitrate itself does.

Commercial pyroxylin or cellulose tetranitrate is decomposed by hot concentrated aqueous potash into carbonic anhydride, oxalic acid, and other substances, the nature of which was not ascertained. Sugar does not seem to be formed. A solution of pyroxylin in dilute aqueous potash reduces alkaline copper tartrate, and the substance itself dissolves in the copper solution and gradually reduces it.

The reducing action of cellulose hexanitrate is not so powerful as that of the tetranitrate.

The products of the action of nitric acid on pinitol, wood-fibre, gum arabic, gum tragacanth, balsam of Tolu, glycogen, starch, and cane sugar reduce alkaline copper tartrate, whilst those resulting from blood-albumin, egg-albumin, egg-yolk, caoutchouc, tartaric acid, beeswax, and tallow do not do so. JN. W.

Cellulose. By C. F. CROSS and E. J. BEVAN (*Chem. News*, **65**, 77—78).—The authors give a few interim notes in connection with points they have under investigation. The precipitates of cotton cellulose hydrates from its solutions in ammoniocupric reagent or in $ZnCl_2,HCl$ are soluble in solutions of alkali hydroxides, and the resulting solutions, when shaken with benzoic chloride, yield a white, curdy precipitate, which, after purification by solution in glacial acetic acid, &c., has the composition of a dibenzoate, $C_6H_8O_3(OBz)_2$. This is soluble in acetic anhydride, and on boiling the solution with fused sodium acetate, what appears to be a triacetyl monobenzoate is formed. A monobenzoate is likewise formed when cellulose soaked in aqueous soda (containing 15 per cent. Na_2O) is shaken with benzoic chloride. Moreover, the authors have obtained large quantities of acetic acid by fusing cellulose with alkali hydroxides at 300—400°. Taking into consideration these and many other facts now known about cellulose, the authors are inclined to assume that cotton cellulose is an anhydro-aggregate of unit groups for which they adopt a C_{12} formula, and in which 8 oxygen atoms are accepted as hydroxylic and two as carbonylic. Lignocelluloses, on the other hand, are regarded as anhydro-aggregates of 1, a cellulose allied to cotton and linen cellulose; 2, a penta-cellulose yielding furfuraldehyde and acetic acid on hydrolysis; 3, a, C_{18}-quinone or quinol, converted by chlorination and reduction into derivatives of the trihydric phenols, and comprising groups of the general form

$$CO<\begin{matrix}C(OH)_2\cdot C(OH)_2\\ CH=\!=\!=CH\end{matrix}>CH_2.$$

Any final adoption of the proposed additions to the terminology of this group of plant constituents is regarded as premature.

D. A. L.

Aliphatic Stereoisomeric Glyoximes. By A. HANTZSCH (*Ber.*, **25**, 705—712).—The glyoxime, $C_2H_4(NOH)_2$, appears to be capable of existing in one modification only, and its diacetyl derivative (m. p. 126°) is only partially decomposed into cyanogen, hydrogen cyanide, and carbonic anhydride by alkalis, so that although it is probable that it is antiglyoxime, $\begin{matrix}H\cdot C\cdot C\cdot H\\ \|\quad\|\\ OH\cdot N\ N\cdot OH\end{matrix}$, this cannot be determined with certainty. Methyl- and dimethyl-glyoximes behave in much the same manner, and neither in the free state nor in that of diacetyl derivatives can they be converted into dimethylazoxazole by dehydration.

Chloramphiglyoxime, $\begin{matrix}Cl\cdot C & ——C\cdot H\\ \|\quad & \quad\|\\ N\cdot OH & N\cdot OH\end{matrix}$, identical with that of Naegeli, is obtained when chloral hydrate (1 mol.) is added to a solution of

sodium carbonate (1·5 mols.) and hydroxylamine hydrochloride (3 mols.); after remaining for four hours, sodium hydroxide (4 mols.) is added to the cooled solution, and on carefully acidifying, the compound separates, the remaining portion being obtained by extracting the filtrate with ether. It crystallises from water in silky needles containing 1 mol. H_2O, melts at 114°, resolidifies above this, and decomposes at 150°, and is sparingly soluble in cold water, readily in hot water, ether, and alcohol; concentrated alkalis decompose it, but it dissolves unchanged in dilute alkalis and ammonia. The *ammonium* salt separates in small prisms when ammonia is passed into an ethereal solution of the glyoxime; the *diacetyl derivative* crystallises in tables, melts at 114°, and is sparingly soluble in alcohol and ether.

Chlorantiglyoxime, $\begin{matrix} Cl\cdot C & - & C\cdot H \\ \| & & \| \\ OH\cdot N & & N\cdot OH \end{matrix}$, produced by passing dry hydrogen chloride into an ethereal solution of the last-described glyoxime, crystallises in small, anhydrous, nodular aggregates, melts at 161° with decomposition, and resembles its isomeride in solubility; it dissolves in alkalis with a yellow colour, and in concentrated ammonia with explosion due to the formation of ammonium hypochlorite. Very dilute alkalis dissolve it, and the amphi-modification separates on acidifying the solution. The *diacetyl* derivative is obtained from chlorantiglyoxime and acetic anhydride, as well as when dry hydrogen chloride is passed through an ethereal solution of diacetylchloramphiglyoxime; it resembles the latter in form and solubility, and melts at 90·5°.

Acetylchlorantiglyoxime, $\begin{matrix} Cl\cdot C & - & C\cdot H \\ \| & & \| \\ OH\cdot N & & N\cdot OAc \end{matrix}$ (?), is formed from chlorantiglyoxime and acetic anhydride, and also when either of the above-described chloroglyoximes is treated in the cold with acetic chloride; it melts at 163°, and is readily soluble in alcohol and ether.

A. R. L.

Condensation of Chloral with Paraldehyde and Ketones. By W. Koenigs (*Ber.*, **25**, 792—802).—*Chloralacetone*,

$$CCl_3\cdot CH(OH)\cdot CH_2\cdot COMe,$$

is prepared by heating acetone (3·2 grams) with chloral (8 grams) and glacial acetic acid (8 grams) in a sealed tube for 15 hours at 100°; the product is mixed with water, well shaken with dilute soda, and extracted with ether, the ether is removed, the residue dissolved in hot water, filtered, and again treated with ether; this is evaporated, and the residue crystallised from light petroleum; it melts at 75—76°, sublimes on cautiously heating, and is readily soluble in alcohol. The yield is 50 per cent. of the acetone employed. The same compound is also obtained by heating chloral with acetone at 150°.

On boiling chloralacetone with soda, an acid is formed in small quantity, which is almost free from chlorine, and melts at about 123°.

Butylchloral also combines with acetone; the product crystallises from a mixture of ether and light petroleum, and melts at 111—114°; the yield is very small.

Chloralacetophenone, $CCl_3{\cdot}CH(OH){\cdot}CH_2{\cdot}COPh$, is obtained from acetophenone (19·2 grams), chloral (24 grams), and glacial acetic acid (24 grams), by heating on the water-bath for 20 hours in a reflux apparatus; the product is treated with water, dissolved in ether, and precipitated with light petroleum; it crystallises from 60 per cent. alcohol, melts at 76—77°, and decomposes on heating; the yield is equal to that of the acetophenone employed. The compound is scarcely volatile with steam; it is very stable towards acids, but readily decomposes on treatment with alkalis, probably into benzoylacrylic acid; on heating with 1 per cent. potash, an acid free from chlorine is formed in small quantity; it melts at 125—127°.

Trichlorethylideneacetophenone, $CCl_3{\cdot}CH{:}CH{\cdot}COPh$, is prepared by dissolving chloralacetophenone in about 9 parts of pure, concentrated sulphuric acid; after remaining over night at ordinary temperatures, the solution is well cooled and treated with water; the compound crystallises from 80 per cent. alcohol in almost colourless plates or prisms which melt at 102°. The same substance is obtained by heating chloral with acetophenone in a sealed tube at 150—160°; it is readily volatile with steam, and sublimes without decomposition on cautiously heating.

Butylchloral also yields a condensation product with acetophenone which crystallises from dilute alcohol and melts at 110°.

Butylchloralaldol, $CHClMe{\cdot}CCl_2{\cdot}CH(OH){\cdot}CH(CHO){\cdot}CHMe{\cdot}OH$, is formed by heating paraldehyde with 4 parts of butylchloral for 6—7 hours at 140—150°; it is a viscid, oily liquid, insoluble in water, soluble in ordinary media, and volatile with steam; it decomposes on heating, and, on distillation over lime, gives a compound which is free from chlorine, melts at about 50°, and has an odour resembling that of diphenyl. The yield of aldol is 20 per cent. of the paraldehyde employed. The aldol does not combine with sodium hydrogen sulphite, but yields a crystalline hydroxime.

Chloralaldol is obtained by heating paraldehyde (2·4 grams) with chloral (8 grams) and glacial acetic acid (8 grams) in a sealed tube for 9—10 hours at 100°; the yield is very small; the analytical results do not agree very closely with the formula $C_6H_9Cl_3O_3$, probably on account of the partial oxidation of the compound.

No condensation product of camphor and chloral could be obtained.

The author discusses a number of syntheses accomplished by means of chloral, and refers particularly to the formation of inactive malic acid from chloral and malonic acid; he points out the general bearing of his work on the theory of the production of acids in fruits and vegetables: for although chloral itself does not occur in nature, the corresponding hydroxyl compound, glyoxylic acid, is frequently found. J. B. T.

Action of Bromine on the Higher Fatty Acids. By F. Krafft and A. Beddies (*Ber.*, **25**, 481—488).—When stearic acid is heated for three hours with bromine (1 mol.) at 130—140°, about half the stearic acid remains unaltered, and three-fourths of the bromine is evolved as hydrogen bromide. By converting the product into the barium salt

and extracting with ether, the barium salt of the bromo-acid is easily dissolved; the barium stearate remaining insoluble. On analysis, the barium salt gives numbers agreeing with the formula of barium bromostearylenate, $(C_{18}H_{32}BrO_2)_2Ba$. When suspended in alcohol, and treated with hydrogen chloride, a liquid ethereal salt is obtained which decomposes on distillation under diminished pressure, and, after three rectifications, distils at 225—227° under 13 mm. pressure, losing all its bromine as hydrogen bromide. The product so obtained yields, on hydrolysis, an acid which boils at 223—225° under 10 mm. pressure, melts at 47—48°, and, on analysis, gave numbers corresponding with those required for stearoleïc acid, $C_{18}H_{32}O_2$.

When palmitic acid is treated with bromine in the same way, half of it is recovered unaltered. The mixed acids are separated by means of the barium salts as described above. The barium salt of the bromo-acid has the formula $(C_{16}H_{28}BrO_2)_2Ba$; the ethyl salt decomposes on distillation with evolution of hydrogen bromide, and the product so obtained, when hydrolysed with alcoholic potash, yields an unsaturated acid. The latter boils at 212—213° under 12·5 mm., melts at 42°, and, on analysis, gave numbers agreeing with the formula of palmitoleïc acid, $C_{16}H_{28}O_2$. It is mixed with a small quantity of a substance melting at 70—71°.

Myristic and lauric acids behave in a similar way. The former yields a bromo-acid, of which the barium salt has the formula $(C_{14}H_{24}BrO_2)_2Ba$, and, when converted into ethyl salt, distilled, and hydrolysed, yields an acid of the formula $C_{14}H_{24}O_2$, which boils at 200—205° under 13 mm., melts about 36°, and contains a small quantity of an acid melting at 56—57°. The barium salt of the bromo-acid derived from lauric acid has the formula $(C_{12}H_{20}BrO_2)_2Ba$, and finally yields an acid $C_{12}H_{20}O_2$, which boils at 182—185° under 13 mm., melts at about 30°, and is mixed with a small quantity of an acid melting at 49—50°. E. C. R.

Alde-acids. By J. A. Wanklyn and W. Johnson (*Chem. News*, **65**, 75).—The authors have treated, severally, with alkaline permanganate, commercial valeric acid, palmitic acid prepared from palm oil, and margaric acid, commercially known as stearic acid. In the first instance, they have obtained a crystalline acid; in the second, an acid yielding a barium salt containing 21·31 per cent. of barium, the exact percentage required by barium aldepalmitate, whilst the barium salt of the palmitic acid employed contained 20·92 per cent. of the metal; and in the third instance, a new acid is obtained.

D. A. L.

Introduction of Acid Radicles into Ethyl Acetoacetate. By H. v. Pechmann (*Ber.*, **25**, 410—411).—The author finds that acid chlorides and anhydrides react with ethyl acetoacetate in alkaline solution with the displacement of 1 or 2 atoms of hydrogen by the acid radicle; for example, ethyl acetoacetate, when shaken with sodium hydroxide and an excess of benzoic chloride, yields ethyl dibenzoylacetoacetate, ethyl benzoylacetoacetate, and unaltered ethyl acetoacetate. Ethyl benzoylacetate, acetone dicarboxylate, and 1 : 3-diketones behave in a manner similar to ethyl acetoacetate.

A. R. L.

Haloïd Derivatives of Ethyl Acetoacetate. By A. Haller and A. Held (*Compt. rend.*, **114**, 398—401).—Ethyl monochloracetoacetate, obtained by direct chlorination, when freshly prepared, yields *ethyl amidomethylthiazolecarboxylate* when treated with thiocarbamide under the conditions described by Zurcher. A similar result was obtained with some of the compound that was a year old. The freshly-prepared compound with potassium cyanide yielded as much as 25 per cent. of the γ-cyano-derivative; whereas the old preparation yielded a very small quantity of the γ-derivative. It would seem that ethyl monochloracetoacetate, obtained by direct chlorination, undergoes a change in constitution with lapse of time.

Ethyl monobromacetoacetate, obtained by Duisberg by direct bromination, yields only ethyl μ-amidothiazylacetate by condensation with carbamide without any trace of the isomeride; when treated with potassium cyanide, it yields ethyl succinosuccinate without any trace of ethyl γ-cyanacetoacetate or the α-derivative. The constitution of Duisberg's product is still uncertain.

These results seem to indicate that, according to their mode of formation and the nature of the reactions in which they take part, the monhaloïd derivatives of ethyl acetoacetate behave sometimes as α-derivatives, sometimes as γ-derivatives, sometimes as a mixture of both. C. H. B.

Constitution of Ethyl Chloracetoacetate. By A. Hantzsch and H. Schiffer (*Ber.*, **25**, 728—732).—By the synthesis of ethyl amidomethylthiazolecarboxylate from ethyl chloracetoacetate and thiocarbamide, and that of ethyl amidothiazylacetate from ethyl bromacetoacetate, Hantzsch and also Steude were led to believe that the chloro-compound is an α-, and the bromo-compound a γ-derivative. Haller and Held obtained, however, a mixture of α- and γ-cyano-derivatives by treating the chloro-compound with potassium cyanide (preceding abstract). The authors find that ethyl amidomethylthiazolecarboxylate is formed in almost theoretical yield from ethyl chloracetoacetate as above. When ethyl dimethylacetoacetate is treated with sulphuryl chloride, a chloro-derivative decomposing at 210—215° is obtained, which, when heated in dilute alcoholic solution with thiocarbamide, gives *ethyl amidothiazylisobutyrate*, $COOEt\cdot CMe_2\cdot C\begin{matrix}CH\cdot S\\ \|\\ N=C\cdot NH_2\end{matrix}$, melting at 137°, and is, therefore, a γ-chloro-derivative,

$$CH_2Cl\cdot CO\cdot CMe_2\cdot COOEt.$$

The authors, therefore, conclude that ethyl chloracetoacetate is an α-derivative, and that the action of potassium cyanide on it is not a normal one. They further confirm the above mentioned statement that ethyl bromacetoacetate is a γ-derivative and not, as supposed by Nef, a mixture of α- and γ-derivatives. A. R. L.

Allylethylsuccinic and Allylmethylsuccinic Acids. By E. Hjelt (*Ber.*, **25**, 488—491).—Ethyl allylbutenyltricarboxylate is first prepared from ethyl butenyltricarboxylate, allyl iodide, and sodium, or from ethyl allylmalonate, ethyl bromobutyrate, and sodium. The portion of the product boiling at 282—291° is hydrolysed with potash

and the solution acidified with hydrochloric acid; allyl ethyltricarboxylic acid is obtained; it melts at 123°, and when heated at 150° yields two allylethylsuccinic acids. The sparingly soluble *parallylethylsuccinic acid* crystallises in rhombic plates, melts at 163—166°, and dissolves in 110 parts of water at 20°. *Mesoallylethylsuccinic acid* crystallises in small tablets, melts at 108—111°, and dissolves in 37 parts of water. The para-acid dissolves easily in acetic chloride, and is precipitated unchanged on the addition of water; when heated above its melting point, it is converted into the anhydride, from which the meso-acid mixed with a small quantity of the para-acid is obtained by treatment with water. The meso-acid is easily converted into the anhydride, from which it is regenerated by the action of water; it cannot be converted into the para-acid by heating with hydrochloric acid.

Ethyl allylpropenyltricarboxylate is prepared from ethyl propenyltricarboxalate, allyl iodide, and sodium, and is hydrolysed with potash; on acidifying the solution, allylmethyltricarboxylic acid is obtained; it melts at 140°, and, when heated at 150°, yields two allylmethylsuccinic acids. *Parallylmethylsuccinic acid* melts at 147—148°, crystallises in prisms, is sparingly soluble in water, and when heated at 170°, yields the anhydride, which is converted by water into the meso-acid. The silver, copper, barium, and calcium salts are described. *Mesoallylmethylsuccinic acid*, melts at 86—87°, crystallises in small needles, and dissolves in 27 parts of water. E. C. R.

Dimethylracemic Acid. By C. Böttinger (*Ber.*, **25**, 397—398).—The author confirms Zelinsky's observation (this vol., p. 430) that the acid obtained by him from pyruvic acid is identical with Fittig, Daimler, and Keller's dimethylracemic acid (Abstr., 1889, 491); the following is an improved method of preparing it. Pyruvic acid (10 c.c.) is dissolved in absolute alcohol (140 c.c.) and allowed to remain at the ordinary temperature for three days in contact with freshly prepared granulated zinc; the liquid is then poured off, and after drying the zinc, the coating of salt is mechanically removed, dissolved in water, treated with hydrogen sulphide, the solution evaporated, and the residue converted into the ammonium salt, from the aqueous solution of which, on adding calcium chloride, calcium dimethylracemate (0·9 gram) separates. The acid prepared from the latter salt contains 1 mol. H_2O, and melts at 177—178°; its further investigation is being carried on by Fittig. A. R. L.

New Method of Preparing Aliphatic Hydroxamic Acids. By A. Miolati (*Ber.*, **25**, 699—701).—Aliphatic hydroxamic acids are obtained when dry hydroxylamine hydrochloride is boiled in a reflux apparatus with an acid anhydride (rather more than 2 mols.) for about an hour; the cold solution is neutralised with sodium carbonate, excess of copper acetate added, and the basic copper salt which separates is dried, suspended in alcohol, and decomposed by a current of hydrogen sulphide; the hydroxamic acid is isolated from the alcoholic filtrate by evaporation. As the solution, before being neutralised by sodium carbonate, does not give a precipitate with

copper acetate, it seems probable that it then contains (in the case of the acetic derivative) the compound OAc·CMe:NOH (compare next abstract). The author obtained C. Hoffmann's acetohydroxamic acid (Abstr., 1890, 127), and *propionohydroxamic acid*,

$$CH_2Me{\cdot}C(OH){:}NOH,$$

by this method; the latter forms transparent prisms, melts at 85°, and is insoluble in ether and benzene, but readily soluble in water and alcohol. *Formohydroxamic acid*, OH·CH:NOH, is prepared by boiling anhydrous formic acid with hydroxylamine hydrochloride. A detailed description of several of these compounds will appear later in the *Gazzetta*. A. R. L.

Action of Hydroxylamine on Chloral. By A. Hantzsch (*Ber.*, **25**, 701—705; compare Naegeli, Abstr., 1883, 728; V. Meyer, Abstr., 1891, 1181).—The additive compound, *chloralhydroxylamine*, $OH{\cdot}CH(CCl_3){:}NH{\cdot}OH$, is obtained by triturating chloral hydrate and sodium carbonate (1 mol. of each) with hydroxylamine hydrochloride (1 mol.), dissolving the mass in a little water, extracting with ether, and crystallising the crude substance from benzene or chloroform; when pure, it forms lustrous scales, melts at 98°, is readily soluble in ether and alcohol, less so in water, and is odourless. It gives no precipitate with silver nitrate, decomposes into trichloraldoxime, hydroxylamine hydrochloride, and other compounds on keeping, gives chloroform when heated with alkalis, and when its aqueous solution is evaporated, chloral is volatilised and hydroxylamine hydrochloride remains; the latter is also precipitated from an ethereal solution of the compound by hydrogen chloride or acetic chloride. *Diacetohydroxamic acid*, OH·CMe:NOAc, is formed when the compound is dissolved in acetic anhydride, and the solution evaporated in a vacuum; it crystallises in white needles, melts at 89°, and dissolves readily in water, forming a solution which only gives a precipitate with copper acetate and a dark-red coloration with ferric chloride when heated with these reagents, due to its decomposition into acetohydroxamic acid (compare preceding abstract). A. R. L.

Oximidoacetic Acid. By C. Cramer (*Ber.*, **25**, 713—721).—*Oximidoacetic acid*, NOH:CH·COOH, is obtained when crude, syrupy glyoxylic acid, prepared by heating dibromoacetic acid at 140° with water, and evaporating the product on a water-bath, is mixed with a concentrated solution of hydroxylamine hydrochloride, and the mixture extracted, after a time, with ether. It crystallises from alcohol in colourless needles containing 1 mol. H_2O; the crystals effloresce over concentrated sulphuric acid, and the anhydrous substance thus produced melts at 137—138° with decomposition; it is readily soluble in water and alcohol, less so in ether, and insoluble in cold benzene. Its aqueous solution decomposes into water, carbonic anhydride, and hydrogen cyanide, when heated at 120°; on boiling it with barium hydroxide, barium carbonate is formed, but it is not decomposed by hot concentrated hydrochloric acid. The solution neutralised with ammonia gives, with silver and mercurous nitrates, white precipitates,

but not with lead, calcium, and barium salts. Experiments to determine if the acid exists in stereoisomeric forms yielded negative results. When dry hydrogen chloride is passed through an ethereal solution of the acid, it is unaltered, as also when it is dissolved in acetic chloride; on gently warming it with acetic anhydride, it dissolves, but the product could not be purified.

Ethyl oximidoacetate, NOH:CH·COOEt, prepared by heating the silver salt with ethyl iodide, is a heavy oil, which commences to decompose a little above 100°, and is easily soluble in alcohol, ether, and benzene; water also dissolves it, and it is readily hydrolysed by alkalis. These characteristics and a direct comparison have proved that it is not identical with the compound obtained by Pröpper from ethyl acetoacetate and nitric acid (*Annalen*, **222**, 48), and attempts to convert one into the other by treatment with hydrogen chloride in ethereal solution were unsuccessful. When fuming nitric acid is added to ethyl oximidoacetate, Pröpper's compound is obtained; it has the constitution $\begin{matrix}\mathrm{COOEt\cdot C{:}N\cdot O}\\ \mathrm{COOEt\cdot C{:}N\cdot O}\end{matrix}$, and is, consequently, produced from 2 mols. of the oximidoacetate with the elimination of 2 mols. H_2O; the sodium and ammonium derivatives described by him are additive compounds of this with the respective hydroxides. The compound obtained by Pröpper from ethyl chloracetoacetate is, as described by him, ethyl chloroximidoacetate. A. R. L.

Imidosulphonic Acids. By F. Krafft and E. Bourgeois (*Ber.*, **25**, 472—477).—Imidosulphonic acids may be prepared by the condensation of amidosulphonic acid with organic substances.

Amidosulphonic acid, $NH_2\cdot SO_3H$, is prepared by saturating a concentrated solution of hydroxylamine hydrochloride with sulphurous anhydride, and keeping the solution saturated for two or three days by means of a slow current of the same gas. It is purified by crystallisation from slightly warm water, but is easily converted, by heating with water, into acid ammonium sulphate, as it is also by heating in damp air at 130—140°. The *barium* salt is characteristic, and is obtained by cautiously digesting the acid solution with barium carbonate, and concentrating the filtrate in a vacuum with the aid of a gentle heat, or it may be obtained in slender, lustrous needles, by adding alcohol to the aqueous solution. Amidosulphonic acid combines with alcohols to form ammonium alkyl sulphates.

Ammonium ethyl sulphate is obtained when finely-powdered amidosulphonic acid is dissolved in absolute alcohol by gently boiling the mixture for three or four hours. It forms colourless, transparent crystals, is very hygroscopic, dissolves easily in water, more sparingly in absolute alcohol, is insoluble in dry ether, and absorbs water from wet ether to form oily drops. It gives up its water over sulphuric acid, and when dry melts at 99°. The dry salt decomposes above its melting point into acid ammonium sulphate and ethylene, and at 210—220° the latter is evolved in a regular stream.

Ammonium methyl sulphate, obtained in a similar way, forms hygroscopic leaflets, melts at 135°, and is precipitated from its solution in methyl alcohol by ether.

Ammonium isobutyl sulphate is precipitated by ether, forms colourless, slightly hygroscopic leaflets, and melts at 215° with evolution of isobutylene.

Benzenylimidosulphonic acid, $CH{\cdot}Ph{:}N{\cdot}SO_3H$, is obtained by heating amidosulphonic acid (5 parts) with pure benzal chloride (8·5 parts) in an oil-bath at 110°, heating the condensation product thus formed at 125—130° under 100 mm. pressure, then under 15 mm. pressure, and, finally, at 140—150°. It is obtained as a solid, yellow mass, which slowly absorbs moisture from the air, and decomposes. When obtained in this way, it is mixed with 2·5 per cent. of chloride and a small quantity of acid ammonium sulphate and resin, but cannot be further purified. It is easily decomposed by water at 0°, and forms benzaldehyde and amidosulphonic acid.

A similar decomposition is observed in the case of the compound of the empirical formula $(MeCN)_2,SO_3,H_2O$, obtained by treating acetonitrile with fuming sulphuric acid, and which decomposes in damp air yielding diacetamide and amidosulphonic acid.

A dimethylmethylenimidosulphonic acid, $CMe_2{:}N{\cdot}SO_3H$, is obtained as a crystalline precipitate on passing a current of sulphurous anhydride into an alcoholic solution of acetoxime. When warmed with water, it is decomposed into acetone and amidosulphonic acid.

E. C. R.

Alkyl Derivatives of Isosuccinimide. By W. J. Comstock and H. L. Wheeler (*Amer. Chem. J.*, **13**, 520—525).—When silver succinimide is treated with alkyl iodides, alkyl succinimides are obtained, which are isomeric with those of the class represented by the ethylsuccinimide prepared by Landsberg from sodium succinimide (Abstr., 1883, 477), and are distinguished from them by yielding a succinamidine when treated with aniline (compare Menschutkin, *Annalen*, **162**, 170; Comstock and Kleeberg, Abstr., 1890, 1414). *Ethylisosuccinimide*, $\begin{matrix}CH_2\text{——}CO\\ |\\ CH_2{\cdot}C(OEt)\end{matrix}\!\!>\!N$, is formed, together with a small amount of ethylsuccinimide, $\begin{matrix}CH_2{\cdot}CO\\ |\\ CH_2{\cdot}CO\end{matrix}\!\!>\!NEt$, when dry silver succinimide (1 mol.) is digested with ethyl iodide (1 mol.) in chloroform solution (2 or 3 vols.) for several weeks at the ordinary temperature. On purification, it is obtained as a colourless oil, boiling with slight decomposition at 144—146° under a pressure of 20 mm. It reacts with aniline to form phenylsuccinamidine (see below), and is reconverted into succinimide by exposure to moist air. *Propylisosuccinimide* is prepared in a similar manner. It boils at 153—154° under a pressure of 19 mm., and reacts in a similar way with aniline. A small amount of *propylsuccinimide*, $\begin{matrix}CH_2{\cdot}CO\\ |\\ CH_2{\cdot}CO\end{matrix}\!\!>\!NPr^{\alpha}$, is likewise formed at the same time, but the latter is best prepared by distilling hydrogen propylamine succinate, after Menschutkin's method of preparing the methyl and ethyl compounds. It is a colourless oil, which boils at 247—248° under 763 mm. pressure, at 136—137° under 20 mm. pressure, and solidifies at 15—16°. It does not react with aniline.

Succinimide thus resembles formanilide and other formyl derivatives of aromatic amines in the behaviour of its silver and sodium derivatives with alkyl iodides (this vol., p. 707); but the assumption that silver and sodium succinimides are different in constitution is hardly tenable in this case, seeing that both normal and iso-succinimides can be obtained from the former salt, and that it is hardly likely that a tautomeric change would take place at the ordinary temperature.

Phenylsuccinamidine, $\begin{matrix}CH_2\text{———}CO\\ |\\ CH_2\cdot C(NHPh)\end{matrix}\!\!>\!N$, is formed by adding aniline to either of the above isosuccinimide derivatives. It is soluble in hot alcohol, crystallises from that solvent in small, transparent, quadrilateral plates, and melts at 216°. The *aurochloride* forms a voluminous precipitate of sulphur-yellow, microscopic needles when prepared in the cold, but crystallises in gold-coloured prisms when allowed to separate from a hot solution. It melts with decomposition at 170°. Jn. W.

Thiocarbamides, Cyanocarbamides, and Cyanothiocarbamides. By O. Hecht (*Ber.*, **25**, 813—823; compare Abstr., 1891, 476 and 1103).—*Symmetrical methylisobutylthiocarbamide*,

$$NHMe\cdot CS\cdot NH\cdot C_4H_9,$$

is prepared from isobutylamine and methylthiocarbimide; it crystallises from water in colourless, lustrous plates, melts at 77·5°, and is extremely soluble in acetone or chloroform. *Symmetrical ethylisobutylthiocarbamide*, $NHEt\cdot CS\cdot NH\cdot C_4H_9$, melts at 77·5°, and is obtained in a manner similar to the preceding compound, which it closely resembles. *Symmetrical allylisobutylthiocarbamide*,

$$C_3H_5\cdot NH\cdot CS\cdot NH\cdot C_4H_9,$$

prepared from allylthiocarbimide and isobutylamine, is somewhat unstable, and crystallises with difficulty; it melts at 28·5°. *Symmetrical isobutylphenylthiocarbamide*, $C_4H_9\cdot NH\cdot CS\cdot NHPh$, formed from isobutylamine and phenylthiocarbimide, crystallises from water in colourless needles, and melts at 82°.

Symmetrical propylpentenethiocarbamide, $C_3H_7\cdot NH\cdot CS\cdot N{:}C_5H_{10}$, is prepared from propylthiocarbimide and piperidine; it crystallises from alcohol in tetragonal pyramids, $a : c = 1 : 0{\cdot}5488$, melts at 75°, and reacts with mercuric oxide and ammoniacal silver solution on warming. A more sparingly soluble bye-product is obtained in the preparation of the carbamide; it contains 27 per cent. of sulphur, crystallises from alcohol in small, lustrous plates, and melts at 167° with decomposition. The observations of Dixon (Trans., 1891, 551) and of Salkowski (Abstr., 1891, 1474) on the thiocarbamide derivatives of benzylamine and benzylthiocarbimide are confirmed. Symmetrical ethylbenzylthiocarbamide may be prepared from benzylthiocarbimide and ethylamine, whilst symmetrical allylbenzylthiocarbamide, $C_3H_5\cdot NH\cdot CS\cdot NH\cdot C_7H_7$, is formed by the mutual action of allylthiocarbimide and benzylamine.

Ethylcarbamine cuprocyamide, $[NHEt\cdot CO\cdot N(CN)]_2Cu + 5H_2O$, is

prepared from the corresponding sodium salt by the addition of cupric sulphate, and is already known. *Allylcarbaminesodiocyamide*, $C_3H_5{\cdot}NH{\cdot}CONa{\cdot}CN$, is prepared by adding allyl isocyanate to sodium cyanamide in absolute alcohol; it is amorphous, and melts at 246° with decomposition. The *cupro-derivative*,

$$C_3H_5{\cdot}NH{\cdot}CO{\cdot}N(CN){\cdot}Cu{\cdot}OH,$$

is precipitated as a green powder on the addition of cupric sulphate solution to the preceding compound.

Phenylthiocarbamineisobutylcyamide, $NHPh{\cdot}CS{\cdot}N(CN){\cdot}C_4H_9$, is obtained by heating phenylthiocarbaminesodiocyamide, from phenylthiocarbimide and sodium cyanamide, with isobutyl iodide; it crystallises from alcohol in colourless, slender needles, and melts at 139°; the compound is not decomposed by heating with mercuric oxide or silver nitrate. J. B. T.

Thiobiurets. By O. Hecht (*Ber.*, **25**, 749—758).—Thiobiuret, $C_2H_5N_3OS$, was first obtained by Wunderlich (Abstr., 1886, 435), and is prepared by digesting silver cyanocarbamide (1 mol.) with an aqueous solution of sodium chlorate (1 mol.), filtering, adding an equivalent quantity of ammonium chloride and ammonia, and passing hydrogen sulphide through the boiling solution, the ammonia being from time to time renewed; the compound separates from the filtrate in long, stout, transparent needles, containing 1 mol. H_2O, and when dried at 100° is anhydrous and melts at 186°; it is readily soluble in alcohol, sparingly in chloroform, slightly in ether, and insoluble in light petroleum. The yield is small.

α-Methylthiobiuret, $NHMe{\cdot}CO{\cdot}NH{\cdot}CS{\cdot}NH_2$, is obtained in small quantity by mixing methylcarbimide with sodium cyanamide in molecular proportion, when the additive compound $NHMe{\cdot}CO{\cdot}NNa{\cdot}CN$ is formed, dissolving this in water, and treating it as above described with ammonium chloride, ammonia, and hydrogen sulphide; it forms lustrous needles, melts at 194° with decomposition, has a very bitter taste, and resembles the ethyl derivative (see below) in solubility and reactions.

α-Ethylthiobiuret, $NHEt{\cdot}CO{\cdot}NH{\cdot}CS{\cdot}NH_2$, is prepared from ethylcarbimide in a manner similar to the methyl compound; the yield is 60 per cent. of the theoretical; it crystallises in long, thin, transparent prisms, melts at 184° with the evolution of gas, has a very bitter taste, and is readily soluble in alcohol and hot water, very sparingly in ether, and insoluble in light petroleum. It dissolves in ammonia and in hydrochloric acid; its aqueous solutions give with copper sulphate a white precipitate, dissolving in potassium hydroxide to a red solution, from which sulphur separates on heating; with ammoniacal silver nitrate in the cold, and with mercuric oxide on heating, it gives precipitates of the sulphides, but it only reacts slowly and partially when heated with alkaline lead salts; silver nitrate, mercuric chloride, and lead acetate give white precipitates.

α-Methyldithiobiuret, $NHMe{\cdot}CS{\cdot}NH{\cdot}CS{\cdot}NH_2$, is produced by mixing an alcoholic solution of cyanamide (6 grams) and sodium (3·3 grams) with methylthiocarbimide (10·6 grams), evaporating the alcohol,

dissolving in water, and treating the solution with ammonium chloride, ammonia, and hydrogen sulphide. It crystallises from water in colourless, delicate, silky needles, melts at 153° with decomposition. tastes bitter, and gives the biuret reaction with copper sulphate and alkali.

α-Ethyldithiobiuret, $NHEt{\cdot}CS{\cdot}NH{\cdot}CS{\cdot}NH_2$, is obtained from ethylthiocarbimide, the yield being 59 per cent. of the theoretical; it crystallises in lustrous, white needles, melts at 175° with decomposition, and is very sparingly soluble in cold water; its aqueous and alcoholic solutions give the biuret reaction.

α-Propyldithiobiuret, $NHPr^{\alpha}{\cdot}CS{\cdot}NH{\cdot}CS{\cdot}NH_2$, prepared from propylthiocarbimide, is a white, crystalline powder, and melts at 121° without decomposition.

α-Allyldithiobiuret, $C_3H_5NH{\cdot}CS{\cdot}NH{\cdot}CS{\cdot}NH_2$, is prepared from allylthiocarbimide; it crystallises in small needles and melts at 138°.

α-Phenyldithiobiuret, $NHPh{\cdot}CS{\cdot}NH{\cdot}CS{\cdot}NH_2$, has been prepared by Wunderlich, and is obtained from phenylthiocarbimide; it melts at 174° with decomposition, and differs principally from the aliphatic analogues in having less affinity for combining with acid.

A. R. L.

Metadinitrobenzene. By C. Willgerodt (*Ber.*, **25**, 608—609).—When metadinitrobenzene is treated with alcoholic stannous chloride, or boiled with zinc-dust in alcoholic solution, it yields the symmetrical metadinitroazoxybenzene previously obtained by Klinger and Pitschke (Abstr., 1886, 53). It is almost white when pure, melts at 145°, and dissolves in nearly all organic solvents.

Metadinitrobenzene gives no coloration with alkalis when free from dinitrothiophen; the latter may be separated by dissolving in alcohol, warming with an excess of soda, precipitating with water, washing the precipitate until almost colourless, and recrystallising from alcohol. It is then almost white, melts at 91° (uncorr.), and, as stated before, gives no coloration with alkalis; with acetone in alkaline solution, it still gives the beautiful, violet coloration observed by Janovsky (Abstr., 1891, 685). H. G. C.

Reduction of Metabromonitrophenol. By F. W. Schlieper (*Ber.*, **25**, 552—555).—Metabromonitrophenol is prepared by treating finely-powdered nitrophenol with twice the theoretical quantity of bromine for several days at the ordinary temperature; the product is washed with water, crystallised several times from concentrated hydrochloric acid, and finally from a mixture of benzene and light petroleum; it melts at 147—148°, not at 110°, as stated by Pfaff. By the action of stannous chloride (5·5 grams) on the phenol (1·3 grams), metamidophenol is obtained together with bromamidophenol, the relative quantities depending on the proportion of stannous chloride employed and on experimental conditions.

Bromonitrophenetoïl may be prepared by the mutual action of bromonitrophenol, sodium ethoxide, and ethyl iodide; on reduction, it also yields ethoxyamidobenzene [1 : 3] as chief product, together with some of the corresponding bromo-derivative.

The above results reconcile the contradictory statements of Pfaff and Lindner on this subject. J. B. T.

Amidine Picrates. By W. Dieckmann (*Ber.*, **25**, 546—547).—*Formamidine picrate*, $NH{:}CH{\cdot}NH_2,C_6H_2(NO_2)_3{\cdot}OH$, is obtained by adding formamidine hydrochloride to picric acid in aqueous solution, and crystallises in long, lustrous, yellow needles melting at 248°. *Acetamidine picrate*, $NH{:}CMe{\cdot}NH_2,C_6H_2(NO_2)_3{\cdot}OH$, is deposited in long, flat needles or in lustrous scales, and melts at 245°. *Benzenylamidine picrate* crystallises in yellow needles melting at 228°.

J. B. T.

Conversion of Aromatic Amines into Chlorine Derivatives of the Hydrocarbons. By Prud'homme and C. Rabaut (*Compt. rend.*, **114**, 362—364).—Sandmeyer has shown that when the chlorides of the diazo-compounds formed by the amines of the benzene series are heated with an acid solution of cuprous chloride, they yield chloroderivatives of the corresponding hydrocarbons, and Möhlau showed that nitrates of the amines are directly converted into diazo-derivatives by the action of zinc powder and hydrochloric acid. The authors find that these two reactions can be combined by treating the nitrates of the amines with a solution of cuprous chloride.

When aniline nitrate is heated with a hydrochloric acid solution of cuprous chloride, nitrogen oxides are evolved, and the liquid when distilled yields chlorobenzene boiling at 132°, and paradichlorobenzene melting at 55° and boiling at 173°.

Cupric chloride yields no dichlorobenzene by its action on diazobenzene chloride. It converts the latter partially into monochlorobenzene. Chromic and ferric chlorides behave similarly. It follows that the production of dichlorobenzene must be attributed to the formation of paraphenylenediamine and its diazo-derivative during the reduction of the aniline nitrate.

Cuprous chloride in this reaction may be replaced by chromous chloride, but not by ferrous or stannous chloride. C. H. B.

Anilides, Isoanilides, and their Analogues. By W. J. Comstock and H. L. Wheeler (*Amer. Chem. J.*, **13**, 514—520).—The sodium and silver salts of form-α-naphthalide react in the same manner with methyl iodide as salts of other aromatic formyl compounds. *Silver form-α-naphthalide* (compare Gattermann, Abstr., 1890, 1112) separates as a voluminous, grey precipitate on gradually adding silver nitrate (1 mol.) in 50 per cent. alcoholic solution to an aqueous alcoholic solution of form-α-naphthalide (1 mol.) and sodium hydroxide. It is sensitive to light. *Methylisoform-α-naphthalide*, $C_{10}H_7{\cdot}N{:}CH{\cdot}OMe$, is obtained as a heavy oil by treating the dry silver salt with a solution of methyl iodide in dry ether. It has a fishy odour, and boils with decomposition at 306—308° under atmospheric pressure. Its behaviour towards water, dilute acids, and primary amines is similar to that of methylisoformanilide (Abstr., 1890, 1258 and 1414).

Gattermann (*loc. cit.*) having found two apparently tautomeric

modifications of nitroparacetoluidide, it was deemed likely that nitroformanilide might also exist in two such modifications, inasmuch as the sodium and silver salts behave towards methyl iodide as if they have the structures $NO_2 \cdot C_6H_4 \cdot NNa \cdot CHO$ and $NO_2 \cdot C_6H_4 \cdot N:CH \cdot OAg$ respectively. Both salts, however, yielded nitroformanilides identical n melting point and microscopic appearance. *Metanitroformanilide* is prepared by boiling metanitraniline with excess of anhydrous formic acid, and then adding water and recrystallising from hot water, alcohol, or benzene. It is sparingly soluble also in ether and light petroleum, forms microscopic tufts of hair-like, bent needles, and melts at 134°. *Sodium metanitroformanilide* is prepared by adding sodium methoxide, made from sodium (1 mol.) and dry methyl alcohol, to a pasty mixture of the nitroformanilide and methyl alcohol. It is readily soluble in methyl alcohol, but insoluble in dry ether, and, when thoroughly washed with the latter, is a lemon-yellow solid, but when crystallised from the former forms orange needles, and contains 1 mol. of alcohol of crystallisation. It is reconverted by water or carbonic anhydride into the nitroformanilide. *Methylmetanitroformanilide* is prepared by heating sodium metanitroformanilide with methyl iodide in a reflux apparatus or sealed tube (100°), until the mixture no longer shows an alkaline reaction. Carbonic anhydride and air must be excluded. It crystallises from alcohol in long, yellowish needles, and melts at 70—71°. The methyl metanitraniline prepared from the anilide melted at 67°, and its nitrosamine at 76° (compare Nölting and Strecker, Abstr., 1886, 544). *Silver metanitroformanilide* is prepared in the same manner as silver formanilide (Abstr., 1890, 1258 and 1414). It is a colourless, amorphous solid, insoluble in hot water. *Methylmetanitroisoformanilide* is prepared by treating the dry silver salt with methyl iodide in ethereal solution. It crystallises in long, slender, pale-yellow needles, melts at 45°, and boils at 172—173° under a pressure of 21 mm. It is converted by dilute hydrochloric acid into metanitraniline hydrochloride.

The isoanilides react with aliphatic and aromatic secondary amines to form formamidines. *Di-α-naphthylformamidine*,

$$C_{10}H_7 \cdot N:CH \cdot NH \cdot C_{10}H_7,$$

is prepared by heating methylisoform-α-naphthalide with α-naphthylamine, and recrystallising the product from hot benzene. It crystallises in colourless plates, melts at 199°, dissolves in alcohol, ether, and benzene, but is insoluble in light petroleum and cold dilute mineral acids. *Phenyl-α-naphthylformamidine*, $C_{10}H_7 \cdot N:CH \cdot NHPh$, is prepared by treating methylisoform-α-naphthalide with aniline, and precipitating the benzene solution of the product with light petroleum. It melts at 142°, and is soluble in alcohol, ether, and benzene, but only sparingly in light petroleum. Its basic properties are much more strongly marked than those of the dinaphthyl compound. *Metadinitrodiphenylformamidine*, $NO_2 \cdot C_6H_4 \cdot N:CH \cdot NH \cdot C_6H_4 \cdot NO_2$, is prepared by slowly heating a mixture of methylmetanitroisoformanilide (1 mol.) and metanitraniline (1 mol.) to 110°, and recrystallising the solid product from alcohol. It forms small, yellow, hair-like needles,

melts at 195—196°, dissolves in alcohol, ether, chloroform, and acetone, but is insoluble in light petroleum. *Metanitrodiphenylformamidine*, $NO_2 \cdot C_6H_4 \cdot N{:}CH \cdot NHPh$, is prepared by mixing methylmetanitroisoformanilide (1 mol.) with aniline (1 mol.), and recrystallising the solid product from absolute alcohol. It crystallises in long, yellow prisms, and melts at 145°.

Diethylphenylformamidine, $NPh{:}CH \cdot NEt_2$, is prepared by boiling methylisoformanilide with a slight excess of diethylamine, in a reflux apparatus, for two hours. It is a colourless oil, boiling, with partial decomposition, at 273—275° under atmospheric pressure. The *aurochloride*, $C_{11}H_{16}N_2,HAuCl_4$, may be crystallised in small, lemon-yellow plates, by adding water to the alcoholic solution. It melts at 147°.

Methyldiphenylformamidine, $CHNPh{:}CH \cdot NMePh$, is prepared by distilling a mixture of methylaniline and methylisoformanilide which has been kept for some days at the ordinary temperature, and heated on the water-bath for a short time previous to the distillation. It is a heavy, yellowish oil, boiling at 214° under 22 mm. pressure. The *aurochloride* may be crystallised in gold-coloured plates by adding water to the alcoholic solution; it melts at 145°.

The isoanilides also react with cyanamide to form cyanogen derivatives of the formamidines. *Cyanophenylformamidine*,

$$NPh{:}CH \cdot NH \cdot CN,$$

separates as a crystalline crust when an ethereal solution of cyanamide and methylisoformanilide is kept for 24 hours at the ordinary temperature. It is insoluble in ether, but soluble in alcohol and water, crystallising from the former in long needles, and from the latter in long, flat, colourless prisms; it melts at 138°. *Cyanoparatolylformamidine*, $C_6H_4Me \cdot N{:}CH \cdot NH \cdot CN$, is prepared from cyanamide and methylisoformanilide in a similar way; it crystallises from alcohol in long prisms, and melts at 176—177°. Jn. W.

Derivatives of Aromatic Formyl Compounds. By W. J. Comstock and R. R. Clapp (*Amer. Chem. J.*, **13**, 525—528).—The sodium and silver derivatives of formorthotoluidide and formoparatoluidide, like those of formanilide (Comstock and Kleeberg, Abstr., 1890, 1414), yield methyl derivatives having different constitutions, the methyl in the first case being linked to nitrogen, in the other through oxygen to carbon. To complete the parallel, the toluidides prepared by various methods from the metallic derivatives were found to be identical, the isomerism thus existing only in the alkyl derivatives.

Silverformorthotoluidide and *formoparatoluidide*, $C_6H_4Me \cdot N{:}CH \cdot OAg$, are prepared in the same way as the formanilide (preceding abstract); the ortho-compound is amorphous, the para-compound crystalline (small needles), and both are insoluble in cold water, and sensitive to light. The methyl derivatives are prepared in the same way as the methyl formanilides (*loc. cit.*). *Methylisoformorthotoluidide*,

$$C_6H_4Me \cdot N{:}CH \cdot OMe,$$

is an oil boiling at 211—213° under 760 mm. pressure, and having an

aromatic odour. *Methylisoformoparatoluidide* is a similar oil, boiling at 216—218° under 761 mm. pressure. The amidines are prepared from the methyltoluidides by means of the toluidines, in the manner previously described (*loc. cit.*), thus proving the oxygen linkage of the methyl groups. Diorthotolylformamidine,

$$C_6H_4Me\cdot NH\cdot CH{:}N\cdot C_6H_4Me,$$

prepared also by Ladenburg (Abstr., 1878, 54) and Senier (Trans., 1885, 762), melts at 150°, and is soluble in alcohol. Diparatolylformamidine, also prepared by Senier (*loc. cit.*), crystallises from benzene in large, flat, transparent, colourless prisms, and melts at 140°.

The sodium formotoluidides may be converted into the corresponding methyltoluidines by treatment with methyl iodide and sodium methoxide in the presence of dry methyl alcohol, or after Hepp's method for the preparation of methylaniline (*Ber.*, **10**, 328).

Other formanilide derivatives have also been prepared. *Ethylisoformanilide*, NPh:CH·OEt, is an oil boiling at 213—215° under 761 mm. pressure, and having an aromatic odour. *Propylisoformanilide* boils at 233—235° under 760 mm. pressure. *Phenylbenzylformamidine* is formed when a mixture of benzylamine (1 mol.) and methylisoanilide (1 mol.) is kept for some time; the solid product is pressed free from oil, dissolved in alcohol, and reprecipitated, eventually in crystalline form, by water. It forms colourless, transparent, flat prisms, and melts at 80°. *Phenylhydroxyformamidine*, OH·NH·CH:NPh, is obtained as a white solid by adding methyl isoformanilide to an aqueous alcoholic solution of hydroxylamine hydrochloride. When purified by solution in alcohol and reprecipitation with ammonia, it crystallises in small, white needles, and melts at 130—131°. When dry silver formorthotoluidide is distilled, diorthotolylcarbamide (m. p. 247°) is formed. Jn. W.

Acetoacetanilide. By L. Knorr (*Ber.*, **25**, 775—778).—*β-Amidocrotonanilide*, $NH_2\cdot CMe{:}CH\cdot CONHPh$, is prepared by treatment of acetoacetanilide in concentrated alcoholic solution with ammonia; it crystallises from dilute alcohol, and melts at 145°. The methylamido-derivative has been previously described (compare preceding abstract). *β-Dimethylamidocrotonanilide*, $NMe_2\cdot CMe{:}CH\cdot CO\cdot NHPh$, is obtained in a similar manner to the amido-compound, and crystallises from alcohol in small needles melting at 160°.

Acetoacetanilide also yields a phenylhydrazone melting at 108·5°, and an oxime melting at 115°, which will be described later; with hydrazine hydrate, methylpyrazolone (m. p. 215°) is formed.

The preceding amido-compounds are very unstable, and are resolved into their components by boiling with water, or by the action of acids; it was therefore impossible to determine their constitution; the formulæ given are derived by analogy from the dimethylamido-derivative. J. B. T.

β-Methylamidocrotonanilide. By L. Knorr and H. Taufkirch (*Ber.*, **25**, 768—775; compare Brühl, this vol., p. 730).—

Brühl's "antipyrine alcohol" appears to be *β-methylamidocrotonanilide*, NHMe·CMe:CH·CO·NHPh, since a compound identical with the alcohol is formed by the action of methylamine on acetoacetanilide in concentrated alcoholic solution. On hydrolysis, the compound is resolved quantitatively into its constituents, whilst antipyrine alcohol would probably yield symmetrical methylphenylhydrazine. The production of β-methylamidocrotonanilide by the reduction of antipyrine affords an additional proof of the correctness of Knorr's formula, $NPh<\begin{matrix}NMe\cdot CMe\\ \|\\ CO—CH\end{matrix}$, for the latter compound, and is analogous to the decomposition of phenylpyrazole by the action of sodium in alcoholic solution.

The authors suggest that the compound supposed by Brühl to be a sodium salt of antipyrine alcohol is really a complicated carbamate, COONa·NPh·CO·CH:CMe·NMe·COONa, which is decomposed by water into sodium carbonate and methylamidocrotonanilide.

J. B. T.

Colour Reaction of Acid Anilides. By J. Tafel (*Ber.*, **25**, 412—413).—When simple anilides, or phenylcarbamides, are dissolved in concentrated sulphuric acid and treated with potassium dichromate, lead dioxide, or ferric chloride, they give a colour resembling that exhibited by strychnine under similar circumstances. Such colours are also produced, according to Bülow (*Annalen*, **236**, 195), in the case of the acid phenylhydrazides, and according to De Neufville and v. Pechmann (Abstr., 1891, 349) in that of phenylhydrazones and phenylosazones. The colours from the anilides are less intense, and more fugitive, than those from the hydrazides and hydrazones, and the latter colours are not produced by ferric chloride. When the substance is dissolved in concentrated sulphuric acid and treated with pulverised potassium dichromate, the anilide and phenylhydrazide of the same acid give a like colour. The products of the action of acetic anhydride or benzoic chloride on ethylaniline and methylaniline, unlike the acetyl and benzoyl derivatives of tetrahydroquinoline, do not exhibit the reaction; further, acetylparatoluidine gives it, whilst acetylorthotoluidine does not. A list is given in the paper, showing the tint produced by several anilides.

A. R. L.

Derivatives of Orthotoluylenediamine. By W. Autenrieth and O. Hinsberg (*Ber.*, **25**, 604—607).—Orthotoluylenediamine is without action on mandelic acid and on benzalacetone, but readily combines with ethyl oxalacetate, forming *ethyl hydroxytoluquinoxalineacetate*, $C_7H_6<\begin{matrix}N:C\cdot OH\\ |\\ N:C\cdot CH_2\cdot COOEt\end{matrix}$, which has a yellow colour, melts at 172—173°, and behaves as a phenol. On long-continued boiling with aqueous soda, alcohol and carbonic anhydride are eliminated, hydroxymethyltoluquinoxaline being formed. Thus prepared, the latter melts at 217—218°, whilst, when obtained from pyruvic acid, it melts at 220° (*Annalen*, **237**, 351). As the latter appears to be a

mixture of two isomerides, the compound melting at 172—173° is also probably a mixture of two isomerides, which crystallise together.

When molecular quantities of ethyl chloracetoacetate and orthotoluylenediamine are allowed to remain together in alcoholic solution, a substance separates out in colourless crystals; it is purified by washing with alcohol, and has then the composition $C_{13}H_{17}N_2O_2Cl$, melts at 110°, is insoluble in water, readily soluble in alcohol and ether, and is resolved by acids and alkalis into the compounds from which it is obtained; it has, therefore, probably the constitution $C_7H_6<^{NH}_{NH}>CMe\cdot CHCl\cdot COOEt$, and is analogous to the compound obtained from orthotoluylenediamine and ethyl acetoacetate. This is confirmed by the fact that the dilute alcoholic solution, when boiled, decomposes into ethenyltoluylenediamine and ethyl chloracetate.

H. G. C.

Mixed (Fatty Aromatic) Azo-compounds. By L. Claisen (*Ber.*, **25**, 746—748).—The sodium derivative of benzeneazoacetylacetone (see Beyer and Claisen; Abstr., 1888, 828) reacts with diazobenzene chloride, forming a diazo-derivative, $CAc_2(N_2Ph)_2$, and a compound having the composition of an acetonedisazobenzene, $C_3H_4O(N_2Ph)_2$, identical with that obtained by the action of diazobenzene chloride on benzeneazoacetoacetaldehyde, and also with the mesoxaldehydebisphenylhydrazone described by Bamberger (this vol., p. 162).

A. R. L.

Action of Hydroxylamine on Paradiazotoluene and Diazobenzene Chlorides. By J. Mai (*Ber.*, **25**, 372—374).—E. Fischer, in 1878, obtained diazoimidobenzene by the action of diazobenzene sulphate on hydroxylamine hydrochloride in aqueous solution. The author finds that when paratoluidine (2 grams) is diazotised in the presence of hydrochloric acid, and to the cooled solution, one of hydroxylamine hydrochloride (3 grams) and potassium hydroxide (4 grams) is added, a mixture of nitrogen and nitrous oxide is evolved; on now acidifying and removing the precipitated oil with ether and adding alkali, paratoluidine separates. In a similar manner diazobenzene chloride yields aniline. He believes that an intermediate product is formed, and is now engaged in studying the reaction between β-methylhydroxylamine and paradiazotoluene chloride, in the hope of obtaining information as to the mechanism of the reaction.

A. R. L.

Acid Hydrazides. By J. Tafel (*Ber.*, **25**, 413—415).—*Acetyldiphenylhydrazine*, $NPh_2\cdot NHAc$, is obtained by boiling acetylphenylhydrazine (1 mol.) with copper acetate (2 mols.) in aqueous or alcoholic solution, preferably the latter; the compound is identical with that obtained by boiling diphenylhydrazine with glacial acetic acid; it forms bunches of lustrous needles, melts at 184°, distils undecomposed, and is sparingly soluble in ether and light petroleum, more readily in warm benzene and chloroform. It gives an intense violet colour on heating with dilute sulphuric acid and potassium dichromate, and dissolves in concentrated sulphuric acid with a green

colour, which on warming, or on the addition of an oxidising agent, passes into a beautiful blue; it yields a colouring matter when heated with concentrated hydrochloric acid and alcohol in a sealed tube at 100°.

Benzoyldiphenylhydrazide, identical with that described by E. Fischer (Abstr., 1878, 313), is obtained by boiling benzoylphenylhydrazine with copper acetate in alcoholic solution. A. R. L.

So-called Physically Isomeric Hydroxylamine Derivatives. By W. Lossen (*Ber.*, **25**, 433—442).—Further investigations carried out in the author's laboratory have proved that about 16 hydroxamic acid derivatives, in addition to the nine previously described (Abstr., 1889, 1064), exist in different modifications; Werner (this vol., p. 461) has discovered the existence of two, or perhaps three, new cases of the same kind. All the derivatives referred to, which have been prepared by the author and his pupils, are ethereal salts of hydroxamic acids, or alkylhydroxamic acids, or triacidyl derivatives of hydroxylamine; Werner has shown that ethereal salts of alkylhydroxamic acids also exist in different modifications.

Only three hydroxamic acid derivatives are known to exist in three different modifications, namely, tribenzhydroxylamine, benzanisobenzhydroxylamine, and ethyl paratolylbenzhydroxamate. The conversion of one modification into the other has been accomplished only in isolated cases; it has also been proved that, in the case of many hydroxamic acid derivatives, the different modifications have the same molecular weight, also that they differ from one another in chemical behaviour. A full description of the experiments here mentioned will be published in the *Annalen*.

The rest of the article consists of a severe criticism of some of Werner's experiments, and of the system of nomenclature suggested by him. F. S. K.

Action of Nitric Acid on Alkyl Phenylcarbamates. By P. van Romburgh (*Rec. Trav. Chim.*, **10**, 135—144).—Methyl phenylcarbamate prepared according to Hentschel's method (Abstr., 1885, 883) is dissolved in nitric acid (sp. gr. 1·46), and the mixture is poured into water; the yellowish-red product is purified by recrystallisation from alcohol and ether, or a purer yield is obtained by boiling methyl phenylcarbamate with nitric acid, since in the cold some trinitro-derivative is also formed. As thus obtained, the *dinitro*-derivative, $C_6H_3(NO_2)_2{\cdot}NH{\cdot}COOMe$, forms pale-yellow needles; it melts at 127°, dissolves in hot alcohol and ether, and in cold acetone, acetic acid, ethyl acetate, chloroform and benzene, but is only slightly soluble in carbon bisulphide and light petroleum. Neither potassium carbonate nor alcoholic ammonia reacts with this compound, and it is but slightly attacked by hydrochloric acid at 150°. Aqueous potash, after some days contact, converts it into dinitraniline melting at 175°, whence its probable constitution is $[NH : (NO_3)_2 = 1 : 2 : 4]$.

The trinitro-derivative $[NH : (NO_2)_3 = 1 : 2 : 4 : 6]$ is formed by dissolving the dinitro-derivative in nitric acid (sp. gr. 1·5), or by adding a solution of methyl phenylcarbamate in 5 parts of sulphuric acid

to fuming nitric acid. Either of these solutions is poured into water, and the yellow product on recrystallisation from alcohol forms needles or plates which melt at 192°. Hentschel (Abstr., 1887, 143) claims to have similarly obtained a tetranitrodiphenylcarbamide; the author, however, identifies the product with his own methyl trinitrophenylcarbamate. This substance dissolves in the same media as the dinitro-derivative, from which it differs in yielding picramide (m. p. 188°) when left in contact with alcoholic ammonia for some days, and on heating with hydrochloric acid at 150° for some hours, carbonic anhydride, chloroform, and picramide are produced. This trinitro-derivative dissolves in potassium hydroxide solution, and decomposes potassium carbonate forming a crystalline salt, $C_9H_7KN_4O_8$; with silver nitrate, it yields a silver salt, which reacts with methyl iodide to form a crystalline methyl derivative. A yellow, crystalline compound, $C_9H_8N_4O_8 + NHMe_2$, of the trinitro-derivative with dimethylamine has been prepared melting at 138° with decomposition.

From ethyl phenylcarbamate corresponding derivatives are similarly prepared. Ethyl dinitrophenylcarbamate has previously been described by Hager (Abstr., 1885, 149). It crystallises from boiling alcohol in clear, yellow needles, melts at 110°, and affords the same dinitraniline as the methyl derivative when left in contact with dilute aqueous potash.

Ethyl trinitrophenylcarbamate forms yellowish-white plates, melts at 144°, is somewhat more soluble than the methyl derivative, but yields the same decomposition products, as also a compound with dimethylamine, and a silver salt which reacts easily with methyl iodide. T. G. N.

Diparatoluamide and Diorthotoluamide. By F. Krafft and H. Karstens (*Ber.*, **25**, 452—460; compare Abstr., 1890, 1289). —*Imidodiparatoluamide*, $C_6H_4Me{\cdot}C(NH){\cdot}NH{\cdot}CO{\cdot}C_6H_4Me$, is precipitated in colourless needles when paratolunitrile is treated with anhydrosulphuric acid in the cold, the product extracted with a large quantity of cold water, and the filtered aqueous extract treated with ammonia; it can be recrystallised from warm alcohol without undergoing any notable decomposition, and then melts at 145°.

Diparatoluamide, $NH(CO{\cdot}C_6H_4Me)_2$, is deposited in lustrous needles when the aqueous extract just referred to is warmed for some time at about 70°; it melts at 155°, and on distillation, even under greatly reduced pressure, it is decomposed into paratolunitrile and paratoluic acid. It is only slowly decomposed by boiling water and very dilute acids, but when heated with water at about 140°, it is quickly converted into paratoluic acid and paratoluamide.

Imidodiorthotoluamide can be obtained by warming orthotolunitrile with anhydrosulphuric acid for some time at 60—70°, then extracting the product with a little cold water, and adding ammonia to the filtered extract; it crystallises from warm alcohol in small, lustrous prisms melting at 103°.

Diorthotoluamide is formed when the aqueous extract just mentioned is heated at 60—70° for some time; it separates from warm alcohol in slender crystals, and melts at 147—148°. It is decomposed

into orthotolunitrile and orthotoluic acid on distillation, but when heated with water, it gives orthotoluic acid and orthotoluamide.

The constitution of the diamides may, according to the present views, be formulated in two ways; the constitution of dibenzamide, for example, may be expressed by the formulæ $NHBz_2$ and NH:CPh·OBz, so that the existence of two phenyl derivatives of dibenzamide is, theoretically, possible. As a matter of fact, two such compounds have been described: the one, $NPhBz_2$, prepared by Gerhardt and Chiozza by heating benzanilide with benzoic chloride, melts at 136°; the other, obtained by Losanitsch by heating phenylthiocarbimide with benzoic acid, melts at 155°. The authors find, contrary to the results obtained by Higgin (Trans., 1882, 133), that Losanitsch's compound is simply benzanilide (m. p. 160—161°), this substance being readily formed, together with carbon oxysulphide, by the interaction of benzoic acid and phenylthiocarbimide in molecular proportion at 130°; a similar reaction takes place when acetic acid is heated with phenylthiocarbimide, acetanilide and carbon oxysulphide being produced. As, therefore, the existence of two isomeric alkyl derivatives of dibenzamide is not yet proved, the symmetrical formula given above should be employed, at any rate provisionally, to represent the constitution of dibenzamide.

F. S. K.

Action of Sulphuric Anhydride on Nitriles. By P. Eitner (*Ber.*, **25**, 461—472; compare preceding abstract).—A neutral additive compound of the composition $(C_6H_5\cdot CN)_2SO_3$ is deposited in yellow crystals when well-cooled benzonitrile is treated with the vapour of sulphuric anhydride. It crystallises from warm benzene in colourless, seemingly monoclinic prisms, begins to decompose at 120° with formation of benzonitrile, melts at 157—158°, and sublimes under reduced pressure with only slight decomposition; it is readily soluble in benzene, toluene, xylene, and chloroform, but only very sparingly in light petroleum and carbon bisulphide, and insoluble in ether, water, and alkalis. The following experiments show that the constitution of this compound is most probably expressed by the formula $N\lessgtr\begin{matrix}CPh:N\\CPh\cdot O\end{matrix}\gtrless SO_2$; it may, therefore, be named *benzoylsulphobenzamidinic anhydride*. When heated with water at about 120°, it is decomposed into benzoic acid and ammonium sulphate; it dissolves in sulphuric acid with development of heat, giving a pale-yellow solution from which, on the addition of water and excess of ammonia successively, imidodibenzamide is precipitated.

Imidodibenzamide (m. p. 105—106°) can be prepared by heating benzenylamidine hydrochloride with benzoic chloride at about 110°; when warmed with dilute sulphuric acid, it is decomposed into ammonia and dibenzamide, and on distillation, even under a pressure of 11 mm., it undergoes decomposition into benzonitrile, benzamide, and small quantities of cyaphenine. The *hydrochloride*, $C_{14}H_{12}N_2O,HCl$, is a colourless, crystalline powder melting at 187—188°. When imidodibenzamide is boiled for a long time with alcohol, it yields ethyl benzoate, benzamide, and cyaphenine with evolution of ammonia.

Sulphobenzamidinic acid, $NH_2{\cdot}CPh{:}N{\cdot}SO_3H$, is formed, together with ethyl benzoate, when benzoylsulphobenzamidinic anhydride is boiled with alcoholic benzene containing a few drops of water; it separates from hot water in prisms, and from cold water in lustrous, monoclinic crystals, and melts at 247°. The *barium* salt,

$$(C_7H_7N_2SO_3)_2Ba + 4H_2O,$$

separates from hot water in large, colourless, transparent, monoclinic crystals, and loses the whole of its water at 140—150°. The *calcium* salt, $(C_7H_7N_2SO_3)_2Ca$, forms anhydrous crystals, and is much more readily soluble in water than the barium salt. When the barium salt is boiled with dilute hydrochloric acid, it is decomposed into barium sulphate and benzenylamidine sulphate. The acid described by Engelhardt (*J. pr. Chem.*, **75**, 363) under the name of sulphobenzamic acid is identical with the sulphobenzamidinic acid described above. F. S. K.

Iodation of Parabromobenzoic Acid: Salts of Parabromometanitrobenzoic Acid. By O. Hough (*Chem. News*, **65**, 64—65).—No iodation of parabromobenzoic acid occurred when it was heated with iodine and mercuric oxide either with or without pressure.

Potassium parabromometanitrobenzoate is anhydrous, and forms long, yellow, prismatic needles, which are soluble to the extent of 33·44 grams in 100 grams of water. The *sodium salt* contains 1 mol. H_2O, and forms needles, of which 100 grams of water dissolve 16·01 grams. The *ammonium salt* crystallises in anhydrous needles, of which 12·22 parts dissolve in 100 of water.

The small, white needles of the *strontium salt* contain $3\frac{1}{2}$ mols. H_2O, those of the *calcium salt* 13 mols. H_2O; of the former, 0·88 part, of the latter, 1·09 part, dissolve in 100 of water. The *zinc salt* forms white needles, 0·70 part dissolving in 100 of water; a *basic zinc salt* is obtained in minute, yellow plates by precipitating a solution of the potassium salt with zinc chloride.

The *mercury salt* is white and anhydrous, and 0·96 gram dissolves in 100 of water. The *nickel salt* forms pale-green crystals containing $2\frac{1}{2}$ mols. H_2O; 1·47 parts of this, and 1·05 parts of the *cobalt salt*, dissolve in 100 of water. The latter salt forms pink needles with 3 mols. H_2O. All solubilities are for a temperature of 26°.

D. A. L.

Hydrobenzoic Acids. By V. Markovnikoff (*Ber.*, **25**, 370—371).—The author informed Aschan in a private communication that hexahydrobenzoic acid melts at 28°, whereas the latter made no mention of this information in his paper (Abstr., 1891, 1481). Pure hexahydrobenzoic acid melts at 28·5—29·5°, is heavier than water, and sparingly soluble in it at the ordinary temperature, more readily in the hot liquid; it has a faint odour recalling that of valeric and ethylcrotonic acids, and boils at 232—233° (compare Aschan, *loc. cit.*). It does not combine with bromine, but when dissolved in sodium carbonate solution and treated with potassium permanganate solution (1 part of the salt in 1000 parts of water), it is scarcely possible to distinguish it from the tetrahydro-acid by the rate at which the per-

manganate is decolorised. Its composition was placed beyond doubt by complete analysis of the silver salt. The crude hydrogenation product contains also a crystalline acid of very low melting point and a liquid acid, both of which combine with bromine and decolorise permanganate; an acid boiling above 260° is also present in small quantity, and valeric acid, evidently produced by the protracted boiling of the sodium amyloxide, is obtained from the lower fractions. A. R. L.

Methyl Mesitylenecarboxylate. By E. Feith (*Ber.*, **25**, 503).—Methyl mesitylenecarboxylate is an oil which boils at 242—244°. The author has erroneously described this compound as crystallising in plates and melting at 139—140° (this vol., p. 329). E. C. R.

Dichlorhydrin Parahydroxybenzoate. By C. Götting (*Ber.*, **25**, 811—813).—By the action of hydrogen chloride on parahydroxybenzoic acid and glycerol at 100°, and treatment of the product with water, a viscid liquid is obtained which solidifies after some time; it is formed in larger quantity at 70—75°. The compound is readily soluble in alcohol, ether, and benzene, crystallises in colourless, radial, feathery aggregates, and melts at 74—76°; on hydrolysis with alkalis, it yields epichlorhydrin together with impure hydroxybenzoic acid; and, from the fact that it is most readily formed at temperatures below 100°, it appears to be *β-dichlorhydrin parahydroxybenzoate*, $OH\cdot C_6H_4\cdot COO\cdot CH_2\cdot CHCl\cdot CH_2Cl$. J. B. T.

Orthohydroxymethylbenzoic Acid. By E. Hjelt (*Ber.*, **25**, 524—525).—Orthohydroxymethylbenzoic acid, $OH\cdot CH_2\cdot C_6H_4\cdot COOH$, is conveniently prepared by heating phthalide with potash or soda, and acidifying the solution with hydrochloric acid; the precipitated acid is quickly filtered and washed with water; it forms aggregates of lustrous, slender needles melting at 120°, and is stable when anhydrous, but in aqueous solution at ordinary temperatures phthalide is regenerated; the same change is produced more rapidly by the action of acetic chloride on the acid; 100 parts of water at 20° dissolve 0·428 part of the acid; the electrical conductivity $k = 0{\cdot}0151$, $\mu\infty = 353$. The *barium salt* is amorphous; the *potassium salt* crystallises in stellate clusters of needles; it is soluble in alcohol, and yields phthalide on treatment with ethyl iodide. J. B. T.

Derivatives of Gallic Acid and of Pyrogallol. By H. Schiffer (*Ber.*, **25**, 721—727).—*Dibromotriethylgallic acid*, $C_6Br_2(OEt)_3\cdot COOH$, is obtained by brominating triethylgallic acid dissolved in boiling carbon bisulphide; it crystallises from benzene in transparent prisms, melts at 107°, is readily soluble in boiling alcohol and benzene, sparingly in the cold liquids, and dissolves without decomposition in hot concentrated alkalis; it is not attacked by silver oxide, but undergoes complete decomposition when fused with potassium hydroxide. When gallic acid is treated with nitric acid, it yields oxalic acid; whereas the triethyl derivative, when dissolved in glacial acetic acid

and treated with nitric acid (sp. gr. 1·48), gives *nitrotriethylpyrogallol*, $[(OEt)_3 : NO_2 = 1 : 2 : 3 : 5]$; this crystallises in yellowish, silky needles, melts at 74°, and is insoluble in alkalis. The dinitrotriethylpyrogallol described by Benedikt and Weselsky (*Monatsh.*, **2**, 217) is in reality identical with the last-described mononitro-derivative. The latter, when dropped into nitric acid (sp. gr. 1·48), yields a *dinitro*-derivative $[(OEt)_3 : (NO_2)_2 = 1 : 2 : 3 : 4 : 5]$, which is identical with Benedikt and Weselsky's supposed trinitro-derivative (*loc. cit.*); it crystallises from alcohol in small, white needles, and melts at 93°. *Amidotriethylpyrogallol* $[(OEt)_3 : NH_2 = 1 : 2 : 3 : 5]$, prepared by reducing the mononitro-compound with tin and hydrochloric acid, crystallises in small, white needles, melts at 104°, and is readily soluble in alcohol and ether, but only sparingly in hot water; the hydrochloride, platinochloride, and sulphate are crystalline. When the amido-derivative is dissolved in strong sulphuric acid and treated with potassium nitrite, the hydroxy-derivative (hydroxytriethoxybenzene) is obtained; this crystallises in small needles, melts at 105°, and is readily soluble in alcohol and ether, sparingly in boiling water, and is not decomposed by alkalis. Will has shown (Abstr., 1888, 458) that trimethylpyrogallol, when treated with nitric acid, yields a nitro-derivative, together with dimethoxyquinone; this the author confirms, but he finds that triethylpyrogallol, on treatment with nitric acid, yields only a nitro-derivative. Schlör obtained asymmetrical tetrahydroxybenzene from the dimethoxyquinone, and the same compound appears to be formed when the above-mentioned hydroxytriethoxybenzene is treated with hydriodic acid.

Nitrotriethylgallic acid $[(OEt)_3 : NO_2 : COOH = 1 : 2 : 3 : 4 : 5]$ obtained by nitrating triethylgallic acid dissolved in glacial acetic acid, crystallises in delicate yellow needles, melts at 104°, and is readily soluble in alcohol and ether, but only sparingly in hot water; when added to moderately concentrated, cooled sulphuric acid, dinitrotriethylpyrogallol (m. p. 93°) is formed, but it remains unaltered when heated at 200° with dilute acid.

Amidotriethylgallic acid is prepared by boiling a solution of the last-described nitro-derivative in aqueous alcohol with tin and hydrochloric acid; it is easily soluble in alkalis and acids, alcohol, and ether, but only sparingly in cold water; it melts at 111°, and appears to yield an amidotriethylpyrogallol when heated.

Trimethylgallic acid, when nitrated in glacial acetic acid solution, yields a nitrotrimethylpyrogallol identical with that prepared by Will and by Schlör, which has the constitution $[(OMe)_3 : NO_2 = 1 : 2 : 3 : 5]$; so that it would seem that, when the alkyl derivatives of gallic acid are nitrated, the carboxyl group is first displaced, and the constitutions given for the compounds described in this paper are therefore established. A. R. L.

Chestnut-wood Tannin. By H. Trimble (*Proc. Chem. Sect. Franklin Inst.*, **3**, 80—83).—The tannin was obtained from the wood of the *Castanea vesca* of Linnæus, or *C. sativa* of Miller, variety *Americana*. The finely powdered wood was percolated with commercial ether, the ether evaporated, and the residue dissolved in cold

water. The filtered solution was precipitated in three portions by lead hydroxyacetate, the precipitate decomposed by hydrogen sulphide, and excess of the latter removed by distillation under reduced pressure. The residual solution was cooled, agitated with ether to extract gallic acid, and then saturated with salt. The tannin separated out and was washed with a saturated solution of common salt, dried, dissolved in ether-alcohol, and the filtered solution evaporated under diminished pressure. The tannin was thus obtained as a porous, light-red mass. It was further purified by a repetition of the above treatment, and was then obtained as a white, porous mass completely soluble in cold water. It appears to be gallotannic acid, for it resembles this substance in all its reactions, and the results of analysis agree moderately well with this view of its composition, after allowance has been made for 8 per cent. of glucose which exists in it, no doubt as a glucoside. When heated to 200°, it decomposes into pyrogallol and metagallic acid. C. F. B.

ε-Chloramylamine and Synthesis of Piperidine. By S. Gabriel (*Ber.*, **25**, 415—422).—*γ-Chloropropyl phenyl ether*,

$$OPh\cdot CH_2\cdot CH_2\cdot CH_2Cl,$$

can be obtained by warming trimethylene chlorobromide with sodium phenoxide in alcoholic solution; it is a colourless oil boiling at 238—240° under a pressure of 745 mm.

Phenoxypropylmalonic acid, $OPh\cdot[CH_2]_3\cdot CH(COOH)_2$, is formed when the preceding compound is boiled with an alcoholic solution of ethyl sodiomalonate, and the oily product hydrolysed with alcoholic potash. It crystallises from hot water, in which it is readily soluble, in flat, colourless plates, sinters together at 70°, and melts at 75—80° to a turbid liquid which does not become quite clear until the temperature has risen to 90—95°, evolution of carbonic anhydride then taking place.

δ-Phenoxyvaleric acid, $OPh\cdot[CH_2]_4\cdot COOH$, prepared by heating the dicarboxylic acid above its melting point, separates from light petroleum in compact, transparent crystals, melts at 65—66°, and boils at 315—320° with partial decomposition; it is readily soluble in alcohol and light petroleum. The *silver* salt, $C_{11}H_{13}O_3Ag$, crystallises in microscopic needles.

δ-Phenoxyvaleronitrile, $OPh\cdot[CH_2]_4\cdot CN$, is obtained when the corresponding acid is heated with lead thiocyanate; it is a colourless, crystalline compound, melts at 28—30°, and boils at 299—304°, seemingly with slight decomposition.

ε-Phenoxyamylamine, $OPh\cdot[CH_2]_5\cdot NH_2$, prepared by reducing the nitrile with sodium and alcohol, is a colourless oil which boils at 274—275°, and solidifies at a low temperature to a mass of crystals; it is only sparingly soluble in water, to which it imparts an alkaline reaction, and it absorbs carbonic anhydride, forming a crystalline carbonate. The *hydrochloride*, $C_{11}H_{17}NO,HCl$, crystallises from dilute hydrochloric acid in compact needles, and melts at 138—140°. The *platinochloride* is a yellow, crystalline, sparingly soluble compound, which sinters together at about 200°, and melts at about 210°. The

picrate separates from hot alcohol in small, rhombic crystals, melts at 147—148°, and is only sparingly soluble in cold water.

ε-Chloramylamine hydrochloride, $CH_2Cl\cdot[CH_2]_4\cdot NH_2,HCl$, is formed when phenoxyamylamine is heated at 180° with concentrated hydrochloric acid. It crystallises from a mixture of alcohol and ethyl acetate in yellowish scales, sinters together at 140°, melts completely at 152°, and is very readily soluble in water. The *picrate*, $C_5H_{12}NCl,C_6H_3N_3O_7$, crystallises in flat, yellow needles, and melts at 123—125°. The *platinochloride*, $(C_5H_{12}NCl)_2,H_2PtCl_6$, crystallises from warm water in lemon-yellow plates, and melts at 95—97° with previous softening. When the hydrochloride (1 mol.) is warmed with dilute soda (1 mol.), it is converted into piperidine hydrochloride. F. S. K.

Nitration of Butyltoluenesulphonic Acid and of Butylxylenesulphonic Acid. By E. Noelting (*Ber.*, **25**, 785—792).—*Dinitrobutyltoluenesulphonic acid*, $C_4H_9\cdot C_6HMe(NO_2)_2\cdot SO_3H$

$$[= 3:1:2:4:6],$$

is prepared by dissolving the sulphonic acid in 6—8 parts of nitric acid (86 per cent.), and allowing it to remain for a considerable time at the ordinary temperature. The product is treated with water, the solution extracted with ether in order to remove trinitrobutyltoluene, neutralised with baryta and barium carbonate, and evaporated to dryness. The *barium sulphonate* is separated from the inorganic salts by treatment with alcohol; it crystallises from water in colourless plates containing 7 mols. H_2O. The *sodium salt*, with 3 mols. H_2O, crystallises from water in large, colourless plates. The *free acid* is readily soluble in water, and, like the salt, is odourless; its constitution is proved by the fact that on warming with nitric acid it yields symmetrical trinitrobutyltoluene; the butyltoluenesulphonic acid, when fused with potash, yields, according to an unpublished research of Baur, butylcresol, $C_4H_9\cdot C_6H_3Me\cdot OH$ [Me : C_4H_9 : OH = 1 : 3 : 6].

Dinitrobutylmetaxylenesulphonic acid, $C_4H_9\cdot C_6Me_2(NO_2)_2\cdot SO_3H$, is prepared in a manner similar to the toluene derivative, which it closely resembles; the *barium salt* is readily soluble in water; the *sodium salt* crystallises in silvery, lustrous plates, and is extremely soluble in alcohol.

By the interaction of metaxylene, isobutyl alcohol, and sulphuric acid at 45°, tertiary butylmetaxylene is formed; it readily yields a sulphonic acid, the *anilide* of which crystallises from dilute alcohol in colourless needles melting at 143·5—144·5°. Tertiary butylmetaxylene is also obtained by the action of zinc chloride on metaxylene and isobutyl alcohol. Trinitrobutylmetaxylene smells strongly of musk, but the dinitrosulphonic acid and its salts are odourless.

J. B. T.

Substitution Products of Stilbene and Thionessal. By K. Kopp (*Ber.*, **25**, 600—603).—By the distillation of polymerised thiobenzaldehyde, Laurent obtained a mixture of stilbene and a substance termed thionessal, which has been proved by Baumann and Klett to be tetraphenylthiophen (this vol., p. 184). The author has investi-

gated the action of heat on other polymerised thioaldehydes, in the hope of obtaining stereoisomeric stilbenes, but hitherto no indication of their formation has been observed. In the present paper, the results obtained with the methoxythiobenzaldehydes are described.

When polymerised methylthiosalicylaldehyde (Abstr., 1891, 1050) is heated for five hours at 145°, a transparent, reddish mass is formed which, by repeated crystallisation from ether, may be obtained in colourless prisms having a blue fluorescence. It consists of *diorthomethoxystilbene*, $C_2H_2(C_6H_4{\cdot}OMe)_2$, melts at 136°, is readily soluble in alcohol, chloroform, and benzene, and insoluble in water. No second isomeride could be obtained from the mother liquors, but the yield is greatly affected by the formation of the substituted thionessal, which takes place almost completely at temperatures above 150°. A better yield of the stilbene derivative is obtained by distilling the aldehyde with iron powder, a small quantity of an unpleasant smelling oil being the only other product; if zinc-dust is employed instead of iron, considerable quantities of the thionessal are formed. To prepare the latter, the mass obtained by heating the aldehyde to temperatures above 150° is powdered, freed from colouring matter by trituration with alcohol, and recrystallised from alcohol or acetic acid. It forms woolly needles, melts at 136°, and has the composition required by the formula $C_4S(C_6H_4{\cdot}OMe)_4$; in its behaviour towards solvents, it is very similar to diorthomethoxystilbene, but dissolves somewhat less readily in hot acetic acid.

When polymerised thioanisaldehyde is heated, sulphur is not eliminated in any quantity until the temperature has reached 160—170°, the reaction being then complete in three hours. The product, after recrystallisation from benzene, consists of *diparamethoxystilbene*, and forms white, lustrous plates which do not show any fluorescence; it melts at 211°, and is only appreciably soluble in boiling chloroform and benzene. No thionessal derivative appears to be formed on heating this thioaldehyde, even at temperatures far above 200°. H. G. C.

Action of Benzene on Benzal Chloride in presence of Aluminium Chloride. By C. E. Linebarger (*Amer. Chem. J.*, **13**, 556—559).—Triphenylmethane and diphenylanthracene dihydride are the principal products of the reaction.

Aluminium chloride (25 grams) is added to a mixture of benzal chloride (200 grams) and benzene (1000 grams), and the whole is heated at about 50° until a little less than the theoretical amount of hydrogen chloride has been given off (two hours). The reaction is then completed by boiling for a few minutes, and the product is washed with water and fractionated. The fraction passing over between 300° and 360° is chiefly triphenylmethane, and is purified by successive recrystallisation from benzene and alcohol. As thus prepared, it melts at 93·4°, and boils at 357° under a pressure of 758 mm. As the yield is about 30 per cent. of the benzal chloride used, and only traces of diphenylmethane are formed if the materials are pure, this forms an excellent, cheap, and expeditious mode of preparing triphenylmethane.

The fractions boiling above 400° are refractionated under a pressure of 25 mm. More triphenylmethane first passes over, but the fraction distilling above 300° contains *diphenylanthracene dihydride*,

$$C_6H_4<\begin{matrix}CHPh\\CHPh\end{matrix}>C_6H_4,$$

which, on recrystallisation from boiling benzene, is obtained in white, microscopic, rhombic prisms. It melts at 164·2°, boils at 437°, dissolves in alcohol, ether, toluene, and xylene, but is insoluble in water. The yield is 1 per cent. of the benzal chloride used. On bromination in boiling chloroform solution, it yields a dibromide. *Diphenylanthracene dibromide*, $C_6H_4<\begin{matrix}CBrPh\\CBrPh\end{matrix}>C_6H_4$, crystallises in small tablets, melts at 127° with slight decomposition, and dissolves in alcohol, benzene, chloroform, and toluene. Jn. W.

Action of Bleaching Powder and of Hypochlorous Acid on Quinones and Diketones. By T. Zincke (*Ber.*, **25**, 399—410).—The lactone of dihydroxyorthocarboxyphenylpropionic acid,

$$CO<\begin{matrix}C_6H_4\\O\text{—}\end{matrix}>CH\cdot CH(OH)\cdot COOH,$$

is obtained when β-naphthaquinone (3 grams), mixed into a paste with water, is treated with a concentrated solution of bleaching powder (80—90 c.c.). It crystallises in tables or in leaflets resembling phthalic acid, is sparingly soluble in benzene, chloroform, and ether, readily so in hot alcohol or glacial acetic acid, and melts at 202°. It neutralises one equivalent of alkali hydroxide in the cold, but two at a higher temperature, giving rise to salts of the above-mentioned bibasic acid. The *methyl* salt, prepared from the *silver* salt, forms rhombic tables, and melts at 131°, whilst the *acetyl derivative*, $CO<\begin{matrix}C_6H_4\\O\text{—}\end{matrix}>CH\cdot CH(OAc)\cdot COOH$, crystallises in long, lustrous needles, melts at 187°, and yields a *methyl* salt melting at 108°. When the lactonic acid is heated with concentrated hydriodic acid and phosphorus at 150—160°, orthocarboxyhydrocinnamic acid, melting at 163—164° (Gabriel and Michael, Abstr., 1878, 427; Wislicenus, *Annalen*, **242**, 27), is produced.

Dihydroxynaphthaquinone, $C_6H_4<\begin{matrix}CO\text{—}CO\\C(OH):C\cdot OH\end{matrix}$ or $C_6H_4<\begin{matrix}CO\cdot C\cdot OH\\CO\cdot C\cdot OH'\end{matrix}$ is formed when β-naphthaquinone is mixed into a paste with water and treated with concentrated bleaching powder solution (25—30 c.c.). It crystallises from toluene in small, delicate, red needles, does not melt at 250°, dissolves readily in acetone, sparingly in cold alcohol, benzene, and chloroform. Alkalis dissolve it, forming a blue solution, which after a time becomes colourless, and it is converted into phthalic acid by an excess of bleaching powder solution. It is identical with isonaphthazarine, described by Bamberger and Kitschelt (this vol., p. 494). A. R. L.

Sulphonic Acid obtained from 1 : 4-Amidonaphthol. By P. Seidel (*Ber.*, **25**, 423—430).—*Amidonaphtholsulphonic acid*,

$$NH_2 \cdot C_{10}H_5(OH) \cdot SO_3H,$$

is formed when 1 : 4-amidonaphthol hydrochloride, prepared from α-naphthol-orange, is triturated with the theoretical quantity of 10 per cent. anhydrosulphuric acid. It crystallises from boiling water, in which it is only very sparingly soluble, in colourless needles, and turns brown when heated above 200°; its freshly prepared solutions in alkalis and alkali carbonates are grass-green, but turn brown on keeping. It reduces ammoniacal silver solutions, gives with diazosulphanilic acid and sodium acetate a reddish-brown coloration on boiling, and is readily oxidised by potassium permanganate in alkaline solution, and also by warm, concentrated nitric acid with formation of phthalic acid. When the dry, finely-divided sulphonic acid is rubbed to a paste with alcohol, and then warmed with nitric acid of sp. gr. 1·3 for a few minutes, or suspended in alcohol and treated with nitrous acid, it is converted into the ammonium salt of a naphthaquinonesulphonic acid of the composition $C_{10}H_{15}O_2 \cdot SO_2 \cdot ONH_4$. This substance is very readily soluble in water, alcohol, and ether, and exists in two crystallographically different forms, namely, in orange plates and in colourless needles, both of which begin to darken when heated at 220°, and melt above 230° with complete decomposition; it is decomposed by concentrated hydrochloric acid with separation of ammonium chloride, and concentrated nitric acid converts it into phthalic acid; when boiled with aniline and alcohol, it yields β-anilidonaphthaquinone anilide, $NHPh \cdot C_{10}H_5 < \begin{matrix} O \\ | \\ NPh \end{matrix}$ [NPh : NHPh : O = 1 : 3 : 4].

Diazonaphtholsulphonic acid, $N \ll \begin{matrix} N \\ O \end{matrix} > C_{10}H_5 \cdot SO_3H + H_2O$, is formed when nitrous acid is passed into alcohol containing moist, finely-divided amidonaphtholsulphonic acid in suspension; it crystallises in yellow needles, turns green at about 140°, and explodes at 160°. It is moderately easily soluble in cold water, but on the addition of hydrochloric, sulphuric, or nitrous acid to the solution, it is precipitated in large crystals; it loses its water of crystallisation over sulphuric acid, but regains it on exposure to the air. Its alkaline solutions give with phenol, naphthol, &c., deep-red colorations, and with excess of potash an orange, crystalline potassium salt; this salt turns brown when dried at 100°, and then dissolves in alkalis with a purple-red coloration.

A violet oxidation product of the composition $C_{20}H_{14}N_2SO_5$ is formed when an aqueous solution of amidonaphtholsulphonic acid is heated; it crystallises in needles, and is moderately easily soluble in hot alcohol, but only sparingly in hot glacial acetic acid, and almost insoluble in water, benzene, and chloroform. It gives a magenta coloration with concentrated sulphuric acid, but it seems to be unchanged by concentrated hydrochloric acid; when treated with potash, it yields a black oil which, especially after the addition of alcohol, is transformed into bronze crystals of the potassium salt; on reduc-

tion with stannous chloride and hydrochloric acid, it is converted into a colourless substance, which is readily soluble in alcohol, but insoluble in water. Crystals of the oxidation product which have been exposed to an atmosphere saturated with aqueous vapour have the composition $C_{20}H_{14}N_2SO_5 + 5H_2O$, but on keeping over sulphuric acid, they lose approximately 4 mols. H_2O without any alteration in colour or in lustre. F. S. K.

Sulphonic Acids of Amido-α-Naphthol and α-Naphthoquinone. By O. N. Witt (*Ber.*, **25**, 735—736).—The author is engaged on this subject in conjunction with his pupils, and wishes to reserve the same. A. R. L.

Reaction between Triphenylmethane and Chloroform in presence of Aluminium Chloride. By C. E. Linebarger (*Amer. Chem. J.*, **13**, 554—556).—The phenylanthracene which occurs as a secondary product in the preparation of triphenylmethane from chloroform and benzene under the influence of aluminium chloride (Friedel and Crafts, *Ann. Chim. Phys.* [6], **1**, 495) results from a precisely similar action between the chloroform and the newly-formed triphenylmethane, which may be utilised for the independent preparation of phenylanthracene.

Aluminium chloride (40 grams) is added in three portions to a solution of triphenylmethane (50 grams) in dry chloroform (600 grams), and the mixture is heated until a little less than the theoretical quantity of hydrogen chloride has been given off. The liquid product is washed in succession with cold and boiling water, the chloroform is distilled off, and the residue dissolved in benzene. Resinous matter is now precipitated by the addition of light petroleum, and the residue left on distilling off the solvent is recrystallised from alcohol. Phenylanthracene prepared in this manner crystallises in white tablets, and melts at 152·8°. The maximum yield was 15 per cent.

A small quantity of a hydrocarbon, $C_{20}H_{16}$, melting at 87—88°, and probably phenylanthracene dihydride, was also isolated from the products. Jn. W.

Terpenes. By J. W. Brühl and F. Müller (*Ber.*, **25**, 547—551).—The present communication deals with the composition of oil of laurel; the specimen examined distilled between 175° and 275° under ordinary pressure, and left a viscous residue. The distillate contains lauric acid, but eugenol could not be detected; after treatment with potash and digestion with sodium, a liquid is obtained which boils at 167—171°; it consists of cineole, pinene, and other hydrocarbons; the cineole was identified by means of its bromo- and hydrogen bromide derivatives, the pinene by the preparation of pinene nitrosyl chloride. The fraction boiling at 171° was optically examined; the molecular refraction $\mathfrak{M}_\alpha = 42{\cdot}55$, $\mathfrak{M}_\gamma - \mathfrak{M}_\alpha = 1{\cdot}26$, the sp. gr. at $18°/4° = 0{\cdot}8785$. In addition to the above substances, the crude oil contains large proportions of alcoholic or ketonic compounds, which, like menthol or camphor, combine with sodium, the salts so formed being

decomposed by water. Wallach's conclusion that "laurene" (b. p. 171°) does not exist is thus confirmed, whilst the earlier observations of Gladstone are criticised. J. B. T.

Russian Peppermint Oil and Menthylamine. By G. Andres and A. Andréeff (*Ber.*, **25**, 609—621).—Hitherto investigators have confined their attention to the oxygen compounds contained in peppermint oil, very little being known of the nature of the hydrocarbons it contains. The authors have therefore examined large quantities of Russian oil of peppermint with especial reference to the latter point.

It was found that very little difference exists between the oil prepared from the fresh and from the dried plants, the latter containing, however, as would be expected, rather more of the oxygen compounds. The combined oils were subjected to distillation, and found to boil between 165° and 225°; the residue, on distilling in a current of steam, gave considerable quantities of oil, which, on redistillation, boiled at 207—225°. The menthol was separated from the higher fractions by freezing, and the rest frequently fractioned and treated with metallic sodium. Eventually six fractions boiling at temperatures between 158° and 175° were obtained, and also a fraction boiling at 200—205°, which consists almost entirely of menthone. The fraction 173—175° has the composition of a terpene, and in its physical properties closely resembles lævo-limomene, but its specific rotatory power is $[\alpha]_D = -41{\cdot}09°$ instead of $-105°$. On treatment with the necessary reagents, it yields the dihydrochloride, nitrosochloride, and nitrosoterpene corresponding with lævo-limonene, and must therefore contain this hydrocarbon. The fraction 170—173° has a specific rotatory power of $[\alpha]_D = -30{\cdot}64°$, and also contains lævo-limonene mixed with a larger quantity of another isomeric hydrocarbon. The lower fractions contain a larger percentage of hydrogen, and consist therefore of a mixture of a terpene with a hydrocarbon of the formula $C_{10}H_{18}$, but the authors have been unable to isolate the latter; no indications of the presence of a naphthene of the formula $C_{10}H_{20}$ were observed.

The fraction 200—205° contains chiefly menthone mixed with more or less menthol, and may be converted into the oily oxime. The menthone is a mixture of both optical isomerides, the dextro-derivative being present in the larger quantity, but as the isomerides so readily change one into the other, it is uncertain whether both occur in the original oil.

Menthylamine, which was first prepared by Moriya (Trans., 1881, 77), may, contrary to the statement of Beckmann, be readily obtained by reducing the oxime with sodium in alcoholic solution, some menthone being re-formed at the same time. The latter is removed by acidifying with acetic acid and extracting with ether; the aqueous solution is then partially evaporated, treated with an excess of potash, and the liberated amine taken up with ether. The menthylamine thus obtained boils at 204°, has the sp. gr. 0·8685 at 0°/0°, and the specific rotatory power $[\alpha]_D = -33{\cdot}6°$; it has an odour resembling that of coniine, and rapidly absorbs carbonic anhydride from the air. It yields a white, crystalline *hydrochloride*, and a *platinochloride*,

$(C_{10}H_{19}\cdot NH_2)_2,H_2PtCl_6$, which separates from hot water in golden plates. The menthylamine obtained from dextro-menthoxime has very similar chemical properties; its sp. gr. is 0·8749 at 0°/0°, and its specific rotatory power $[\alpha]_D = -9·26°$, and it is therefore probably a mixture of lævo- and dextro-menthylamine, the first variety consisting of lævo-menthylamine. H. G. C.

The Camphor Group. By G. Oddo (*Gazzetta*, **21**, ii, 505—559).—The author gives an exhaustive summary of our knowledge of camphor and its derivatives. After a criticism of the various constitutional formulæ which have been proposed for camphor by previous authors, he assigns to it the following constitution:—

$$\begin{array}{l} CH_2\cdot CH_2\cdot CH_2 \\ | \qquad\quad | \\ CH\cdot CH_2\cdot CH \\ | \qquad\quad | \\ CH_2\cdot CO\cdot CHMe \end{array}$$

W. J. P.

Stereochemistry of the Camphor Group. By G. Oddo (*Gazzetta*, **21**, ii, 560—567).—The author develops the constitutional formula for camphor mentioned in the preceding abstract, and gives spacial formulæ, representing the isomeric camphors, borneols, and camphoric acids. W. J. P.

The Camphor Group. By G. Oddo (*Gazzetta*, **21**, ii, 567—569).—Oppenheim (*Ber.*, 1872, 631) has stated that on oxidising cymene by chromic mixture, a solid substance, having the properties of camphor, is obtained.

The author has repeated this work, taking especial care to purify the cymene employed, but no trace of any substance resembling camphor could be detected. It seems probable, therefore, that the cymene employed by Oppenheim contained traces of terpenes which, on oxidation, yielded isomerides of camphor. W. J. P.

Sapotin: a Glucoside. By G. Michaud (*Amer. Chem. J.*, **13**, 572).—Sapotin exists in the almond-like kernels of the seeds of *Achras sapota*, L., from the dry raspings of which it may be extracted with boiling 90 per cent. alcohol, after the removal of the fat by benzene.

Pure *sapotin*, $C_{29}H_{52}O_{20}$, separates from alcoholic solution in microscopic crystals, which form a white powder, having an acrid, burning taste, and irritating the nose and eyes. It melts with decomposition at 240°, is very soluble in water, easily soluble in boiling alcohol, sparingly soluble in cold alcohol, and insoluble in ether, chloroform, and benzene. It is lævogyrate, the rotatory power in alcoholic solution being $[\alpha]_j = -32·11$. Basic lead acetate produces a gelatinous precipitate in aqueous solutions of sapotin; this is soluble in excess of the reagent, and concentrated sulphuric acid gives a garnet-red colour with the dry substance. It does not react with tannin or alkaline copper tartrate.

Sapotin is hydrolysed by hot dilute sulphuric acid into glucose and

sapotiretin, $C_{17}H_{32}O_{10}$, an amorphous substance, which is very soluble in alcohol, soluble in chloroform, but insoluble in water and ether.

JN. W.

Preparation of Collidine. By J. MAI and K. ASCHOFF (*Ber.*, **25**, 374—375; compare Hantzsch, Abstr., 1883, 82).—When a mixture of ethyl collidinedicarboxylate (5 grams) and dry soda-lime (25 grams) is heated in a retort, at first gently and later strongly, collidine passes over, and is rectified, its amount being 70—75 per cent. of the theoretical. When ethyl hydrocollidinedicarboxylate is distilled with soda-lime, ammonia is evolved, and a product having the odour of collidine, consisting apparently of a mixture, is obtained; a homogeneous product is not produced when the last-mentioned ethyl derivative is distilled with sodium ethoxide. A. R. L.

γ-Amidoquinoline. By S. HOOGEWERFF and W. A. VAN DORP (*Rec. Trav. Chim.*, **10**, 144—147).—Ephraim (Abstr., 1891, 1509) has described an α-amidoquinoline which differs from the author's γ-amidoquinoline, prepared by another method. From a solution of cinchonamide in alkaline potassium hypobromite, acetic acid precipitates a bromamide which melts at 138°. On warming the alkaline solution with aqueous potash, decomposition ensues, and γ-amidoquinoline separates on cooling in hydrated acicular crystals which melt at 70°, or at 90° when dried; when crystallised from hot benzene, the melting point rises to 152—154°. The aqueous solution is alkaline to litmus, and the substance is freely soluble in alcohol, chloroform, hot benzene, and ether, although but slightly soluble in carbon bisulphide and light petroleum. It volatilises slowly in a current of steam and yields crystalline salts with chloroplatinic, picric, and chromic acids. Carbonic anhydride precipitates from the ethereal solution a white, crystalline compound which, melting at 96°, resolidifies and remelts at 150°. The platinochloride, $(C_9NH_6{\cdot}NH_2)_2,H_2PtCl_6 + 2H_2O$, forms fine, salmon-yellow needles which are almost insoluble in water; it melts at 266—270° with decomposition. The dichromate, $(C_9H_8N_2)_2,H_2Cr_2O_7$, forms dark-red, acicular crystals, which are slightly soluble in water. A double silver salt, $(C_9H_8N_2)_2,AgNO_3$, forming long, silky, needles, and combinations with mercuric and cadmium chlorides have been prepared. T. G. N.

Attempted Synthesis of a Nitramine of the Quinoline Group. By J. C. SIMON-THOMAS (*Rec. Trav. Chim.*, **10**, 148—154).—The author has attempted to make a nitramine of the quinoline series by reactions similar to those employed by Franchmiont and Klobbie (Abstr., 1889, 1143) in obtaining a nitramine from piperylcarbamide.

Tetrahydroquinolylcarbamide, prepared according to Hoffmann and König's directions (Abstr., 1883, 1143), melts at 150·5°, and not at 146·5°, as stated by these authors. This substance, when added to nitric acid at low temperatures, is decomposed with evolution of gas, and no definite crystalline product separates; it is oxidised also even on slightly warming with dilute nitric acid. Advantage is taken of its solubility, without alteration, in concentrated sulphuric acid, and this solution is dropped into a large excess of nitric acid at 0° with

vigorous shaking; no gas is evolved, and on pouring the mixture into water at 0°, yellow flakes separate which, after washing, are crystallised from alcohol. Two products are thus obtained, the more soluble of which is dinitrotetrahydroquinolylcarbamide, the less soluble being dinitrotetrahydroquinoline, resulting from the decomposition of the former substance by dilute nitric acid; it melts at 161°.

Dinitrotetrahydroquinolylcarbamide, $NH_2 \cdot CO \cdot C_9NH_8(NO_2)_2$, forms yellow plates, melts at 191°, dissolves easily in warm acetone, is but slightly soluble in warm water and benzene, and quite insoluble in ether; at its melting point it decomposes, and resolidifies at a much lower temperature. When heated for five hours with barium hydroxide in a reflux apparatus, ammonia is evolved, and from the insoluble residue dinitrotetrahydroquinoline, melting at 161°, is separated, and an almost quantitative yield of this compound is obtained when the carbamide is treated with diluted sulphuric acid (1 in 2) at 100°.

On placing dinitrotetrahydroquinolylcarbamide in nitric acid at 0° and allowing the temperature to rise slowly, equal volumes of nitrous oxide and carbonic anhydride are evolved, but no crystalline compound can be isolated from the liquid.

It thus appears that in the corresponding reactions, tetrahydroquinolylcarbamide differs from piperylcarbamide in the substitution of two nitro-groups for two hydrogen atoms in the benzene nucleus, whereas in the latter substance the substitution occurs in the hydrogen of the carbamide group.

As a dinitro-derivative of methyltetrahydroquinoline exists (Abstr., 1885, 1245), and as tetrahydroquinoline is easily methylated (Abstr., 1883, 1143), the author attempted to prepare the methyl derivative of dinitrotetrahydroquinoline, but was unsuccessful.

Dinitrotetrahydroquinoline is a secondary amine, since it yields a nitrosamine melting at 125—127°, and gives Liebermann's reaction with phenol and sulphuric acid. It does not reduce silver nitrate solution, is not affected by chromic acid mixture, and when heated with nitrobenzene in sealed tubes at 290—300°, a black mass is obtained, whereas by similar treatment, tetrahydroquinoline yields quinoline (Abstr., 1889, 905). T. G. N.

Derivatives of the Methylquinolines and of Metadimethylquinoline. By E. Noelting and E. Trautmann (*Chem. Centr.*, 1891, ii, 942—944; from *Bull. Soc. Ind. Mulhouse*, 1891, 285—324).—The methylquinolines, C_9NH_6Me [Me = 3 and 1 respectively], were prepared by Skraup's method from para- and ortho-toluidine; if the heating was continued long enough, the whole of the toluidine was converted into quinoline. Metadimethylquinoline, $C_9NH_5Me_2$ [Me_2 = 1 : 3], was prepared directly from the acetyl derivative of asymmetrical metaxylidine, which derivative had been made in order to separate this base from the isomeric bases. It is saponified and simultaneously converted into a quinoline derivative, and the reaction is less violent then when the base itself is used. The above-named quinoline derivatives can be more easily nitrated than quinoline itself.

Nitromethylquinoline, $C_9NH_5Me{\cdot}NO_2$ [Me : $NO_2 = 3:4$], is the only product of the nitration of 3-methylquinoline. It melts at 116—117°, and crystallises from alcohol in light-yellow needles, which dissolve very readily in ether, sparingly in hot and scarcely at all in cold water. It is a very feeble base; its salts crystallise well, and are decomposed by water. The *methiodide*, $C_9NH_5Me{\cdot}NO_2$,MeI, crystallises from hot water in nearly colourless rhombohedra, which turn yellow when heated to 100°. *Amidomethylquinoline*, $C_9NH_5Me{\cdot}NH_2$, is obtained by reducing the nitro-compound with iron and acetic acid; it forms pale-yellowish needles melting at 145°, and dissolving very readily in hot water, very sparingly in cold. It yields both mon-acid and di-acid salts. When treated with acetic acid and anhydride, it yields an *acetyl derivative*, $C_9NH_5Me{\cdot}NHAc$, which melts at 160°, and crystallises from hot water in colourless needles. *Hydroxymethylquinoline*, $C_9NH_5Me{\cdot}OH$, is obtained from the amido-compound by the diazo-reaction. It melts at 230°, and forms flat needles which easily turn pink, but become colourless when sublimed. It dissolves in alcohol, but not in cold water, and only very sparingly in hot. It yields well crystallised compounds with bases and acids, and with diazobenzene chloride, it yields an *oxyazo-derivative* which melts at 176°, and crystallises from alcohol in red needles, soluble in alkalis. *Nitroso-oxymethylquinoline* (*methylquinoline quinone oxime*), $NOH{:}C_9NH_4MeO$ [NOH : Me : O = 1 : 3 : 4], is obtained by the action of sodium nitrite on a fairly concentrated hydrochloric acid solution of hydroxymethylquinoline. It decomposes above 200°, crystallises from alcohol in yellow plates, and dissolves sparingly in hot water, benzene, and chloroform, moderately in acetic acid. With iron mordants, it gives a brilliant green colour, which stands washing and is not affected by light. *Nitrohydroxymethylquinoline*,

$$NO_2{\cdot}C_9NH_4Me{\cdot}OH,$$

is obtained by oxidising the oxime with potassium ferricyanide in hot dilute aqueous soda. It decomposes above 200°, crystallises from acetic acid, or alcohol, in brilliant, yellowish-brown plates, and forms salts with acids and alkalis.

Hydroxymethylquinoline, $OH{\cdot}C_9NH_5Me$ [OH : Me = 1 : 2], is obtained by the action of glycerol, strong sulphuric acid, and picric acid on the hydrochloride of amidoorthocresol. It melts at 72—74°, crystallises from dilute alcohol in colourless needles, and volatilises with steam. It gives a green colour with ferrous chloride, and when mixed with copper oxide colours the Bunsen flame green; it will print upon mordanted calico. *Nitroso-oxymethylquinoline* (*methylquinoline quinone oxime*), $C_9NH_4MeO{:}NOH$ [O : Me : NOH = 1 : 2 : 4], is obtained by the action of sodium nitrite on an acetic solution of the hydroxymethylquinoline. It decomposes above 200°, crystallises from alcohol in yellow needles, yields soluble salts with acids and bases, and does not print on mordanted calico. *Nitrohydroxymethylquinoline*, $OH{\cdot}C_9NH_4Me{\cdot}NO_2$, is obtained by oxidising the oxime in alkaline solution with ferricyanide. It melts at 192—193°, is precipitated in yellow needles by the addition of acetic acid to an aqueous solution, and crystallises in red needles from alcohol. It

forms salts with acids and alkalis, and prints a fine yellow with aluminium mordants; with iron mordants, brown.

Hydroxymethylquinoline, $OH\cdot C_9NH_5Me$ [OH : Me = 1 : 4], is obtained by heating amidoparacresol with glycerol, sulphuric acid, and picric acid. It melts at 122—124°, crystallises from dilute alcohol in colourless needles, is but little soluble in water, but dissolves in acids and alkalis, yielding yellow solutions; it gives a yellow colour with aluminium mordants. *Nitroso-oxymethylquinoline (methylquinoline quinone oxime)*, $C_9NH_4MeO{:}NOH$ [O : NOH : Me = 1 : 2 : 4], gives a green colour with iron mordants. *Nitrohydroxymethylquinoline*, $OH\cdot C_9NH_4Me\cdot NO_2$, obtained from the oxime by means of ferricyanide, melts at 205—206°, crystallises from alcohol in yellow needles, and gives a yellow colour with aluminium and a brown with iron mordants.

Nitromethylquinoline, $C_9NH_5Me\cdot NO_2$ [Me : NO_2 = 3 : 4], is obtained from the nitroparatoluidine, $NH_2\cdot C_6H_3Me\cdot NO_2$ [NH_2 : Me : NO_2 = 6 : 3 : 4], melting at 76° by Skraup's reaction; it melts at 116—117°.

Nitromethylquinoline, $NO_2\cdot C_9NH_5Me$ [NO_2 : Me = 1 : 3], is obtained by Skraup's reaction from the nitrotoluidine [NH_2 : NO_2 : Me = 6 : 1 : 3] melting at 114°, using picric acid instead of nitrobenzene. It crystallises from alcohol in yellow needles, and forms no compound with methyl iodide. *Amidomethylquinoline*, $NH_2\cdot C_9NH_5Me$, is obtained from the last-mentioned compound by reducing it with alcoholic ammonium sulphide. It melts at 62—64°, forms white needles very soluble in alcohol, and can be sublimed; its *hydrochloride* forms orange-yellow needles very soluble in water. Its *acetyl derivative*, $NHAc\cdot C_9NH_5Me$, obtained by the action of acetic acid and anhydride on the preceding compound, melts at 91—92°, crystallises from hot water in plates, dissolves in alcohol, and yields with acids well crystallised colourless salts. Hydroxymethylquinoline, $OH\cdot C_9NH_5Me$, obtained from the amido-compound by the diazo-reaction, is identical with that obtained by Fischer and others from methylquinolinesulphonic acid. *Nitroso-oxymethylquinoline (methylquinoline quinone oxime)*, $C_9NH_4MeO{:}NOH$ [O : Me : NOH = 1 : 3 : 4? ?], decomposes above 200°, forms very slightly soluble brown plates, and gives no colours with mordants. *Amidochloromethylquinoline*, $NH_2\cdot C_9NH_4MeCl$ [NH_2 : Me : Cl = 1 : 3 : ?], is obtained as a bye-product when the nitromethylquinoline is reduced with tin and hydrochloric acid. It melts at 129—130°, crystallises from alcohol in pale-yellow needles, almost insoluble in water, and forms well-crystallised, orange-red mon-acid salts, which are decomposed by water. Its *acetyl derivative*, $NHAc\cdot C_9NH_4MeCl$, obtained by the action of acetic acid and anhydride, melts at 136—137°, and crystallises from water or alcohol in white needles.

Nitromethylquinoline, $C_9NH_5Me\cdot NO_2$ [Me : NO_2 = 1 : 4], is formed when 1-methylquinoline is treated with nitric acid (sp. gr. 1·39) and strong sulphuric acid. It has been obtained synthetically from nitrotoluidine [Me : NO_2 : NH_2 = 1 : 4 : 6]. It melts at 93°, crystallises from alcohol in yellow needles, and is almost insoluble in cold water. *Amidomethylquinoline*, $C_9NH_5Me\cdot NH_2$, is obtained from it by reduction with iron and acetic acid. This substance melts at 143°,

crystallises from water or dilute alcohol in yellow needles, and when heated with glycerol, sulphuric acid, and picric acid, yields *methylphenanthroline*, $C_{12}N_2H_7Me$, which melts at 95—96°, and separates from light petroleum in white crystals. Hydroxymethylquinoline, $C_9NH_5Me{\cdot}OH$, may be prepared from the amido-compound by the diazo-reaction, and is identical with the product obtained by Herzfeld, when orthotoluidinesulphonic acid is converted into a quinoline and fused with an alkali. It melts at 262—263°, and turns black at 240° when slowly heated. It crystallises from alcohol in white needles, and forms with diazobenzene chloride an *oxyazo-derivative* melting at 138—139°, and crystallising from alcohol in red needles, insoluble in water, but soluble in aqueous alkalis. *Nitroso-oxymethylquinoline* (*methylquinoline quinone oxime*),

$$NOH{:}C_9NH_4MeO\ [Me : NOH : O = 1 : 3 : 4],$$

obtained by the action of sodium nitrite on an acetic acid solution of the hydroxymethylquinoline, decomposes above 100°, forms brownish-yellow plates, soluble in alcohol, &c., sparingly soluble in water, and dyes calico, that has been mordanted with iron, green. *Nitrohydroxymethylquinoline*, $NO_2{\cdot}C_9NH_4Me{\cdot}OH$, obtained by oxidising the oxime with ferricyanide in alkaline solution, melts at 181—182°, and crystallises from alcohol in orange needles. *Azomethylquinoline*, $C_9NH_5Me{\cdot}N_2{\cdot}C_9NH_5Me\ [Me : N = 1 : 4]$, is obtained as a bye-product when 4 : 1-nitromethylquinoline is reduced with iron and hydrochloric acid. It melts at 260°, crystallises from acetic acid in orange needles, and is insoluble in hot water and nearly so in alcohol, benzene, and chloroform. *Azoxymethylquinoline*, $\begin{matrix} C_9NH_5Me{\cdot}N \\ | \\ C_9NH_5Me{\cdot}N \end{matrix}\!>\!O$, is obtained as a second bye-product; it melts at 201°, and crystallises from alcohol in small, yellow needles insoluble in water.

Nitrodimethylquinoline, $C_9NH_4Me_2{\cdot}NO_2\ [Me_2 : NO_2 = 1 : 3 : 4]$, is obtained by treating 1 : 3-dimethylquinoline with nitric and sulphuric acids. It melts at 107—108°, and crystallises from alcohol in yellow needles, very slightly soluble in hot water. *Amidodimethylquinoline*, $C_9NH_4Me{\cdot}NH_2$, obtained by reducing the nitro-compound with iron and acetic acid, melts at 91°, crystallises from dilute alcohol in yellow needles, slightly soluble in hot water, and forms red mon-acid and colourless di-acid salts. Treated with acetic acid and anhydride, it yields an *acetyl derivative*, $C_9NH_4Me{\cdot}NHAc$, which melts at 201°, crystallises from hot water in white needles, very soluble in alcohol, and forms colourless salts with acids. *Hydroxydimethylquinoline*, $C_9NH_4Me_2{\cdot}OH$, obtained by adding sodium nitrite to a hydrochloric acid solution of the amido-compound, melts at 197—198°, crystallises from chloroform in white tables, very soluble in alcohol, slightly soluble in benzene and chloroform, and forms salts with acids and bases. C. F. B.

Some Ammonium Compounds. By H. Decker (*Ber.*, **25**, 443—444; compare this vol., p. 630).—When quinoline methyl hydroxide is oxidised with an alkaline solution of potassium ferricyanide, it is converted into 1′-methyl-α-quinolone (m. p. 72°), identical with

the compound prepared by Friedländer and Müller from carbostyril. Quinoline ethiodide behaves in like manner, and yields 1'-ethyl-α-quinolone (m. p. 52°) under the same conditions.

When isoquinoline methiodide is oxidised with an alkaline solution of potassium ferricyanide, it gives 2'-methylisoquinolone, which boils at 325—330° with decomposition; pyridine methiodide and pyridine ethiodide give, under the same conditions, 1-methyl-α-pyridone and 1-ethyl-α-pyridone respectively. Since the methiodides of pyridine, quinoline, isoquinoline, and acridine all show, in this respect, the same behaviour, it follows that the ammonium hydroxides of these bases have all the same structure, their difference in basicity being caused simply by a difference in the carbon nucleus in which the tertiary nitrogen atom is situated. F. S. K.

Pyrogenic Synthesis of Isoquinoline. By A. Pictet and S. Popovici (*Ber.*, **25**, 733—735).—When benzylideneethylamine, prepared according to Zaunschirm's directions (Abstr., 1888, 1077), is slowly distilled through a tube which is filled with pumice, and heated to dull redness, and the dried product fractionated, the fraction passing over between 235° and 240° is found to consist of isoquinoline, which is converted into sulphate, and the latter crystallised from alcohol; it was characterised by several of its derivatives.

A. R. L.

Nitro-derivative of Antipyrine. By E. Jandrier (*Compt. rend.*, **114**, 303—304).—*Nitro-antipyrine* is obtained by dissolving antipyrine in 10 times its weight of monhydrated sulphuric acid, and then adding, drop by drop, nitric acid of sp. gr. 1·35, in quantity equal to about 75 per cent. of the antipyrine. The product is poured slowly into cold water, and the precipitate is crystallised from boiling acetic acid. Nitro-antipyrine forms straw-coloured needles melting at 260°. It is insoluble in cold water, slightly soluble in alcohol, but readily soluble in hot acetic acid. With zinc and acetic acid, or tin and hydrochloric acid, it yields amido-antipyrine, and its diazo-derivative yields a ponceau colouring-matter with β-naphthol. C. H. B.

Alcohol of Antipyrine. By J. W. Brühl (*Ber.*, **25**, 395—397).—The observation that camphor is converted into borneol and camphocarboxylic acid, and menthone into menthol and a dicarboxylic acid, by the simultaneous action of sodium and carbonic anhydride (this vol., p. 201), led the author to examine the behaviour of dimethylphenylpyrazolone (antipyrine), under similar treatment. The *alcohol*, $C_{11}H_{14}N_2O$, is thus prepared:—To a solution of antipyrine (3 mols.) in boiling toluene, through which a current of carbonic anhydride is passing, sodium in the form of wire (4 equivs.) is added; a small quantity of methylamine is evolved, and a yellow precipitate separates; on now adding ice-cold water, the latter dissolves, but reprecipitates in a crystalline form after a time, and is collected; when repeatedly crystallised from dilute alcohol, it forms white prisms, melts at 145°, is sparingly soluble in water, light petroleum, and ether, readily so in other solvents. It combines in

molecular proportion with phenylcarbimide with the formation of the *compound* $C_{18}H_{19}N_3O_3$, melting at 173°, and gives a *benzoyl* derivative melting at 175° with decomposition. When its solutions in water, dilute alcohol, glacial acetic acid, and hydrochloric acid are boiled, it is converted into a compound which crystallises from light petroleum in satiny leaflets, and melts at 86°, whilst methylamine and aniline pass over. (Compare Knorr and Taufkirch, this vol., p. 708.)

A. R. L.

Pyrazole Derivatives. By L. Knorr and P. Duden (*Ber.*, **25**, 759—768).—*Phenylmethylpyrazolidone*, $NPh<^{NH\cdot CHMe}_{CO\cdot CH_2}$, is prepared by heating a mixture of crotonic acid with phenylhydrazine in molecular proportion, first at about 125°, and afterwards for a short time at 160°; the compound crystallises from alcohol in small, colourless needles, and from water in well-developed prisms, melts at 84°, boils at 321° (corr.), is not volatile with steam, and has basic, but not acid, properties, thus differing from the isomeric compound obtained by Lederer from phenylhydrazine and the β-haloïd butyric acid. The yield is 77 per cent. of the theoretical. By the oxidation of the pyrazolidone in alcoholic solution with ferric chloride, the corresponding pyrazolone (m. p. 127°) is obtained, and is identical with the compound formed from ethyl acetoacetate. By the action of ferric chloride in excess in aqueous solution at high temperatures on the pyrazolidone, pyrazole-blue, $NPh<^{N:CMe\quad CMe:N}_{CO\cdot C=\!=C-CO}>NPh$ is produced.

Nitrophenylmethylpyrazolone, $NPh<^{N:CMe}_{CO\cdot CH\cdot NO_2}$, is prepared by dissolving the parazolidone in warm, dilute nitric acid; it is precipitated by the addition of water, and crystallises from alcohol in transparent prisms, and from water in small, colourless needles, which melt at 127° when rapidly heated. By the action of sodium nitrite on the pyrazolidone hydrochloride, nitrosophenylmethylpyrazolone,

$$NPh<^{N:CMe}_{CO\cdot C:NOH},$$

is obtained as a brown, viscid liquid. The dichloropyrazolone, $NPh<^{N:CMe}_{CO\cdot CCl_2}$, is formed from the pyrazolidone by treatment with hydrochloric acid and calcium hypochlorite.

Phenylmethylpyrazole is prepared by the action of bromine or of phosphorus pentasulphide on the pyrazolidone; with bromine in excess, *mono-*, *di-*, and *tri-bromopyrazolones* are formed; the first melts at 128°, and the last at 83°.

On heating the pyrazolone with methyl iodide and methyl alcohol in excess, for 12 hours at 110—140°, *phenyldimethylpyrazolidone* (hydroantipyrine), $NPh<^{NMe\cdot CHMe}_{CO-CH_2}$, is obtained; the product is treated with soda, the alcohol removed, and the base purified by extraction with chloroform and recrystallisation from water; it is

deposited in long, flat needles melting at 107°. The *hydrochloride* crystallises in small, slender, hygroscopic needles; the *picrate* melts at 145—146°. Attempts to convert the base into antipyrine by oxidation were unsuccessful. The difference in behaviour between phenylmethylpyrazolone and phenyldimethylpyrazolidone towards oxidising agents is explained by the formation of a double linking between the carbon and nitrogen atoms, consequent on the removal of two hydrogen atoms in the positions 2 : 3 from phenylmethylpyrazolidone; the removal of hydrogen atoms in the position 3 : 4 would not explain the greater relative stability of the dimethyl compound towards oxidising agents; this affords a further proof of the correctness of Knorr's pyrazolone formula, but tells against the one, $NPh<\begin{matrix}NH\cdot CMe\\ \|\\ CO\cdot CH\end{matrix}$, recently suggested by Nef.

Although the action of phenylhydrazine on crotonic acid differs from its action on cinnamic acid, in so far as no intermediate compounds could be isolated, it is probable that the production of the pyrazolidone is preceded by the formation of a compound

$$NHPh\cdot NH\cdot CHMe\cdot CH_2\cdot COOH.$$

The authors comment on recent papers by Lederer (*Annalen*, **238**, 146) and Claisen (this vol., p. 506), regarding the nomenclature of this class of compounds; Lederer's "hydropyrazolone" and "isopyrazolone" are termed pyrazolidone and 3-pyrazolone respectively. Claisen's suggestion to distinguish the carbon atoms in the pyrazole ring by means of Greek letters is considered to be undesirable, it being simpler to number the whole of the atoms comprising the ring. J. B. T.

Hydroxyquinoxalines and Ethoxyquinoxalines. By W. Autenrieth and O. Hinsburg (*Ber.*, **25**, 492—503).—*Parethoxyquinoxaline*, $OEt\cdot C_6H_3<\begin{matrix}N:CH\\ |\\ N:CH\end{matrix}$, is obtained by adding glyoxal hydrogen sulphite to a hot solution of ethoxyphenylenediamine and precipitating with soda. It is easily soluble in hot water, alcohol, and ether, melts at 81°, is volatile with steam, and has an odour resembling that of aniseed. When reduced with tin and hydrochloric acid, it is partly converted into resinous products, partly split up to form ethoxyphenylenediamine.

Parahydroxyquinoxaline cannot be obtained by hydrolysing the preceding compound with hydrochloric acid. It is easily prepared by adding glyoxal hydrogen sulphite to hydroxyphenylenediamine dissolved in acetic acid. It resembles parahydroxyquinoline in general properties, crystallises from hot water in pale-yellow needles, forms yellow salts both with acids and alkalis, and melts at 245°.

Parethoxydiphenylquinoxaline, $OEt\cdot C_6H_3<\begin{matrix}N:CPh\\ |\\ N:CPh\end{matrix}$, is obtained by boiling a mixture of ethoxyphenylenediamine and dibenzoyl in alcoholic solution for a short time. It crystallises from alcohol in slender, lustrous, pale-yellow needles, melts at 150°, gives a deep-red colora-

tion with concentrated sulphuric acid, and is easily soluble in ether, alcohol, and chloroform, insoluble in water.

Parahydroxydiphenylquinoxaline is obtained by hydrolysing the preceding compound with concentrated hydrochloric acid at 160—180°. It crystallises from alcohol in pale-yellow prisms, melts at 251°, and forms unstable salts both with mineral acids and with alkalis.

Ethoxynaphthazine, $OEt\cdot C_6H_3{<}\overset{N}{\underset{N}{\vdots}}{>}C_{10}H_6$, is obtained by mixing ice-cold acetic acid solutions of β-naphthaquinone and ethoxyphenylenediamine. It is best purified by cautious sublimation, crystallises from dilute alcohol in slender, yellow needles, is insoluble in water, and melts at 186—187°. Its solution in sulphuric acid is green by reflected light, violet-red by transmitted light. A small quantity of a lower melting isomeride is formed at the same time, but it has not yet been obtained pure.

Parethoxyphenanthrazine, $OEt\cdot C_6H_3{<}\begin{matrix}N\cdot C{-}C_6H_4\\ \|\quad\ \ |\\ N\cdot C{-}C_6H_4\end{matrix}$, is obtained in quantitative proportions by adding an alcoholic solution of the diamine to a hot acetic acid solution of phenanthraquinone. It forms slender, yellowish-white crystals, melts at 210°, is sparingly soluble in ether, alcohol, and acetic acid, more soluble in chloroform, and gives with concentrated sulphuric acid a beautiful, bluish-violet coloration, which, on the addition of water, changes to yellow.

Parahydroxyphenanthrazine is obtained by hydrolysing the preceding compound with hydrochloric acid. It crystallises from acetic acid in slender, sulphur-yellow needles, melts above 300°, sublimes almost unchanged, gives a reddish-violet coloration with concentrated sulphuric acid, and forms salts with sodium hydroxide and hydrochloric acid, which are decomposed by water. It dyes wool and cotton yellow in alkaline baths.

Ethyl ethoxyhydroxyquinoxalineacetate, $OEt\cdot C_6H_3{<}\begin{matrix}N{:}C\cdot OH\\ |\\ N{:}C\cdot CH_2\cdot COOEt\end{matrix}$, is obtained by gently heating a mixture of ethyl oxalacetate and ethoxyorthophenylenediamine in dilute acetic acid. It crystallises from dilute alcohol in slender, yellow needles, melts at 186°, is almost insoluble in water, easily soluble in alcohol and ether, and gives a colourless solution with sodium hydroxide, and a yellowish-red coloration with concentrated sulphuric acid.

Ethoxyhydroxymethylquinoxaline, $OEt\cdot C_6H_3{<}\begin{matrix}N{:}C\cdot OH\\ |\\ N{:}CMe\end{matrix}$, is obtained by heating the preceding compound with aqueous sodium hydroxide; it crystallises from dilute alcohol in white leaflets, melts at 224°, and has feeble basic and acid properties.

Parethoxyquinoxalinedicarboxylic acid, $OEt\cdot C_6H_3{<}\begin{matrix}N{:}C\cdot COOH\\ |\\ N{:}C\cdot COOH\end{matrix}$, is obtained by the condensation of sodium dihydroxytartrate with ethoxyphenylenediamine. It melts at 186° with evolution of carbonic anhydride, is easily soluble in hot water and alcohol, more sparingly so in ether, and gives a deep-red coloration with concentrated sulphuric acid.

Parethoxydihydroxyquinoxaline is obtained by heating metethoxyorthophenylenediamine oxalate at 150—160°; it crystallises in slender, colourless needles, melts above 300°, and is somewhat easily soluble in hot water and alcohol.

Trihydroxyquinoxaline, $OH\cdot C_6H_3<\begin{matrix}N:C\cdot OH\\ |\\ N:C\cdot OH\end{matrix}$, is obtained by heating the preceding compound with concentrated hydrochloric acid at 180°. It forms microscopic needles, is sparingly soluble in the usual solvents, sublimes with partial decomposition, and gives a yellowish-green coloration with concentrated sulphuric acid.

Parethoxypiazthiole, $OEt\cdot C_6H_3.N_2S$, is obtained by heating ethoxyphenylenediamine with sodium hydrogen sulphite at 180° and distilling the product with steam. It crystallises from alcohol in colourless needles, melts at 76—77°, has an intense odour resembling anise seed, and is easily soluble in alcohol and ether, sparingly so in cold water. It yields yellow salts with concentrated mineral acids which are decomposed by water. When boiled with tin and hydrochloric acid, it is converted into hydrogen sulphide and ethoxyphenylenediamine.

Parahydroxypiazthiole is obtained by heating the preceding compound with concentrated hydrochloric acid at 170°; it crystallises in leaflets, is easily soluble in alcohol and ether, and melts at 157—158°.

E. C. R.

Synthesis of Phenotriazines. By M. Busch (*Ber.*, **25**, 445—452).—*β-Phenophenyldihydrotriazine*, $C_6H_4<\begin{matrix}N=N\\ |\\ CH_2\cdot NPh\end{matrix}$, can be obtained by gradually adding an aqueous solution of the theoretical quantity of sodium nitrite to a well-cooled solution of orthamidobenzylphenylhydrazine in a slight excess of dilute hydrochloric acid; it is, however, best prepared from orthamidobenzylaniline (m. p. 86—87°) in a similar manner. It crystallises from dilute alcohol in lustrous, almost colourless plates, melts at 128° with decomposition, and is readily soluble in alcohol, ether, and benzene, but more sparingly in light petroleum, and almost insoluble in water; its salts with mineral acids are only stable in acid solution. The *hydrochloride* crystallises in slender, yellowish-green needles; the *sulphate* is also yellowish-green. The *platinochloride*, $(C_{13}H_{11}N_3)_2,H_2PtCl_6$, crystallises in dark-yellow needles which melt and explode at 130°. The *picrate*, $C_{13}H_{11}N_3,C_6H_3N_3O_7$, crystallises in orange-red needles and melts at 111°, exploding at the same time.

Orthamidobenzylparatoluidine hydrochloride, $C_{14}H_{17}N_2,2HCl$, crystallises from dilute hydrochloric acid in long, compact, seemingly rhombic prisms, and is readily soluble in cold water; the free base has been previously described by Söderbaum and Widman (Abstr., 1890, 1258).

β-Phenoparatolyldihydrotriazine, $C_6H_4<\begin{matrix}N:N\\ CH_2\end{matrix}>N\cdot C_6H_4Me$, prepared by treating orthamidobenzylparatoluidine hydrochloride with nitrous acid under the conditions already described, crystallises from alcohol in lustrous, yellow plates, melts at 151° with decomposition, and is

only sparingly soluble in ether and cold alcohol, but more readily in hot alcohol and benzene; it is very sparingly soluble in light petroleum, and almost insoluble in water. Its salts with mineral acids are only stable in acid solution. The *hydrochloride* crystallises in slender, yellow needles, and is readily soluble in alcohol. The *platinochloride*, $(C_{14}H_{13}N_3)_2,H_2PtCl_6$, crystallises in lustrous, orange needles, begins to turn brown at 148°, and melts at 190° with decomposition and previous softening. The *picrate*, $C_{14}H_{13}N_3,C_6H_3N_3O_7$, crystallises in dark-yellow, lustrous needles, melts and explodes at 132°, and is only sparingly soluble in alcohol. F. S. K.

Triazole. By J. A. Bladin (*Ber.*, **25**, 741—745).—*Nitrophenyltriazolecarboxylic acid*, $CH\ll^{N\cdot N\cdot C_6H_4\cdot NO_2}_{N:C\cdot COOH}$, is prepared by boiling phenyltriazolecarboxylic acid with a mixture of nitric acid (10 parts) and sulphuric acid (5 parts) for 8—10 minutes, pouring into water at 0°, and crystallising the precipitated compound from glacial acetic acid, from which it crystallises in colourless leaflets containing 1·5 mols. of acetic acid, which are given off at 100°; it melts at 202°.

Amidophenyltriazolecarboxylic acid, $CH\ll^{N\cdot N\cdot C_6H_4\cdot NH_2}_{N:C\cdot COOH}$, obtained by reducing the nitro-compound, is a white, crystalline powder which dissolves readily in ammonia, the solution becoming coloured on boiling; it is also soluble in boiling hydrochloric acid, and melts at 212°.

Triazolecarboxylic acid, $CH\ll^{N\cdot N}_{N:C\cdot COOH}$, is produced when the last-described amido-acid (8 grams) is dissolved in 50 per cent. sodium hydroxide (60 grams), and to the warm solution a concentrated one of potassium permanganate (40 grams) is gradually added; after 12 hours heating on the water-bath, it is filtered, the filtrate acidified with acetic acid, and copper sulphate added, whereby an amorphous, blue salt separates; this is washed, and boiled with alkali and a few drops of ammonium sulphide, on acidifying the filtrate, the acid separates as a white, amorphous precipitate which melts at 137° with the evolution of gas and the formation of triazole, identical with Andreocci's pyrrodiazole (this vol., p. 637). The acid has therefore properties different from those of the pyrrodiazolecarboxylic acid described by Andreocci (*loc. cit.*), and it forms, in addition to the above-mentioned copper salt, a second one, which is a green, crystalline powder containing 2 mols. H_2O. A. R. L.

Synthesis of Closed Chains: Piperylbiguanide. By E. Bamberger and L. Seeberger (*Ber.*, **25**, 525—533).—By the action of potassium hydroxide on piperylbiguanide in chloroform solution for 8 to 10 days at ordinary temperatures, *piperylformoguanamine*, $C_5NH_{10}\cdot C<^{N\text{——}CH}_{N\cdot C(NH_2)}>N$, is formed, and is separated by removing the excess of chloroform, dissolving the residue in highly dilute

sulphuric acid, and precipitating the base with soda; on crystallisation from water or dilute alcohol, it is deposited in slender, lustrous prisms or needles melting at 194·5°. The compound resembles formoguanamine in general properties, and is either unacted on by acids and alkalis, or is decomposed with elimination of ammonia and piperidine. The *oxalate* is sparingly soluble; the *hydrochloride* crystallises from water or alcohol in small, colourless needles melting at 201° with previous softening at 100°. The *sulphate* is deposited in lustrous plates containing 1 mol. H_2O, and melts at 221—222°; the *picrate* forms yellow, dendritic needles which soften at 175° and melt at 188°. The *platinochloride* crystallises in orange-yellow, flat needles melting at 219° with decomposition; the *aurochloride* crystallises with difficulty in slender, yellow needles; it melts at 90°, and slowly undergoes decomposition at ordinary temperatures. The base yields two *argentonitrates;* the one has the formula $(C_8H_{13}N_5)_2,AgNO_3$, and is formed by mixing aqueous or alcoholic solutions of piperylformoguanamine and silver nitrate; it crystallises from water in colourless, concentric needles melting at 229—238° with decomposition; the second compound, $C_8H_{13}N_5,AgNO_3$, is amorphous, and is precipitated by the cautious addition of highly dilute ammonia to dilute solution in alcohol of its components. Piperylformoguanamine is also formed by heating anhydrous piperylbiguanide with half its weight of anhydrous sodium formate for a short time at about 160°. *Piperylacetoguanamine*, $C_5NH_{10}\cdot C<\begin{matrix}N---CMe\\ N\cdot C(NH_2)\end{matrix}>N$, is obtained in a similar manner by heating piperylbiguanide sulphate with sodium acetate at 190—200°, or together with ammeline, by heating piperylbiguanide acetate at about 215° (see below); it crystallises from alcohol in long, flat needles or small plates which melt at 177—179°; the yield is very small.

Piperylbiguanide acetate is prepared from the cupro-derivative, and crystallises in needles melting at 193°.

The authors explain the production of piperylformoguanamide from chloroform and piperylbiguanide by assuming that piperyldichloromethylbiguanide, $NH{:}C(NH_2)\cdot NH\cdot C(C_5NH_{10}){:}N\cdot CHCl_2$, is first formed, and changes spontaneously into a closed chain compound,

$$C_5NH_{10}\cdot C<\begin{matrix}N---CHCl\\ NH\cdot C(NH_2)\end{matrix}>N;$$

from this a molecule of hydrogen chloride is eliminated by the action of potash, giving rise to piperylformoguanamide. J. B. T.

Synthesis of Guanamine. By E. Bamberger and W. Dieckmann (*Ber.*, **25**, 534—542; compare preceding abstract).—Formoguanamine may be prepared by heating biguanide sulphate with anhydrous sodium formate at 150—200°, and also by the action of alcoholic potash and chloroform on biguanide hydrochloride. Isoamylguanamine can be obtained in a similar manner by heating biguanide caprate, or by fusing biguanide sulphate with sodium caprate for 1—1½ hours at 220—230°.

Acetoguanamine and ammeline are the sole products formed, the latter in larger proportion, by heating biguanide acetate at 230°; it is

also produced during the preparation of formoguanamine from guanidine formate.

Attempts to obtain tricyanogen derivatives from formic acid and formamidine, acetamidine, or benzamidine by a method analogous to Nencki's guanamine synthesis were fruitless.

The authors believe the production of formoguanamine from biguanide and chloroform to be preceded by the formation of the intermediate products $NH{:}C(NH_2)\cdot NH\cdot C(NH_2){:}N\cdot CHCl_2$ and

$$NH_2\cdot C\lessdot\begin{matrix}NH\cdot C(NH_2)\\ N\text{——}CHCl\end{matrix}\gtrdot N,$$

and they regard the synthesis of guanamines from guanidine salts as consisting, in a condensation to the corresponding biguanide salt, which then, by dehydration, yields an intermediate compound, $NH{:}C(NH_2)\cdot NH\cdot C(NH_2){:}N\cdot CR{:}O$; this readily forms a closed chain, and finally a guanamine derivative $NH_2\cdot C\lessdot\begin{matrix}N\cdot C(NH_2)\\ N\text{——}CR\end{matrix}\gtrdot N$, by the elimination of a second molecule of water. J. B. T.

Biguanide. By E. Bamberger and W. Dieckmann (*Ber.*, **25**, 543—546).—According to the explanation given by the authors of Nencki's guanamine synthesis (compare preceding abstract), the first step consists in the formation of biguanide and ammonia from guanidine. Anhydrous guanidine hydrochloride is heated in portions of 1 gram in an oil-bath at 180—185° for 3—4 minutes, the residue is dissolved in water, filtered in order to separate any ammeline which may have been formed, and the filtrate treated with cuprammonium sulphate solution; cuprobiguanide sulphate, $(C_2H_6N_5)_2,CuSO_4$, immediately separates in slender, lustrous, rose-coloured needles. The reaction proceeds so readily that it may be employed as a lecture demonstration.

The failure of Nencki and Rathke to obtain biguanide from guanidine was probably caused by their employing the free base or the carbonate.

The authors have investigated Smolkau and Friedrich's method of preparing biguanide; the best yield is obtained by intimately mixing anhydrous ammonium chloride (8 grams) with dicyanodiamide (5 grams), and heating at 195° for 5—10 minutes; the residue is extracted with water. *Biguanide picrate* crystallises from water in golden-yellow, lustrous, broad needles which melt at 232°, and are sparingly soluble. *Biguanide hydrogen sulphate* crystallises in lustrous, rhombic prisms, $a : b : c = 0{\cdot}5802 : 1 : 0{\cdot}3607$. J. B. T.

Alkaloïds of the Areca Nut. By E. Jahns (*Arch. Pharm.*, **229**, 669—707).—The coarsely-powdered areca nut was extracted three times with very dilute, cold sulphuric acid, the united extracts concentrated to about the same weight as the original material, and the alkaloïds precipitated with potassium bismuthoiodide, an excess of the latter being avoided, since it has a solvent action on the precipitate. The washed precipitate was then boiled with an excess of barium carbonate, the solution filtered, concentrated to a syrup, an

excess of barium hydroxide added, and the mixture repeatedly extracted with ether. The ether separates one alkaloïd, arecoline, which remains, after distilling off the ether, as a liquid.

The alkaline liquid remaining after exhaustion with ether was freed from barium and iodine by the addition of sulphuric acid and silver carbonate, the excess of silver and sulphuric acid precipitated by hydrogen sulphide and the cautious addition of barium hydroxide respectively, and the solution evaporated nearly to dryness. The residue was then exhausted with repeated quantities of absolute alcohol, which separates choline, whilst there remain three alkaloïds, arecaïne, arecaïdine, and guvacine. These three cannot be readily separated from one another by mere crystallisation. The arecaïdine was converted into arecoline (see below) by dissolving the mixture of the three alkaloïds in methyl alcohol and passing dry hydrogen chloride into the solution. The arecoline hydrochloride thus formed remains dissolved, whilst the hydrochlorides of the other two alkaloïds are almost insoluble. They were collected, and the bases liberated by the addition of silver carbonate. These were then separated from one another by dissolving the mixture of the two in hot water, and carefully adding absolute alcohol until crystallisation commenced, guvacine separating first. The process must, however, be repeated several times.

Arecoline, $C_8H_{13}NO_2$, was purified by converting it into the hydrobromide, recrystallising, liberating the base by the addition of solid potash, and extracting with ether. It is a colourless, odourless, strongly-alkaline, oily liquid, miscible in water, alcohol, ether, and chloroform, volatile with steam, and boiling at 209° with partial decomposition. Its normal salts are readily soluble, sometimes hygroscopic, but crystallisable. With potassium bismuthoiodide, they form a dark-red precipitate; with phosphomolybdic acid, a white precipitate; potassium mercury iodide precipitates a yellow, oily liquid which becomes gradually crystalline; iodine precipitates a brown liquid; picric acid, a tarry, gradually crystallising precipitate; auric chloride, a liquid which does not crystallise. Platinic chloride, mercuric chloride, and tannin produce no precipitates. The aqueous solution of the free alkaloïd is, however, precipitated by tannin.

Arecoline hydrobromide, $C_8H_{13}NO_2,HBr$, is readily soluble in water and in hot alcohol, less readily in cold alcohol. It forms long, thin, anhydrous prisms, permanent in the air, and melts at 167—168°. The *hydrochloride*, *sulphate*, *nitrate*, and *acetate* are crystalline, hygroscopic, and soluble in alcohol, water, and in a mixture of ether and alcohol; the *aurochloride*, $C_8H_{13}NO_2,HAuCl_4$, is a yellow, oily liquid, sparingly soluble in cold alcohol, more readily in hot alcohol; the *platinochloride*, $(C_8H_{13}NO_2)_2,H_2PtCl_6$, forms orange-red plates belonging to the rhombic system. (For the physiological properties of these alkaloïds, see Marmé, *Pharm. Zeit.*, 1889, 97; and Therap, *Monatsh.*, 1890.)

By heating arecoline with concentrated hydrochloric acid, either on the water-bath or in a sealed tube at 150°, arecaïdine and methyl chloride are formed. The same change is effected by hydriodic acid at a boiling heat, and concentrated alkalis act in a similar manner.

Arecaïdine, $C_{17}H_{11}NO_2 + H_2O$, was separated (see above) by converting it primarily into arecoline, which may be reconverted into arecaïdine by the methods just named. Boiling with barium hydroxide is the preferable method. It is recrystallised from 60 or 70 per cent. alcohol. It forms colourless, permanent crystals, readily soluble in water and in dilute alcohol, almost insoluble in absolute alcohol, insoluble in ether, chloroform, and benzene. The aqueous solution is neutral; with ferric chloride, it is coloured slightly red. It loses its water of combination at 100°, and melts at 223—224°. Its simple salts are crystalline, readily soluble in water, less readily in alcohol, and the solutions are acid. The *platinochloride*, $(C_7H_{11}NO_2)_2,H_2PtCl_6$, forms yellow octahedrons, and melts at 208—209°; the *aurochloride*, $C_7H_{11}NO_2,HAuCl_4$, decomposes when warmed with water; it melts at 197—198°.

Methylarecaïdine, $C_7H_{10}MeNO_2$, prepared by dissolving the alkaloid in methyl alcohol and passing dry hydrogen chloride into the solution, was found to be identical with arecoline.

The *ethyl* compound, *homarecoline*, $C_7H_{10}EtNO_2$, is prepared in the corresponding manner, and forms a colourless, strongly alkaline liquid, miscible with water, alcohol, and ether, and may be distilled with steam. It is poisonous, like arecoline. The simple salts resemble the corresponding arecoline salts. The aurochloride and the platinochloride are also similar.

Methylarecaïdine and ethylarecaïdine are salts of arecaïdine, this base containing a carboxyl group. The acid character of arecaïdine is, however, much less pronounced than its basic properties; it does not decompose carbonates readily, and its salts with the metals could not be obtained pure. When heated with barium hydroxide, methylamine is eliminated, indicating the presence of a methyl group attached to the nitrogen, and accordingly the formula $C_5NH_7Me{\cdot}COOH$ is assigned to arecaïdine, which thus would seem to be a tetrahydropyridine derivative. Attempts to remove the side chains and so arrive at pyridine proved fruitless. It may, however, readily be reduced and converted into a piperidine derivative by the action of sodium on the amyl alcohol solution. After the completion of the reaction, water is added, the amyl alcohol separated, the solution acidified with hydrochloric acid, and brought to dryness, extracted with alcohol, evaporated, water added, and the chlorine separated again by addition of silver oxide. The *dihydroarecaïdine* is then separated by chloroform and recrystallised from alcohol and ether. It forms very small crystals, readily soluble in water, alcohol, and chloroform, insoluble in ether; its solutions are neutral. Its formula is $C_7H_{13}NO_2 + H_2O$; it melts at 120°, but if first dried at 100°, the water separates, and the anhydrous base then melts at 162—163°. The *platinochloride* crystallises from ether-alcohol in anhydrous prisms, and melts at 215—216°. The *aurochloride* melts at 158—159°.

The *methyl salt*, *dihydroarecoline*, $C_5NH_9Me{\cdot}COOMe$, prepared by passing hydrogen chloride into the methyl alcohol solution, is, like arecoline, a colourless, strongly alkaline liquid, volatile with steam, and miscible with water, alcohol, and ether. The *hydrochloride* and *hydrobromide* are well characterised salts.

The constitution of these bases, arecaïdine, arecoline, and dihydroarecaïdine was eventually arrived at by synthesising them from methyltetrahydronicotinic acid. Methyl nicotinate was converted into methylnicotinic anhydride, and this was then reduced by tin and hydrochloric acid at the boiling temperature during one or two days. Both *methylhexahydronicotinic acid* and *methyltetrahydronicotinic acid* are formed, and are separated from one another by chloroform, the former being soluble. Methyltetrahydronicotinic acid,

$$C_5NH_7Me\cdot COOH,$$

is identical with arecaïdine; methylhexahydronicotinic acid,

$$C_5NH_9Me\cdot COOH\ [Me : COOH = 1 : 3],$$

is identical with dihydroarecaïdine, whilst methyl methyltetrahydronicotinate, $C_5NH_7Me\cdot COOMe$, is identical with arecoline.

Guvacine, $NH<\begin{matrix}CH_2\text{---}CO\\CH_2\cdot CHMe\end{matrix}>CO$, forms lustrous, colourless, permanent crystals, readily soluble in water, less soluble in dilute alcohol, insoluble in absolute alcohol, ether, chloroform, and benzene. The aqueous solution is neutral, and is coloured deep red by ferric chloride. It melts at 271—272° with decomposition. It has no action on the animal organism. Its salts are crystalline, soluble in water, of acid reaction, and insoluble in alcohol. The *hydrochloride* is anhydrous; the *platinochloride* crystallises with 4 mols. H_2O, which are liberated at 100°, and the salt melts a little above 210° with decomposition; the *aurochloride* is anhydrous, and melts at 194—195°.

Nitrosoguvacine, $C_6H_8NO_2\cdot NO$, prepared by heating the hydrochloride with sodium nitrite, is crystalline, sparingly soluble in cold water, readily soluble in hot water, fairly soluble in alcohol and ether. It is anhydrous, and melts at 167—168°. It gives Liebermann's nitroso-reaction, and does not colour a solution of potassium iodide and starch blue. No methyl *salt* could be prepared by treating the base in methyl alcohol with hydrogen chloride, thus showing the absence of the carboxyl group. It unites with potassium hydroxide as a phenol would do. Further, an *acetylguvacine*, $C_6H_8AcNO_2$, is obtained by treating guvacine with sodium acetate and acetic anhydride. It crystallises from absolute alcohol in anhydrous plates, and is sparingly soluble in cold water and alcohol; its solution is strongly acid.

Methylguvacine, $NMe<\begin{matrix}CH_2\text{---}CO\\CH_2\cdot CHMe\end{matrix}>CO$, is obtained by heating guvacine with sodium methoxide and an excess of potassium methyl sulphate at 140—150°. It forms a colourless, neutral, crystalline base, readily soluble in water and dilute alcohol, sparingly in hot absolute alcohol, and insoluble in cold alcohol. It crystallises with 1 mol. H_2O, which separates at 100°. It melts at 214—215°. Methylguvacine is identical with arecaïne. If it be heated with hydriodic acid at 150°, no change occurs, thus showing that the methyl group is not combined to the carbonyl group, but to the nitrogen. It is not strongly coloured by ferric chloride. It forms acid salts, readily soluble in water, less soluble in alcohol. The *platino-*

chloride forms orange-yellow, anhydrous, octahedrons, which melt at 213—214°; the aurochloride melts at 186—187°. J. W. L.

Cholic Acid and Dehydrocholic Acid. By Lassar-Cohn (*Ber.*, **25**, 803—811).—On heating potassium cholate with potassium hydroxide at a temperature of 245° (in amyl benzoate vapour), an amorphous acid is obtained, which probably has the formula $C_{19}H_{30}O_3$, and does not give a blue coloration with iodine. An amorphous product containing 33·6 per cent. of chlorine, is also formed by the action of phosphoric chloride on cholic acid in chloroform solution.

Dehydrocholic acid may be obtained by the oxidation of crude cholic acid; it combines with alcohol on warming, and consequently a pure preparation cannot be obtained by crystallisation from this solvent. The acid is readily deposited from a mixture of acetone and benzene, has the formula $C_{24}H_{34}O_5 + \frac{1}{2}C_6H_6$, and then melts at 239°; cholic acid, therefore, has the formula $C_{24}H_{40}O_5$. *Ethyl dehydrocholate* melts at 221°.

By the action of phosphoric chloride (4 mols.) on dehydrocholic acid (1 mol.) in chloroform solution, and treatment of the product with zinc-dust, a compound is formed which has the formula $C_{24}H_{32}O_3Cl_2$; it is proposed to term this *dichlorisodehydrocholal*. It crystallises from dilute alcohol, melts at 257°, and may be heated above its melting point without decomposition; the yield is one-seventh of the acid employed.

Isodehydrocholal, $C_{24}H_{34}O_5$, is obtained by dissolving the preceding compound in concentrated sulphuric acid, and adding water. It crystallises from alcohol, melts at 242°, has neither acid nor basic properties, and is isomeric with dehydrocholic acid.

The aqueous mother liquor obtained during the preparation of dichlorisodehydrocholal contains *chlorodehydrocholic acid*, $C_{24}H_{33}O_3Cl$; it is purified by means of the sodium and barium salts, crystallises from dilute acetic acid in thin plates, melts at 241°, and yields dehydrocholic acid on treatment with phosphorus and hydriodic acid. The *silver salt* is sparingly soluble. J. B. T.

Oxidation of Albumin in presence of Sulphur. By E. Rösing (*Chem. Centr.*, 1891, ii, 946—947).—When considerable quantities of an emulsion of pure sulphur are injected subcutaneously into dogs and rabbits, symptoms of hydrogen sulphide poisoning are developed. In investigating the cause of this, it was found that formation of hydrogen sulphide takes place when a current of air, hydrogen, or carbonic acid is aspirated through defibrinated animal blood mixed with the sulphur emulsion. The same occurs if the blood is diluted with 10 times its volume of water, but not if potassium ferricyanide or large quantities of sodium or potassium chloride are present, or if the blood has been previously boiled. With egg-albumin similar results are obtained. Doubtless the albumin is oxidised, a hydroxyl group, derived from a molecule of water replacing a hydrogen atom in the albumin molecule, whilst the displaced hydrogen atom unites with the remaining hydrogen atom of the water molecule and with an atom of sulphur to form hydrogen sulphide. In support

of this view it was shown that in the absence of water the formation of hydrogen sulphide does not take place, and it is hindered by the presence of neutral salts that can combine with water. And again if the albumin has been previously "hydroxylated" with ferricyanide, permanganate, or iodine solution, no hydrogen sulphide is formed; the same happens after a previous boiling of the albumin with water, hence a "hydroxylation" of albumin must take place when it is boiled with water. Parallel cases of oxidation may be observed with benzaldehyde and acetaldehyde; if these substances are mixed with sulphur and exposed to air and light, they oxidise, hydrogen being replaced by hydroxyl, and formation of hydrogen sulphide can be observed.

Many proteïds react in this way when mixed with sulphur; some at the ordinary temperature, some not until heated to 37°, or even to 100°. But most plant-proteïds do not react, neither do horn-shavings, human hair, α- and β-gluten, fibrin preserved in glycerol, hemi-albumose, nor peptone. On the other hand, it is remarkable that albumin, after it has been boiled with water, still forms hydrogen sulphide when digested with gastric juice. C. F. B.

Physiological Chemistry.

Influence of Amido-acids on Gastric Digestion. By E. Salkowski (*Virchow's Archiv*, **127**, 501—518).—In a previous communication (Abstr., 1891, 593), it was stated that although amido-acids, like glycocine and leucine, form loose combinations with hydrochloric acid, they have no important action on the digestive processes carried on by artificial gastric juice, and this has since been adversely criticised by T. Rosenheim (*Centr. klin. Med.*, 1891, No. 39), and F. A. Hofmann (*ibid.*, No. 42). The former has used fibrin, the latter white of egg, and both find that the amido-acids very considerably lessen the activity of gastric juice. In the present research, fresh experiments are recorded in which it is found that the lessening when fibrin is used is almost negligible; with white of egg, it is greater, although not so great as Hofmann states. A factor which appears to influence the result is the amount of proteïd in proportion to the total volume of the digesting mixture. W. D. H.

Assimilation of Carbohydrates. By Hanriot and by A. Gautier (*Compt. rend.*, **114**, 371—374; 374—375).—Hanriot and Richet have shown previously that during the digestion of farinaceous food the coefficient of respiration rises, and may become greater than unity. Hanriot now finds that the coefficient exceeds unity whenever a fasting person is fed with a carbohydrate mixed with a large quantity of water. With 50 grams of glucose dissolved in 1000 c.c. of

water, the coefficient rose in every case to nearly 1·25. This increase in the coefficient is not affected by administration of capsules containing naphthol, and therefore is not due to intestinal fermentation.

Direct experiment shows that the oxygen absorbed, and the carbonic anhydride evolved, during the complete digestion of a known weight of glucose by a person previously fasting, are almost identical with the quantities calculated on the assumption that the glucose is directly converted into fat (that is, oleostearopalmitin), in accordance with the equation $13C_6H_{12}O_6 = C_{55}H_{104}O_6 + 23CO_2 + 26H_2O$. The time of conversion of the glucose is practically constant whatever the quantity of glucose absorbed, but with a quantity greater than 75 grams there is considerable oppression.

Gautier points out that Hanriot's experiments furnish conclusive proof that in many vital processes even warm-blooded animals behave like anaërobic organisms. His own researches on ptomaïnes established this point several years ago. The hydropyridic bases formed in the tissues, the extractive matters, and urea may be regarded as products of the anaërobic fermentation of the proteïds.

C. H. B.

Absorption of Carbonic Oxide by the Blood of a Living Mammifer. By N. Gréhant (*Compt. rend.*, **114**, 309—310).—Carbonic oxide dissolves in the blood corpuscles of living animals in accordance with Dalton's law. By means of his method the author was able to detect 1 part of carbonic oxide in 20,000 parts of the atmosphere of a carriage that had been heated for five hours with a briquette.

C. H. B.

Sugar in Blood. By J. Seegen (*Centr. Physiol*, **5**, 821—826, 869—872).—Bernard was the first to show that in drawn blood the sugar somewhat rapidly disappears. Lépine has recently attributed to this considerable importance, as he believes glycolysis occurs in the circulating blood, and is due to a ferment contained in the white corpuscles, but primarily formed in the blood by the pancreas. After extirpation, diabetes occurs, and this, according to Lépine, is the result of the absence of the glycolytic ferment.

In the present research, the fact that the sugar disappears when the blood is shed is fully confirmed; its disappearance is not influenced by the addition of chloroform, which, according to Salkowski, kills the organised ferments, but not the unorganised. Exclusion of bacteria by other methods does not prevent the disappearance of sugar. The ferment action is hindered by cold, occurs rapidly at 39—40°, and is destroyed at 54·5°. The conclusion is drawn that the ferment is formed by *post-mortem* changes in the blood.

W. D. H.

Excretion of Nitrogen in Kidney Disease. By H. Kornblum (*Virchow's Archiv*, **127**, 409—445).—Very complete observations are recorded, comparing the quantity and specific gravity of the urine, together with the nitrogen and phosphoric acid excreted in four cases

of Bright's disease with the normal. The food given was also analysed. The urine was collected and examined at intervals of six hours. In estimating the nitrogen in the urine, that contained in the albumin passed in the urine in such cases must also be taken into account. The main outcome of the examination is that in nephritis, although nitrogenous metabolism is slow, there is no actual diminution in the output of nitrogen as compared with that ingested.

W. D. H.

Urohæmatoporphyrin. By A. E. GARROD (*Lancet*, i, 1892, 793).—The pigment present in the urine of rheumatic patients rarely, if ever, imparts a characteristic colour to the urine; after separation of the pigment, however, it usually shows in an alkaline solution the five-banded spectrum described by MacMunn as characteristic of urohæmatoporphyrin. In some cases it appears to be ordinary hæmatoporphyrin, and in acid solutions gives the two-banded spectrum characteristic of that substance. The occurrence is quite independent of drug treatment.

In 14 out of 20 cases of chorea, the same urinary pigment was present. In these 14 cases there was either a rheumatic history or the presence of cardiac murmurs. In the remaining cases, where the pigment was absent, cardiac trouble and rheumatic history (personal and family) were both absent.

W. D. H.

Chemical Pathology of Diphtheria, Anthrax, and Infective Endocarditis. By S. MARTIN (*Brit. Med. J.*, i, 1892, 641—644, 696—701, 755—759).—Just as the gastric cells produce a soluble ferment which produces the effect called digestion, so, in infective diseases, the organism which is the primary infective agent produces a soluble ferment which, acting on the substance that it comes in contact with, produces digestive products from them. These digestive products are the poisons that produce the symptoms of the disease. In the case of the anthrax bacillus, the products of digestion are very similar to those of peptic and tryptic digestion; these are proteoses, peptones, leucine, tyrosine, and, in addition, an alkaloïd. The chief symptoms of anthrax are fever and coma. The proteoses are the fever producers; the alkaloïd is the coma producer.

These results which have been previously obtained pointed the way to the further investigation of other infective disorders; and the present papers deal especially with diphtheria and ulcerative endocarditis. The tissues examined were chiefly the blood and spleen; in the spleen, the products of diphtheritic digestion accumulate to a great extent. The poisons are chiefly proteïds of the proteose class, and associated with these is an organic acid of uncertain nature. The proteoses formed by the *Bacillus diphtheriæ* in artificial cultivation have in single and multiple doses the same physiological action as those found in cases of diphtheria in man. The *Bacillus diphtheriæ* is, therefore, the primary infective agent. The following table gives a scheme of what may be termed diphtheria digestion:—

Primary infective agent.	Secondary infective agent.	Digestive products.
Bacillus diphtheriæ	Diphtheria ferment (Roux and Yersin's poison) in membrane	Hetero-proteose, Proto-proteose, Deutero-proteose } in membrane. Organic acid ..... } in body.

A soluble ferment is liberated in the membrane which, when absorbed, digests the proteïds of the body, forming proteoses and an organic acid. The diphtheritic products do not all come from the membrane direct, as often the products are abundant in the blood and spleen, but only small flecks of membrane may be present. The proteïds are more or less stagnating in the spleen; hence they are readily digested, and, moreover, digestion goes further, resulting in the formation of deutero-proteose and the organic acid.

The physiological effects of the proteoses are fever, loss of weight, a loss of coagulability of the blood, and a transient, local œdema. There is, however, nothing specific about these symptoms. The specific result, especially if the poison is given in successive small doses, is the production of paralysis exactly like that which is so characteristic of diphtheria. The anatomical cause of this is found to be a degeneration of the peripheral nerves; the medullary sheath and, subsequently, the axis cylinder are affected. The organic acid causes the same nerve degeneration, but is not so toxic as the proteoses.

In ulcerative endocarditis, the spleen is again the repository and manufactory of the chemical poisons, which are proteoses, and of a non-proteïd residue which is strongly acid. These produce fever and wasting, but no paralysis or nerve degeneration. Fatty degeneration of the heart is found, but this occurs also in the case of the diphtheritic and anthrax poisons. A preliminary examination of the blood in a case of tetanus shows that chemical poisons of the same nature are present in that disease. W. D. H.

Impure Chloroform. By R. du Bois-Reymond (*Brit. Med. J.*, i, 1892, 209—214).—Pictet's new method of refining chloroform enables one to divide commercial chloroform into two parts, the pure material and the residue of foreign substances. Physiological experiments with these two substances led to the following results, which will be interesting to those who have followed the work of the Hyderabad Commission:—

1. The shape of the pulse waves and the frequency of respiration is about equally affected by both substances, the rate of respiration varying freely.

2. The pulse rate, compared in 19 cases, is higher at the close of the experiments with the residue than of those with pure chloroform.

3. The blood pressure in by far the greater number of experi-

ments at the moment the respiration stops is higher after inhalation of pure chloroform than after inhalation of the impure residue.

4. The residue causes stoppage of respiration much more quickly than pure chloroform. W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

Compounds accompanying Chlorophyll in Leaves. By A. Étard (*Compt. rend.*, **114**, 364—366).—Vine leaves gathered in July when treated with carbon bisulphide in the cold yield 3·7 per cent. of solid extract. This extract contains about 40 per cent. of a greenish plastic substance, insoluble in cold alcohol. It can be crystallised from ethyl acetate, melts at 74°, and boils at about 300°. It has the composition $C_{17}H_{34}O$, and the author gives it the name *vitole*. If the alcohol is expelled from the alcoholic solution of the carbon bisulphide extract, and the residue is agitated with dilute aqueous potash and ether, the ether dissolves a readily crystallisable substance, $C_{23}H_{42}(OH)_2$, *vitoglycol*, which yields a dibenzoic derivative. The potash solution contains semi-solid fatty acids. Possibly the function of the palmitic acid, which occurs constantly in leaves, is to limit the entrance of inorganic salts, and especially those of sodium, which are readily precipitated by potassium palmitate.

The carbon bisulphide extract of lucerne yields a large proportion of a white substance, which crystallises from ethyl acetate, melts at 80°, and boils at 395°, without sensible decomposition; with bromine, it yields a substitution derivative, but no additive compound. The compound has the composition $C_{20}H_{41}OH$, and yields a monobenzoic derivative; the author calls it *medicagol*. Direct experiment shows that medicagol passes unaltered through the alimentary canal of a horse when the latter is fed on lucerne.

Bryonia dioica, when treated in the same way, yields a hydrocarbon, $C_{20}H_{42}$, which crystallises in large, white lamellæ, melts at 69°, and boils without decomposition at 400°.

The compounds described constitute an important part of what is known as the *wax of leaves*. C. H. B.

Proteïds of Maize. By R. H. Chittenden and T. B. Osborne (*Amer. Chem. J.*, **13**, 529—552).—A further instalment of the work plotted out in the first paper (this vol., p. 379). The proteïd matter of the first class, namely, that soluble in 10 per cent. aqueous sodium chloride, but insoluble in water, may be resolved by fractional heat coagulation into three distinct globulins, two of which have much in common with phytomyosin and phytovitellin, although they are not identical with those substances.

The globulin which gradually coagulates when the temperature of a sodium chloride solution of the proteïds, prepared in the manner previously described, is slowly raised to 80°, contains relatively less nitrogen, the average percentage composition of several specimens made in this and other ways being:—C, 52·70; H, 7·02; N, 16·74;

S, 1·30; the nitrogen of the undifferentiated proteïd being 17·82 per cent. The globulin thus approximates closely in composition to animal myosin, which contains per cent.:—C, 52·82; H, 7·11; N, 16·77; S, 1·27; but the bulk of it coagulates at 70°, a temperature markedly different from the coagulation point of the myosin. The globulin also resembles the vegetable myosin which was obtained by Martin from papaw juice (Abstr., 1886, 642), and may thus be called *maize-myosin*. The tendency to coagulate at several different temperatures may be explained by assuming that maize-myosin undergoes a gradual change when heated, and this assumption accords with Martin's observation (Abstr., 1887, 507) that the myosins of wheat and rye are transformed into insoluble substances by heating their sodium chloride solutions at 35—40° for some time, and with Vines' view (*J. Physiol.*, **3**, 91—114) that phytovitellin may be transformed into phytomyosin. Maize-myosin is characterised by its solubility in cold, dilute, saline solutions, such, for instance, as those of the alkali phosphates naturally present in maize meal, and by taking advantage of this property may be extracted directly from the meal without dissolving the second globulin. The cold aqueous extract of the meal is saturated with ammonium sulphate, and the crude maize-myosin thus precipitated is successively treated with water and 10 per cent. aqueous sodium chloride. The mixed extracts are then dialysed in a stream of water, and the myosin thus precipitated is washed with water, alcohol, and ether, and dried.

The second globulin, *maize-vitellin*, which forms the bulk of the original proteïd matter, is obtained in small spheroïds when the solution from which the maize-myosin has been separated by heat coagulation is dialysed in a stream of water. Its solution in aqueous sodium chloride is coagulable by acetic acid, but not by heat, and it contains more nitrogen than the original proteïd matter, the average composition of several specimens prepared in this and other ways being:—C, 51·71; H, 6·83; N, 18·12; S, 0·86; thus closely approximating to that of the phyto-vitellin of pumpkin seeds:—C, 51·88; H, 7·51; N, 18·08; S, 0·60. It contains less sulphur than the myosin, and is, perhaps, as much akin to heteroalbumose as to the true globulins. Maize-vitellin is distinguished from maize-myosin by its solubility in weak, cold, saline solutions, and by its tendency to separate in spheroïdal form from sodium chloride solutions. It may, therefore, be extracted without the aid of heat coagulation from the crude proteïd matter, prepared in the manner previously described, or from the meal remaining after the extraction of the myosin. The proteïd matter, for example, is dissolved in 5 per cent. aqueous sodium chloride, and the vitellin is first precipitated by dilution with a large bulk of water, then redissolved by heating the whole to 45°, and finally caused to separate in spheroïdal form by cooling the solution slowly to 8°. The crude product thus obtained may be purified and caused to aggregate into larger spheroïds by repeating the treatment. Maize meal from which the myosin has been previously extracted by cold water may be treated with 10 per cent. aqueous sodium chloride, the crude vitellin precipitated by saturating the solution with ammonium sulphate, and purified by a somewhat long process, which comprises dissolving the crude product in sodium chloride

solution, reprecipitating it by dialysis, dissolving it again in salt solution, heating the solution to separate coagulable impurities, precipitating the now nearly pure product with acetic acid, redissolving the precipitate in sodium chloride solution, and, finally, precipitating the pure vitellin by dialysis.

The third globulin, which is characterised by its solubility in dilute solutions of salts other than chlorides, and its insolubility in water, is obtained by long-continued dialysis of the solutions from which the other globulins have already separated. It was not observed in the preliminary experiments, owing to the slow rate at which ammonium sulphate and the alkaline phosphates diffuse. This globulin has the composition C, 52·38; H, 6·82; N, 15·21; S, 1·26, and is thus distinct from the myosin and vitellin. It is further distinguished from these globulins by the low temperature, 62°, at which it is completely coagulated.

Various other substances isolated during the investigation were probably formed from the solutions by the incidental treatment, and do not exist as such in maize.

A substance, for instance, soluble in water, not coagulated by heat, and in general behaviour resembling the proteoses, was left in solution in the dialyser after the removal of the myosin and vitellin in the differentiation experiments first described. It did not exist in the original proteïd substance, since the latter did not yield any proteïd matter to boiling water; possibly it was formed by the hydrolysis of one of the less stable globulins.

Another substance, precipitated by the addition of a slight excess of very dilute hydrochloric acid to the sodium chloride solution of the undifferentiated proteïd matter, was possibly an acid globulin. It contained 17·39 per cent. of nitrogen.

The most prominent of these secondary products, however, are certain substances insoluble in aqueous sodium chloride, which are invariably formed during the dialysing operations by the prolonged action of the water or sodium chloride on the myosin or vitellin, which in this respect resemble animal myosin and certain vegetable globulins. When, for instance, the clear sodium chloride extract of maize meal is dialysed, the precipitated globulins are no longer completely soluble in sodium chloride solution; and the same thing happens when the globulins are precipitated by the addition of ammonium sulphate to the solution, especially if the sulphate is somewhat acid, although in the latter case the insoluble portion of the precipitate may contain the acid globulin mentioned above. In the early stages of transformation, these insoluble substances resemble the alkali albuminates, for they dissolve in dilute aqueous sodium carbonate, and are reprecipitated on neutralising the solution; but after more prolonged action they seem rather to resemble coagulated proteïd matters. Their composition is fairly uniform; the mean percentage composition, for instance, of the products formed by the action of aqueous ammonium sulphate or water on the sodium chloride or aqueous extracts of maize meal and subsequent purification was:—C, 53,45; H, 6·99; N, 16·11; S, 1·14; so that if these substances are formed from the globulin, the latter must undergo considerable modification. The change is not due to the

alkali used in the purification, since a specimen which had not been purified in this manner was found to contain the same percentage of nitrogen. Since this percentage is low, it is probable that the insoluble substances are formed from the myosin and the soluble globulin, and not from the vitellin, and it is probably this tendency of the first two to pass into such insoluble modifications which facilitates the purification of the vitellin. Jn. W.

Proteïds of Maize. By R. H. Chittenden and T. B. Osborne (*Amer. Chem. J.*, **14**, 20—40; compare this vol., p. 379, and preceding abstract).—An aqueous or sodium chloride extract of maize meal yields, after the three globulins and the soluble salts have been removed by dialysis, two albumins and a proteïd soluble in alcohol (proteose). The solution is treated with 10 per cent. of sodium chloride, and rendered slightly acid with 0·2 per cent. hydrochloric acid. The precipitated albumin (I) dissolves when washed with water, doubtless owing to the presence of hydrochloric acid; it is reprecipitated when the solution is carefully neutralised with dilute sodium carbonate, but dissolves in excess of the latter; after drying, this precipitate is no longer soluble in sodium carbonate.

The filtrate from I, when boiled, yields a coagulum of a second albumin (II); the portion first formed contains appreciably less nitrogen than the later portions.

The filtrate from (II) contains a proteose (III) which may be obtained by adding absolute alcohol to the concentrated solution. It is doubtful if these three substances all exist as such in the maize kernel; some of them may be formed in the processes used to separate them.

The maize meal, after extraction with water, contains another proteïd, *zeïn*, or *maize-fibrin* (IV), which can be extracted with warm 75 per cent. alcohol, and is precipitated when the alcoholic solution is poured into water. It is quite insoluble in 0·5 per cent. sodium carbonate, and in 0·2 per cent. hydrochloric acid; it dissolves in 0·2 per cent. aqueous potash, but is not converted into alkali-albumin, for the precipitate produced when the alkaline solution is neutralised is not soluble in excess of dilute acid, but dissolves in alcohol. It is converted, when warmed with water or dilute alcohol, into an insoluble variety, which, however, has the same chemical composition. Both of these varieties exhibit the ordinary proteïd reactions. The carbon-content of this proteïd is large.

The results of analyses of these substances are tabulated below:—

	I.	II.	III.	IV.
C	52·86—53·53	51·02—52·06	50·07—51·13	54·97—55·42
H	6·86— 6·79	6·57— 6·79	6·54—69·1	7·15— 7·35
N	15·69—15·41	17·28—15·78	15·88—16·59	16·01—16·31
S	1·48	25·75—24·64	2·37— 1·62	0·53— 0·67
O	23·26		24·52—23·75	21·05—20·52

C. F. B.

Phosphoric Acid in Soil and its Estimation. By C. L. Wiklund (*Landw. Jahrb.*, **20**, 909—928).—The attempts which have been made to ascertain the fertility of soils by analysis have met with little success, owing, largely, to the want of vegetation experiments showing the physiological value of the nutritive matters dissolved by the various reagents. Of all soils, the peaty soils seem most likely, when subjected to total analysis, to yield results which would indicate fertility, such soils being almost wholly derived from plant residues. For this reason it has been usual to determine the total amount of ash constituents in such soils. As regards sulphates and phosphates, however, the amounts found in the ashes do not represent the amounts pre-existing in the soils, being partly formed from sulphur and phosphorus present in other forms in the soil (compare Eggertz and Nilson, Abstr., 1890, 192; Berthelot and André, Abstr., 1888, 384). Nilson and Eggertz's method, which is generally used in Sweden, consists in treating the powdered soil, at the ordinary temperature, with 4 per cent. hydrochloric acid for 48 hours (using for 1 gram of dry soil 10 c.c. of acid), and analysing the filtrate in the usual manner.

The author describes a number of experiments made with the Eggertz-Nilson method. The results show that the method gives too low results with peaty soils containing much lime or ferric oxide; in the case of a sample containing 35·49 per cent. of lime and 0·35 per cent. of phosphoric acid, no phosphates were extracted at all. Such soils require either stronger acid, or repeated extraction with 4 per cent. acid, to remove all the soluble phosphates. It can also not be considered as proved that the amount of phosphoric acid dissolved by the method is the maximum assimilable amount for all plants. The amount of phosphoric acid found by the method will not show whether the soil requires manure for any particular kind of plant. A soil extracted by 4 per cent. acid may be rendered unsuitable for the growth of one plant, and yet contain sufficient phosphates for another.

In order to ascertain the relation between the amounts of phosphates dissolved by 4 and by 12 per cent. acid, and the amount found in the burnt soils, 47 different peaty soils were examined. The results show that, in some peaty soils, the greater part of the phosphorus exists as phosphoric acid; but in most of those examined the amount of pre-existing phosphates was much less than that of the burnt soils. In the case of soils which did not contain much lime or ferric oxide, the amounts of phosphates extracted by 4 and by 12 per cent. acid were essentially the same, showing that the stronger acid does not liberate phosphoric acid from the organic matter of the soil.

With regard to the question as to the manner in which the phosphoric acid is combined, several of the soils were extracted with 10 per cent. acetic acid, and the results compared with those obtained with dilute hydrochloric acid. Most of the pre-existing phosphate was found to be insoluble in acetic acid, and is, therefore, probably, in combination with iron.

In order to ascertain the amount of phosphorus in the substance extracted from soils by 5 per cent. ammonia (Grandeau's "matière

noire"), three samples of soils were three times extracted with 4 per cent. hydrochloric acid and then with ammonia (10 c.c. to 1 gram of dry soil), and the extract precipitated with hydrochloric acid. The dried "matière noire" from the three samples contained 0·553, 0·409, and 0·200 per cent. of phosphoric acid respectively, and the amounts shown as percentages in the original soil will be 0·040, 0·049, and 0·020. Practically the same results were obtained (with two of the samples) when the soils were only once extracted with 4 per cent. acid (and were known to still contain phosphates) before extracting with ammonia. The results confirm those of Eggertz, that "matière noire" does contain phosphorus. N. H. M.

Analytical Chemistry.

Asbestos in Filtration. By W. P. Barba (*Chem News*, **65**, 101).—To aid filtration it is recommended to add finely-divided asbestos, suspended in a suitable liquid, to the freshly-precipitated troublesome precipitate, and then to collect on an asbestos plug. The precipitate may then be washed, redissolved, and titrated with great ease. D. A. L.

Estimation of Nitrogen. By E. B. Voorhees (*Chem. News*, **65**, 99—100, 111—112).—As reporter to the Association of Official Agricultural Chemists, Washington, the author records the results of the analysis of the following test mixtures sent to various chemists:—1. A mixture of 400 grams of potassium nitrate and 56 grams of sodium nitrate. 2. A mixture of 250 grams of linseed meal, 250 grams of cotton-seed meal, and 100 grams of sodium nitrate. 3. A mixture of 300 grams each of dried blood and ammonite. By far the majority of the analyses were made by the Kjeldahl method, modified for nitrates when necessary, and taken all round, the results are satisfactory; a few analyses were made by the soda-lime and Ruffle methods, the former giving results practically identical with the Kjeldahl results, whilst the Ruffle results were lower, but were too few for a fair comparison. Test experiments using 2 grams of zinc sulphide and 1 gram of salicylic acid instead of 2 grams of zinc-dust and 2 grams of salicylic acid have proved satisfactory, and therefore the adoption of this modification is recommended, because the zinc sulphide can all be added at once, and so saves trouble; the oxidation too is more rapid, and as less salts are present, the distillation is quieter. It is further recommended to digest in and distil from the same flask, and to use metallic mercury instead of mercuric oxide. D. A. L.

Estimation of Nitrous Acid. By A. G. Green and F. Evershed (*Chem. News*, **65**, 100—101).—The authors point out that Lunge in condemning the diazotisation method of estimating nitrous acid, has only tried Schultz' modification and not the method suggested by the

authors (Abstr., 1887, 396), in which normal aniline hydrochloride solution is titrated, in a flask surrounded by ice and water, with a normal solution of the nitrite, using zinc iodide and starch solution as an indicator. D. A. L.

Oxidation of Arsenic by the Electric Current. By L. K. Frankel (*Chem. News*, **65**, 54—57, 66—68).—Stimulated by the good results obtained by E. F. Smith in the oxidation of sulphides by the electric current (Abstr., 1890, 1342), the author has tried, with success, the oxidation of arseniferous minerals by means of the same agency. His general mode of procedure has been to drop the pulverised mineral into fused potash contained in a nickel crucible, attached to the positive pole of an electric circuit, a platinum wire, dipping in the molten potash, serving for the other electrode, and when sufficiently electrolysed, to disintegrate the mass with water, filter, acidify with hydrochloric acid, render strongly alkaline with ammonia, and again filter. The arsenic is then precipitated as ammonium magnesium arsenate, collected on a Gooch crucible, and weighed as pyroarsenate.

In the case of gersdorfite, niccolite, arsenopyrite, cobaltite, and proustite, about 25—30 grams of potash is used for from 0·2 to 0·3 gram of mineral, and a current of 1 ampère is passed for from 20 to 30 minutes, reversing the current at the end for 3—5 minutes, to remove any particles of mineral retained by the deposit on the cathode.

With free arsenic or orpiment, when loss by volatilisation has to be avoided, the molten potash is allowed to cool down so as just to let the current pass, the powdered metal or mineral is then spread over the surface, and, if necessary, a very small flame is applied to reinstate conductivity. In 10 minutes the temperature of the mass is raised, and a current of 1 ampère sustained for 25 minutes, reversing for five minutes at the end. With rammelsbergite, chloanthite, and smaltite, a larger quantity, 40 grams, of potash and a longer time, 45 minutes, with in the case of rammelsbergite 3-minute reversals after each 10 minutes, were required to effect the oxidation of the arsenic. Thus these arsenical minerals show some analogy to the sulphides in their behaviour under the above treatment; ferrous sulphide was observed by E. F. Smith to oxidise more readily than iron pyrites, and now the author finds that minerals with 1 atom of arsenic in the molecule are more readily decomposed than those containing 2 atoms of arsenic in the molecule. Domeykite and enargite are also amenable to this treatment.

With regard to the estimation of the arsenic, neither weighing as sulphide nor collecting the ammonium magnesium arsenate on paper filters was found satisfactory, nor did Pearce's method of estimating as silver arsenate in a carefully neutralised solution of an alkaline arsenate, prove successful in the author's hands. As, however, the precipitation of ammonium magnesium arsenate is slow in the presence of much alkali, it is sometimes advantageous to reduce with sulphurous acid, precipitate as arsenious sulphide, and subsequently reconvert into arsenic acid, and weigh as magnesium pyroarsenate.

In the treatment of sulphides, E. F. Smith noticed the transition of the sulphur through the stages hydrogen sulphide, sulphurous anhydride, and finally sulphuric anhydride. No such phases have been noticed in the behaviour of arsenic in the above experiments.

Estimation of Phosphoric Acid in Soils. By C. L. Wiklund (*Landw. Jahrb.*, **20**, 909—928).—See this vol., p. 750.

Estimation of Sulphur in Red Copper. By C. A. Lobry de Bruyn (*Rec. Trav. Chim.*, **10**, 125).—The method proposed by Fresenius is not available, since barium nitrate does not precipitate small quantities of free sulphuric acid in copper nitrate solutions. The author dissolves 25 grams of the copper in nitric acid and electrolyses the solution until about 20 grams are deposited, he then evaporates the liquor to remove the excess of nitric acid, and again electrolyses until the whole of the copper is deposited; the sulphuric acid is then estimated in the copper-free liquid. As pointed out by v. Meyer, the employment of a gas flame in the evaporation is objectionable on account of the likelihood of sulphurous contamination.

T. G. N.

New Method of Organic Analysis. By Berthelot (*Compt. rend.*, **114**, 317—318).—The substance is burnt in compressed oxygen in the calorimetric bomb, the heat developed being measured if desired. The gases in the bomb are then allowed to pass through tubes containing pumice moistened with sulphuric acid, and through tubes containing solid potash or potash solution. The residual gas is extracted by means of a pump, pure air is allowed to enter, this in its turn is extracted, and the process is repeated two or three times. When an estimation of the hydrogen is required, dry oxygen must be used, and the bomb must be heated before the operation in order to expel the moisture derived from previous experiments. Allowance must be made for the traces of nitric acid formed during combustion, since they volatilise with the water. In the case of compounds containing sulphur, a small quantity of water is placed in the bomb before the experiment, and the whole of the sulphur remains in solution in the form of sulphuric acid. Phosphorus may be estimated in a similar way.

C. H. B.

Electrolytic Estimation of Metals as Amalgams. By W. Gibbs (*Amer. Chem. J.*, **13**, 570—571).—The author points out that his experiments on the electrolytic separation of certain metals from solutions of their salts by means of mercury cathodes and platinum anodes (*Nat. Acad. Sciences*, October, 1883) were purely qualitative. He thinks, however, that the method should be applicable to the estimation not only of the metals, but also of the electronegative elements or radicles with which they may be combined.

Jn. W.

Estimation of Copper by De Haen's (Brown's) Method. By C. A. Lobry de Bruyn and F. H. Van Leent (*Rec. Trav. Chim.*, **10**, 119—124).—The authors publish data of the determination of copper in pure copper sulphate and in alloys by De Haen's method,

and compare the results with those obtained electrolytically and by precipitation as copper sulphide. By well shaking the not too dilute copper solution with 5 c.c. of potassium iodide solution (20 per cent.) in a 500 c.c. stoppered flask for 5—10 minutes, adding the greater part of the sodium thiosulphate solution, whilst preventing undue access of air, then adding starch solution, and determining the end of the reaction by the change of the dirty-blue coloration to a cream-yellow on subsequent addition of thiosulphate, concordant results are obtained which do not differ by more than 0·1 per cent. from the calculated percentage. The presence of free acid, of nickel, manganese, and iron sulphates does not affect the results, nor does lead nitrate, but bismuth nitrate masks the end of the reaction, owing to formation of bismuthous iodide, and the results are low.

In the case of alloys, 0·3—0·4 gram is dissolved in dilute nitric acid, and 1 c.c. of sulphuric acid (sp. gr. 1·4) is added, the whole is then evaporated to dryness on a water-bath, and the residue dissolved in water is treated as above described (compare Westmoreland, Abstr., 1887, 80). T. G. N.

Quantitative Separation of the Metals of the Hydrogen Sulphide Group by means of Bromine Vapour. By P. Jannasch and P. Etz (*Ber.*, **25**, 736—741 ; compare this vol., pp. 385 and 540).—Wood's metal, containing bismuth, lead, tin, and cadmium in the proportion 15 : 8 : 4 : 3 respectively (1 gram) is dissolved in *aqua regia*, the solution evaporated to dryness, the chlorides redissolved in dilute hydrochloric acid, and a current of hydrogen sulphide passed through the boiling solution for about half an hour ; the sulphides are then collected on a tared filter, dried at 100°, and subsequently cautiously heated in a boat as described (*loc. cit.*) in a current of air containing bromine vapour, when stannic and bismuth bromides volatilise, and are condensed in dilute nitric acid, whilst a fused mixture of lead and cadmium bromides remains, and is allowed to cool in a current of the same gaseous mixture. A slight sublimate of lead chloride is sometimes found on the upper portion of the combustion tube when commercial bromine is employed. The fused bromides are repeatedly evaporated with chlorine-water on the water-bath, the resulting chlorides dissolved in water, and the lead and cadmium estimated as sulphate and oxide respectively. The nitric acid containing the tin and bismuth is evaporated on the water-bath with fresh quantities of nitric acid, the tin being weighed as stannic oxide, and in the filtrate, from which the excess of nitric acid is removed by boiling, the bismuth is precipitated with ammonium carbonate, and weighed as oxide, the latter, when necessary, being separated from silica, derived from the porcelain vessels, by a second precipitation. Good results are obtained.

The following method is much quicker and quite as accurate. The alloy is mixed with sulphur, and the mixture heated in a porcelain boat in a current of carbonic anhydride ; after volatilising the excess of sulphur, the operation is repeated, if necessary, and the mixed sulphides treated with bromine vapour as above described. The complete analysis occupies from one and a half to two days.

A. R. L.

Estimation of Iron and Aluminium by the Glaser Method. By B. H. Gibbins (*Chem. News*, **65**, 51).—Referring to a suggestion made by Teschemacher and Smith in connection with the Glaser method for the estimation of iron and aluminium (Abstr., 1890, 420), the author remarks that in this method, even when 25 per cent. of magnesia is present, there is no fear of precipitating any ammonium magnesium phosphate, from the alcoholic solution, by adding ammonia carefully and in only slight excess; he therefore adopts the following procedure:—An aliquot part of the alcoholic solution is neutralised with ammonia (sp. gr. 0·96), the alcohol is driven off over a steam-bath, without evaporating to dryness, water and a few drops of ammonia are then added, the whole boiled vigorously, cooled rapidly, and the iron and aluminium phosphates filtered off without delay. In the presence of manganese, the precipitate is redissolved in dilute nitric acid, and the solution treated with ammonium phosphate, and neutralised with ammonia; a precipitate free from manganese is then obtained. D. A. L.

Estimation of Iron and Aluminium in the presence of Phosphoric Acid. By W. H. Krug (*Chem. News*, **65**, 68—69, 78—79, 89—90, 98—99).—The author has compared the various methods proposed for the estimation of iron and aluminium in the presence of phosphoric acid, and finds that the molybdate methods give oxides of iron and aluminium contaminated with molybdic anhydride; whilst in the alcohol methods, the results are vitiated either by the inclusion of calcium sulphate in the oxides, as in the Glaser method, or by the retention of oxides by the calcium sulphate, as in the Jones method. In the latter case, the quantity of iron oxide retained not alone increases with the amount of iron present, but is also augmented by the precipitation of iron as an alum, when potassium, or, to a less extent, when ammonium, salts are present. The following modification of the molybdate method is stated to be free from all the above defects, and is, moreover, short and rapid:—100 c.c. (1 gram of substance) of a nitric acid solution is mixed with ammonium molybdate and some ammonium nitrate, and, after remaining over night, is filtered. 200 c.c. of the filtrate containing ammonium nitrate is cautiously precipitated in the cold with ammonia, the precipitate is washed, redissolved in a few c.c. of a solution of ammonium nitrate in dilute nitric acid, reprecipitated with ammonia, filtered, washed, ignited, and weighed. In this way the oxides of iron and aluminium are obtained free from molybdic anhydride, and the iron can be readily determined in the usual way. D. A. L.

Reactions of Hydrastine and other Alkaloïds. By D. Vitali (*L'Orosi*, **14**, 405—416).—If a small crystal of hydrastine, or of one of its salts, is placed on a porcelain capsule and covered with concentrated sulphuric acid (0·5—1 c.c.), it turns yellow, and, on stirring, the liquid acquires the same colour; on adding a small fragment of nitre (an excess must be avoided), the colour changes to a more or less intense brownish-yellow; if a solution of stannous chloride is now added drop by drop, the solution acquires a magnificent, re ddish-

violet colour, the intensity of which depends on the amount of alkaloïd present. This coloration is not destroyed on dilution with water.

If a particle of hydrastine is treated with nitric acid (4 to 6 drops), the alkaloïd turns yellow; on heating for an instant to the boiling point, nitrous fumes are evolved, and, on evaporating to dryness at a gentle heat, a yellowish residue is left which, when cold, is coloured brownish-yellow by alcoholic potash, and remains as a greenish-brown mass on evaporating the alcohol. When cold, this becomes deep-violet on treatment with sulphuric acid. Solutions of hydrastine must be evaporated to dryness before applying the tests, which are sufficiently delicate to detect 0·0001 gram of the alkaloïd.

Bebeerine turns blood-red on treatment as described with concentrated sulphuric acid and nitre, the colour changing to green on the addition of stannous chloride.

Codeïne turns dark brick-red when alcoholic potash is added to its solution after treatment with nitric acid, and coffee-coloured when further treated with sulphuric acid; similarly, *narcotine* acquires an orange colour on the addition of potash, the colour changing to violet-red on adding sulphuric acid, and red to yellow on diluting with water.

A rather less delicate test for hydrastine is as follows:—A particle of the solid alkaloïd is fused with five or six times it weight of caustic potash, the melt allowed to cool, acidified with hydrochloric acid, extracted with chloroform, the extract evaporated to dryness on the water-bath, and the residue treated with a very dilute solution of ferric chloride; a fine, blue coloration is obtained if a few milligrams of the alkaloïd has been employed; the colour is destroyed by acids, and changed to brownish-red by alkalis.

A characteristic reaction for *aconitine* is obtained by adding to it in small quantities a solution of potassium permanganate in sulphuric acid (1 : 200) and stirring; the green colour of the reagent is replaced by a violet-tint which disappears on further agitation, and is restored on adding more of the reagent, and so on. A point is ultimately reached at which the colour is not affected by agitation, but at once disappears on diluting with water.

Clear indications of the presence of hydrastine in putrid animal matter cannot be obtained if the latter is treated by the Stas-Otto method, on account of the ptomaïnes and other impurities contained in the extract. Hydrastine is however extracted from alkaline, but not from acid, solutions by light petroleum, and, by taking advantage of this fact and substituting baryta for sodium carbonate, and light petroleum for ether, in the extraction, it is possible to isolate the alkaloïd in a state of sufficient purity. The author recommends the use of light petroleum in place of chloroform, ether, or amyl alcohol in the extraction of alkaloïds from urine and animal remains, as they are nearly all soluble in that menstruum (the exceptions are morphine, curarine, and pilocarpine) whilst ptomaïnes, leucomaïnes, pigments, and extractive matters are insoluble. S. B. A. A.

General and Physical Chemistry.

Refractive Powers of Isocyanides and Nitriles. By T. Costa (*Gazzetta*, **22**, i, 104—109).—A comparison of the refractive powers of the isomeric nitriles and isocyanides might be expected to show whether in the latter class of substances the carbon atom in the CN group is bi- or quadri-valent. The author has examined ethyl isocyanide, propionitrile, and benzonitrile; his results are contained in the following table:—

	n_α.	n_β.	n_γ.	Molecular refraction.
Ethyl isocyanide....	1·35870	1·36569	1·36999	16·26
Propionitrile	1·36314	1·36925	1·37309	15·64
Benzonitrile	1·52555	1·54494	1·55721	31·33

The molecular refraction is calculated by means of the formula $\frac{M(n_\alpha^2 - 1)}{d(n_\alpha^2 + 2)}$. The molecular refraction of ethyl isocyanide will be seen to be somewhat higher than that of its isomeride, propionitrile. The carbon atom in the CN group must therefore be supposed to be saturated, and the isocyanide should hence have either the constitution C≡N·X or X·N:C:C:N·X. The author has endeavoured to determine the molecular weight of ethyl isocyanide by the cryoscopic method, using benzene as the solvent. On cooling, however, the isocyanide separates, forming an emulsion, and renders the experiment futile.

W. J. P.

Absorbent Power of Coloured Salts and Electrolytic Dissociation. By G. Magnanini (*Gazzetta*, **22**, i, 131—140).—The author criticises unfavourably the deductions drawn by Knoblauch (*Wied. Ann.*, **43**, 738) from observations made on the absorption spectra of solutions of coloured salts. Knoblauch concluded that on varying the degree of concentration of the coloured salt solution no change in the absorption spectrum occurred; no photometric measurements were made, however, and the spectra were simply compared by the eye. As, however the most concentrated solutions used by Knoblauch contained the salt in a considerably dissociated condition, mere inspection of the absorption spectra could not be expected to afford any criterion of the progress of dissociation as the solution became more dilute. Knoblauch's conclusion, that his experiments are in disaccord with the electrolytic dissociation hypothesis, is therefore unfounded.

The author has measured the extinctions for solutions of various coloured salts, reducing the electrolytic dissociation of the dissolved salt by adding to the solution a colourless salt or free acid having one ion in common with the coloured salt. Thus, to solutions of copper sulphate were added considerable proportions of sodium sulphate and sulphuric acid. The coefficients of extinction in this

and similar cases were found to be unaltered by the decrease in the electrolytic dissociation. The author concludes that for the salts examined, that is, copper sulphate and nitrate, nickel sulphate, and potassium permanganate, the colour of the aqueous solution is independent of the electrolytic dissociation. W. J. P.

Molecular Dissymmetry. By P. A Guye (*Chem. Centr.*, 1892, i, 10; from *Arch. sci. phys. nat. Geneva* [3], **26**, 333—369).—In addition to the examples which the author has already given (this vol., p. 399) in proof of the correctness of the symmetrical and unsymmetrical arrangement of the groups of atoms in relation to the carbon atom, he now names derivatives of tartaric, malonic, aspartic, lactic, and malic acids, of leucine, and phenyl mercaptan. Exceptions occur in the case of glutamic acid, the constitution of which is not certain, and in those of some asymmetrical compounds the groups of which have approximately equal masses.

J. W. L.

Stereochemistry of Diacetyltartaric Acid. By A. Colson (*Compt. rend.*, **114**, 175—178).—Diacetyltartaric acid has been obtained by the author in the crystalline form, with 3 mols. H_2O. It fuses at 58°, is very deliquescent and soluble in water, alcohol, and ether, less soluble in benzene. In these four solvents it rotates the plane of polarisation to the left, although it is derived from dextrorotatory tartaric acid. Its salts are lævorotatory in aqueous solution.

It may be obtained in the crystalline form:—(1) By allowing diacetyltartaric anhydride to deliquesce, taking up with dry ether, and slowly evaporating in dry air. By this means rhomboidal, almost square, tables are obtained. (2) By treating the anhydride with ether saturated with water, and slowly evaporating the ether.

The conversion of the dextrorotatory tartaric acid into a lævorotatory compound is not due to the heat evolved during the formation of the latter, for dextrorotatory tartaric acid is regenerated by slow hydrolysis through the action of the moisture of the air. The optical inversion is due to the action of the inactive acetic acid. It is concluded that an inactive substance such as water may affect the rotatory power, but the tetrahedron formula fails to indicate this. The tetravalency of carbon, founded on the Le Bel-Van't Hoff notation, excludes also molecular combinations such as the crystallised acid described.

According to Guye's method of accounting for diacetyltartaric acid being lævorotatory, on the assumption of the tetrahedron formula the diacetyltartrates should be dextrorotatory, whereas they are lævorotatory. According to Guye, diacetyltartaric anhydride should be more strongly lævorotatory than the acid; on the contrary, it is dextrorotatory.

The conclusion is therefore drawn that the chemical notation based on the properties of the regular tetrahedron is insufficient to represent the constitution of active substances, and may lead to inaccurate predictions. W. T.

Stereochemistry and the Laws of Rotatory Power. By P. A. Guye (*Compt. rend.*, **114**, 473—476).—A reply to some objections recently brought by Colson (preceding abstract) against the author's method of calculating the sign of the rotatory power of carbon compounds. The method was not intended to be applied to ring compounds, on account of the uncertainty as to the amount of deformation of the angles of the tetrahedra in the molecules of such compounds. As the particular compound, diacetyltartaric anhydride, which Colson selects in illustration of his argument, is a ring compound, his conclusions are necessarily invalid. Jn. W.

Coexistence of Dielectric Power and Electrolytic Conductivity. By E. Bouty (*Compt. rend.*, **114**, 533—535).—The measurements were made by the method previously employed to determine the dielectric constant of mica at high temperatures. The dielectric constant for pure terebenthene was found to be 2·25, which is exactly the mean of the determinations of Silow, Quincke, Palaz, and Negreano. The conductivity of distilled water is so great that the measurements of time cannot be made with sufficient accuracy. The determination of the dielectric constant of ice, however, presents no great difficulty, and the value of the constant is found to be 78 at −23°. As the temperature rises, the conductivity increases rapidly, but the dielectric constant shows no appreciable variation. The constant remains the same even if a small quantity of sodium chloride is added to the water before freezing, or if river water is used instead of distilled water. It follows that dielectric power and electrolytic conductivity may coexist in the same substance, the former remaining practically constant, whilst the latter varies within wide limits.

C. H. B.

Galvanic Polarisation at Small Electrodes. By K. R. Koch and A. Wüllner (*Ann. Phys. Chem.* [2], **45**, 475—507; 759—797).—Fromme found that with great current density strong polarisation appeared at small electrodes (Abstr., 1890, 316, 675). Richarz, on the other hand, concluded that the polarisation does not alter with the current density, but that the resistance in the electrolyte does. (Abstr., 1890, 676). The authors have investigated the question afresh, using a new method of measurement. They observed simultaneously the current strength, the difference of potential of the electrodes, and also, by an electrometric method, the polarisation at each electrode. From the data, the resistance of the electrolytic cell could be calculated. Their results with solutions of sulphuric acid of various strengths, and with electrodes of different sizes and shapes, are given in numerous tables.

In the second portion of their paper, the authors give an account of their investigations on the phenomena of "current reversal" (sudden reduction of the direct current and increase of polarisation), produced by increasing the current strength beyond a certain limit. The results obtained with various solutions and electrodes are given in tabular form; and figures, after instantaneous photographs, show the evolution of gas, &c., at the electrodes, with the current below and above the limit for reversal.

The authors state the conclusions at which they have arrived, as follows:—

1. There is, at short electrodes of platinum wire in dilute sulphuric acid, a polarisation which increases considerably with the current strength.

2. This polarisation is due to an electromotive force opposed to that of the direct current, and to the resistance of a badly conducting layer which is formed round the electrodes. The electromotive force of polarisation is not dependent on the length of the wire electrodes, or, in general, on the concentration of the solution; and has the value to which the polarisation of large electrodes approximates with increasing current density, namely, 3·79 volts.

3. The resistance of the transitional layer is independent of the current strength with a given electrode and a given solution. For the same pair of electrodes it is proportional to the specific resistance of the solution; and for the same solution it diminishes as the length of the wire electrodes increases.

4. These rules are only valid for current strengths below a certain limit, which depends on the length of the electrodes and on the conductivity of the solution. When this limit is reached, an increase of the electromotive force causes a "reversal"; by the sudden increase of polarisation at the smaller electrode, the current becomes very weak. The strength of the residual current is not increased by an augmentation of the electromotive force, and is greater for long than for short wire electrodes.

5. If the reversal is caused by the great polarisation at the anode, this electrode becomes incandescent, sometimes splits, and is rapidly destroyed. If the seat of the reversal is at the cathode, a bluish-white glow, due to a gaseous envelope, surrounds this electrode, which may itself become incandescent. It is, however, not destroyed.

6. Zinc electrodes in zinc sulphate solution and copper electrodes in cupric sulphate solution exhibit, likewise, a polarisation which increases with the current strength. At a certain current strength a sudden increase of the polarisation at the anode take place; and this great polarisation can be obtained at large anodes with small current density by producing it first at a small portion of the surface by means of a large current density. J. W.

Electro-capillary Phenomena. By Gouy (*Compt. rend.*, **114**, 211—214).—If a dilute solution of sulphuric acid is taken, and with the capillary electrometer the law determined which connects the height of the mercurial column with the polarisation of the meniscus, on taking the polarisations as abscissæ and the heights as ordinates, the well-known parabolic curve of Lippmann is obtained. If iodide of potassium is substituted for sulphuric acid, the maximum is found to be less, and the portion of the curve during which the capillary meniscus plays the part of the anode, or the anodic portion, is steeper in the case of the sulphuric acid, or, in other words, the electrometer is more sensitive with this liquid. It follows from this that the two curves cannot be made to coincide by moving them along the axis of abscissæ, but by this means it is found that their cathodic portions

can be made to coincide at a short distance below the maximum. The same is true of other potassium salts besides the iodide. The reason for this is very evident. On the anodic side, the surface tension will depend on the nature of the mercury compound, oxide, iodide, &c., which tends to form, but at the cathode, hydrogen alone is liberated in the above cases. H. C.

Optical Measurement of High Temperatures. By H. Le Chatelier (*Compt. rend.*, **114**, 214—216).—The author recommends for the measurement of high temperatures, the photometric determination of the light emitted from a substance at the temperature under observation. The principal difficulties are, that the intensity of the radiation from such a substance depends not only on its temperature but also on its chemical nature, the physical condition of its surface, and the temperature of the substances which surround it. In cases where its diffusive power is nothing, the radiation is independent of the temperature of its surroundings, and depends only on its own temperature. This is the case with the magnetic oxide of iron, and carbon. The emissive power of other substances may be checked, as the author shows, by reference to these two, and scales constructed by means of which high temperatures can be measured by determining the light emitted from different incandescent substances. H. C.

Optical Measurement of High Temperatures. By H. Becquerel (*Compt. rend.*, **114**, 255—257) —Observations on a paper by Le Chatelier, dealing with the same subject (see preceding abstract). The author points out that the principle of the method recommended by Le Chatelier for the measurement of high temperatures is one which was put forward and fully explained by his father in 1862 (*Ann. Chim. Phys.* [3], **68**). H. C.

Specific Heat of the Diamond. By C. E. Carbonelli (*Gazzetta*, **22**, i, 123—130).—The author points out that the non-metallic elements in the seventh, sixth, and fifth groups of the Mendeléeff classification possess the general property of existing in the gaseous state in molecules containing two, three, and four atoms respectively. He considers that this periodicity may extend to the fourth group, which contains carbon, so that the gaseous molecules of elements in this group would contain five atoms. If this pentatomic molecule be supposed to preserve its individuality in the solid state the atomic heat of carbon must be multiplied by 5 to give the constant (6·4) of Dulong and Petit's law. The product of the specific heat of the diamond and the atomic weight of carbon is 1·25. On multiplying this by 5 a number (6·25) is obtained which accords with that required by Dulong and Petit's law. W. J. P.

Measurement of the Specific Heat of Liquids at Temperatures above their Boiling Points under Ordinary Pressure. By G. P. Grimaldi (*Real. Accad. Linc.*, **7**, ii, 58—63).—All the determinations of the specific heat of liquids at temperatures above

their boiling points under ordinary pressure have been hitherto made by the method of cooling, and the results obtained are very inconsistent. The author has devised an apparatus for making these measurements by the method of mixtures.

The liquid to be experimented on is contained in a steel cylinder A, whose sides are 3 mm. thick and whose volume is about 170 c.c. The cover communicates by means of a worm with another strong steel vessel B, in order to allow for the expansion of the liquid. When this whole arrangement has been raised to the required temperature in suitably heated jackets, the cylinder A is transferred to the calorimeter and the necessary thermometric measurements are made. The calorimeter, which has a capacity of about 5 litres, is made of very light polished brass, and contains petroleum, boiling above 300°, as the cooling liquid.

The specific heat of a cylinder of zinc is subsequently measured in the same apparatus, such a weight of metal being taken as to give approximately the same thermometric data as were obtained with the cylinder containing the liquid. From the two sets of measurements thus obtained, the specific heat of the liquid can be calculated. The results are satisfactory. W. J. P.

Heats of Combination of Bromine and Iodine with Magnesium. By N. Beketoff (*Chem. Centr.*, 1892, i, 11; from *Bull. Acad. St. Pétersbourg* [2], **34**, 291—292).—The author has determined the heats of solution of magnesium bromide and iodide. He takes Thomsen's determinations of the heat of combination of iodine and bromine with magnesium in solution; the difference being the heats of combination of the metal with the halogens. The results are: for magnesium bromide, 165000 − 43300 = 121700 cal., and for magnesium iodide, 134600 − 49800 = 84800 cal. Thus the combining heats of these halogens with magnesium are less than that of the oxide (140000 cal.) and the author suggests that it is another proof that the nearer the masses of two elements approximate to one another, the greater is the energy displayed in their combination. He prepared the anhydrous salts by means of Lerch's method—the direct combination of the halogen with excess of magnesium, in sealed tubes. J. W. L.

Heat of Formation of Potassium Tricarballylates. By G. Massol (*Compt. rend.*, **114**, 487—489).—The heat of solution of tricarballylic acid, melting at 163° (1 mol. in 6 litres of water) is −6·55 Cal. The heat of neutralisation with potash is +27·22, +24·94, and +19·58 Cal. for the first, second, and third acid radicles respectively (all substances calculated as solid).

Monopotassium tricarballylate, $C_6H_7O_6K + 2H_2O$, as obtained by evaporating the solution to dryness, is a hard, white, non-deliquescent mass. It loses the first molecule of water of crystallisation at 120°, and the second at 140°. *Dipotassium tricarballylate* crystallises in rhombic plates, and loses its water of crystallisation at 100°. *Tripotassium carballylate* is obtained in a similar way as a syrupy mass

which slowly thickens and solidifies when cooled. It loses its water of crystallisation at 130—135°. Jn. W.

Citric Acid. By G. Massol (*Compt. rend.*, **114**, 593—595).—The following thermal values were obtained with the sodium and potassium salts :—

	Potassium.	Sodium.
	Cal.	Cal.
Heat of neutralisation, MOH	+12·70	+12·65
„ „ 2MOH	+25·40	+25·52
„ „ 3MOH	+38·67	+38·40
$C_6H_8O_7$ sol. + MOH sol. = $C_6H_7O_7M$ sol. + H_2O sol.	+30·74	+26·59
$C_6H_7O_7M$ sol. + MOH „ = $C_6H_6O_7M_2$ „ + H_2O „	+25·32	+18·95
$C_6H_6O_7M_2$ „ + MOH „ = $C_6H_5O_7M_3$ „ + H_2O „	+17·63	+17·60
$C_6H_8O_7$ sol. + 3MOH „ = $C_6H_5O_7M_3$ „ + $3H_2O$ „	+73·69	+63·14
Heat of dissolution of the anhydrous salt, $C_6H_7O_7M$	− 7·97	− 6·35
„ „ „ „ $C_6H_6O_7M_2$	− 6·70	− 1·22
„ „ „ „ $C_6H_6O_7M_3$	+ 2·83	+ 5·27

The heats of neutralisation and of formation in the solid state are higher than the corresponding values of carballylic acid, the result being analogous to those obtained in the case of malonic and succinic acids and their hydroxy-derivatives. C. H. B.

Thermochemistry of the Carbohydrates and Polybasic Alcohols and Phenols. By F. Stohmann and H. Langbein (*J. pr. Chem.*, **45**, 305—356).—Continuing their work on the thermochemistry of food constituents and their derivatives (this vol., p. 4), the authors have determined the heats of combustion of a large number of carbohydrates and polybasic alcohols. The method employed was that described in former communications, and great care was taken to obtain the different substances dealt with in a state of purity. The results obtained are recorded in the following table, which contains in Columns I and II the heats of combustion per gram-molecule for constant volume and for constant pressure, and, in Column III, the heats of formation.

	I.	II.	III.
Pentoses :—	Cal.	Cal.	Cal.
Arabinose, $C_6H_{10}O_5$	558·3	558·3	256·7
Xylose, $C_6H_{10}O_5$	561·9	561·9	253·1
Rhamnose, $C_6H_{12}O_5$	718·2	718·5	259·5
Rhamnose, cryst., $C_6H_{12}O_5,H_2O$	711·5	711·8	335·2
Fucose, $C_6H_{12}O_5$	711·9	712·2	265·8
Hexoses :—			
d-Glucose, $C_6H_{12}O_6$	673·7	673·7	304·3
d-Fructose, $C_6H_{12}O_6$	675·9	675·9	302·1
Galactose, $C_6H_{12}O_6$	669·9	669·9	308·1
Sorbinose, $C_6H_{12}O_6$	668·6	668·6	309·4
Saccharin, $C_6H_{10}O_5$	656·9	656·9	252·1

	I.	II.	III.
Disaccharides:—			
Cane sugar, $C_{12}H_{22}O_{11}$	1352·7	1352·7	534·3
Milk sugar, $C_{12}H_{22}O_{11}$	1351·4	1351·4	535·6
Milk sugar, cryst., $C_{12}H_{22}O_{11},H_2O$	1345·2	1345·2	610·8
Maltose, $C_{12}H_{22}O_{11}$	1350·7	1350·7	536·3
Maltose, cryst., $C_{12}H_{22}O_{11},H_2O$	1339·8	1339·8	616·2
Trehalose, $C_{12}H_{22}O_{11}$	1349·9	1349·9	537·1
Trehalose, cryst., $C_{12}H_{22}O_{11},2H_2O$	1345·3	1345·3	679·7
Trisaccharides:—			
Melitose, $C_{18}H_{32}O_{16}$	2026·5	2026·5	769·5
Melitose, cryst., $C_{18}H_{32}O_{16},5H_2O$	2019·7	2019·7	1121·3
Melicitose, $C_{18}H_{34}O_{17}$	2043·0	2043·0	822·0
Polysaccharides:—			
Cellulose, $(C_6H_{10}O_5)x$	678·0	678·0	231·0
Starch, $(C_6H_{10}O_5)x$	677·5	677·5	231·5
Dextran, $(C_6H_{10}O_5)x$	666·2	666·2	242·8
Inulin, $C_{36}H_{62}O_{31}$	4092·1	4092·1	1230·9
Alcohols:—			
Ethylene glycol, $C_2H_6O_2$	281·4	281·7	113·3
Glycerol, $C_3H_8O_3$	396·8	397·1	160·9
Erythritol, $C_4H_{10}O_4$	504·1	504·4	216·6
Penterythritol, $C_5H_{12}O_4$	660·8	661·4	222·6
Arabitol, $C_5H_{12}O_5$	611·7	612·0	272·0
Mannitol, $C_6H_{14}O_6$	727·6	727·9	319·1
Dulcitol, $C_6H_{14}O_6$	723·6	723·9	323·1
Perseitol, $C_7H_{16}O_7$	835·8	836·1	373·9
Phenols:—			
Phenol, C_6H_6O	731·9	732·5	38·5
Catechol, $C_6H_6O_2$	684·9	685·2	85·8
Resorcinol, $C_6H_6O_2$	683·1	683·4	87·6
Quinol, $C_6H_6O_2$	683·0	683·3	87·7
Pyrogallol, $C_6H_6O_3$	639·0	639·0	132·0
Quercitol, $C_6H_{12}O_5$	704·1	704·4	273·6
Inositol, $C_6H_{12}O_6$	662·3	662·3	315·7

It will be noticed that the heats of combustion of many isomerides, such as arabinose and xylose, are very nearly identical, although this rule is not without several exceptions. Among the dihydroxybenzenes, the ortho- has the greatest and the para- the smallest heat of combustion, a fact which holds also for other benzene di-derivatives. It may be pointed out that a similar relation was observed by Ostwald to hold in the case of the affinity coefficients of these compounds. The combination of water of crystallisation with the different carbohydrates is, as an examination of the table will show, an exothermic process, and the same is true also of the action of hydrolytic agents in several cases which the authors examined. In the conversion of the sugars into the corresponding alcohols, also, heat is evolved, and it will be noticed that the difference between the heats of combustion of the alcohol and the sugar is in all cases

very nearly the same. A comparison of the heats of combustion of the alcohols with those of the hydrocarbons shows that the addition of each hydroxyl group in place of hydrogen in the hydrocarbon reduces the heat of combustion by about 44·7 cal., or that the heat of combustion of any alcohol will be $x44{\cdot}7$ cal. lower than that of the corresponding hydrocarbon. The constant varies from 39·5 to 47·0 cal. in different cases. H. C.

Theory of Heat of Solution and of Osmotic Pressure. By C. Dieterici (*Ann. Phys. Chem.* [2], **45**, 589—590).—An appendix to the author's paper under the same title (this vol., p. 676), in which he draws attention to some points connected with osmotic pressure raised by Lothar Meyer (*Sitz. Akad. Wiss. Berlin*, December, 1891). J. W.

Cryoscopic Communications. By J. Traube (*Ber.*, **25**, 1242—1243).—The author finds that in determining the freezing point of a liquid it is necessary that the temperature of the atmosphere in the surrounding space should not be more than 5° higher than the freezing point of the liquid, as, otherwise, the latter is found too high; thus, in a room at a temperature of 15—20° the freezing point of water was found, after 15 minutes, to be 0·03° higher than when first taken. The numbers previously given by the author for very dilute solutions, therefore, require a slight correction, which brings them more in accordance with those of Pickering. H. G. C.

Specific Gravities of Aqueous Solutions. By G. Charpy (*Compt. rend.*, **114**, 539—542).—In aqueous solutions of chlorides and sulphates, the sp. gr. corresponding to a given concentration is higher the greater the molecular weight of the salt, provided that the concentration is represented by the ratio of the number of molecules of the dissolved compound to the total number of molecules of the solution.

Increased sp. gr. of the solution with increased molecular weight is not general. In the case of the fatty acids, for instance, the sp. gr. diminishes as the molecular weight rises. Since there is always a contraction, if the sp. grs. of the two liquids are not widely different, there will be a particular degree of concentration showing a maximum sp. gr., and the solution showing the maximum will be weaker the greater the contraction, or, in other words, the higher the molecular weight of the acid. The existence of such a maximum in the case of acetic acid is well known; the author finds that the molecular concentration corresponding with this maximum is 55 in the case of acetic acid, 45 with propionic acid, 10 with butyric acid, and 1 with valeric acid.

The variation in the sp. gr. of a solution as a function of the concentration is a very complex phenomenon, and cannot be used in the investigation of the state of dissolved compounds as in the experiments of Pickering and of Mendeléeff.

Mixtures of methyl alcohol and amyl alcohol, and of benzene and ethyl acetate have sp. grs. which vary with absolute regularity as the concentration varies, and hence in these cases there is no contraction.

It follows that the contractions observed in the case of aqueous solutions are due either to a peculiar constitution of the water molecule or to the existence of a real chemical combination between the solvent and the dissolved substances. C. H. B.

Changes of Volume of Solutions of Salts. By Skubich (*Chem. Centr.*, 1892, i, 118—119; from *Apoth. Zeit.*, **6**, 662—663).—The author discusses the causes which occasion a change in volume when substances are dissolved in water: (1) the volume of a chemical compound is usually less than the sum of its components; (2) most salts occupy a less volume in solution than in the anhydrous state; (3) if a reduction in volume occurs in the preparation of a saturated solution of any salt, such a solution will dissolve a further quantity of the salt when subjected to increased pressure, whereas if the volume of the salt increase, pressure will cause a separation of salt from the solution saturated under the ordinary pressure. J. W. L.

Compressibility of Saline Solutions. By H. Gilbault (*Compt. rend.*, **114**, 209—211).—The method of experimenting was similar to that made use of by Cailletet in his researches on the compressibility of solutions, special precautions being taken to remove all traces of gas from the liquid and to maintain a constant temperature during each experiment. The observations were made at temperatures between 10° and 35°. For dilute solutions, the difference between the compressibility of water and that of the solution, or, as the author terms it, the saline compressibility, is proportional to the concentration whatever be the nature of the salt or the solvent. When a certain concentration is reached, the compressibility, increases less rapidly than the amount of salt dissolved, and if the behaviour of different salts throughout is represented in curve form, all the curves are, after suitable orientation, superposable. The compressibility of dilute solutions is affected more by change of temperature than that of concentrated solutions, and usually in the reverse manner, so that for each salt there generally exists a certain concentration for which the compressibility remains unaltered by change of temperature. If the same salt is dissolved in different solvents, the saline compressibilities will be in the same order as the compressibilities of the pure solvents, and the quotients of the saline compressibility divided by the compressibility of the solvent will be all the same. H. C.

Nature of Colloïd Solutions. By C. E. Linebarger (*Amer. J. Sci.* [3], **43**, 218—223).—Colloïd solutions differ from emulsions in their power of diffusion, emulsions not having the power of diffusion, but being subject only to the action of gravity. Diffusion, as has been shown by Nernst, is due to osmotic pressure, and a solution that diffuses should have an osmotic pressure. Osmotic pressure affords, as Van't Hoff has shown, a means of determining molecular mass, and determinations of the osmotic pressure of colloïd solutions should throw some light on the nature of the substances contained in such solutions.

The author determined the osmotic pressures of two solutions of

colloïd tungstic acid, one containing 0·02467 gram and the other 0·0100 gram of tungstic acid in 1 c.c. As a mean of the two determinations the molecular mass of colloïd tungstic acid was found to be about 1700, or nearly seven times 250, the number corresponding with the simple molecule H_2WO_4. The colloïd molecule would therefore consist of seven simple molecules in the case of tungstic acid, and this is in keeping with the ordinary assumption that the molecules of colloïds are very large.

A colloïd solution may be regarded as a step between a true solution and a true emulsion. The colloïd molecule is so much larger than the water molecule that it stands to reason that the properties of colloïd solutions must differ markedly from solutions of substances which have a molecule but several times heavier than water. Hence diffusion of colloïds takes place slowly; the osmotic pressure is small, and there is only a slight lowering of the freezing point or raising of the boiling point. H. C.

The Recognition of Changes of Curvature by means of a Flexible Lath. By S. U. Pickering (*Phil. Mag.*, **33**, 436—466.)—The author gives an exhaustive examination of four series of experiments which shows that the use of a flexible lath and of parabolas deduced from the experimental values leads to the same conclusions as to the existence and position of any changes of curvature. He first obtains a method for estimating the error of a drawing; the mean apparent error of the points, the number of points represented as showing excessive errors, and the arrangements of errors with like signs into groups are the three factors taken as constituting the total error of the drawing, and this error should be very nearly identical with the ascertained experimental error, if the drawing is to be acceptable. In all the cases investigated, this is so when the drawing represents the existence of the breaks in question, whereas a drawing or parabola which obliterates them exhibits an error many hundred and even thousand times greater than the experimental error. On the other hand, the introduction of fictitious breaks into a curve which is really continuous produces little or no reduction in the total error, and such a drawing can, therefore, not be accepted as "the simplest interpretation which is in harmony with the experimental error."

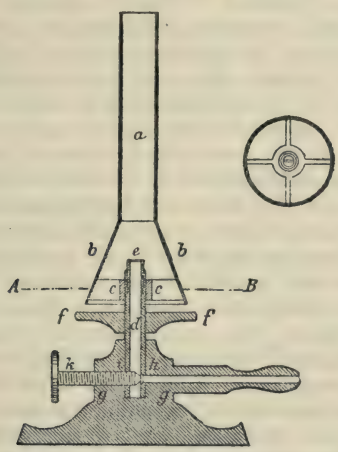
In the case of well-marked breaks, their position cannot be shifted even a short distance without increasing the apparent error beyond legitimate limits. Neither the position nor the existence of these breaks are subject to the "taste" of the draughtsman. In the case of a true break, it will appear consistently whatever form of plotting be adopted; six instances are given. The author also found that in a case where two parabolas, showing a break, and containing together seven constants, represented the results perfectly, a single parabola obliterating the break, but with the same number of constants, exhibited an error 25 times greater than the experimental error.

The author adds a few words in answer to some additional remarks of Rücker's on his interpretation of the densities of sulphuric acid. S. U. P.

Velocity of Decomposition of Diazo-Compounds by Water. By P. T. Muller and J. Hausser (*Compt. rend.*, **114**, 549—552, 669—671 and 760—763).—Diazo-compounds dissolved in water decompose with evolution of nitrogen and formation of the corresponding phenol. The reaction takes place slowly at the ordinary temperature, and more rapidly as the temperature is raised. If a convenient temperature is chosen, it is possible to measure the velocity of the reaction by measuring the volume of nitrogen liberated in a given time.

The authors find that the decomposition of 1 : 4-diazobenzenesulphonic acid obeys the ordinary laws of mass action, and takes place in accordance with the equation $dx/d\theta = C(A - x)$, where x represents the amount of nitrogen liberated in the time θ, and A the total amount of nitrogen present. The constant C is independent of the concentration. The decomposition of the 1 : 3-acid does not take place in quite so simple a manner, but may be expressed by the equation $dx/d\theta = (A - x)(C + 2k\theta)$. The constant C varies with the concentration. The decomposition of the meta-acid is also far more rapid than that of the para-acid. Diazotoluenesulphonic acid (Me : SO_3 : N_2 = 1 : 2 : 4) behaves like the paradiazobenzenesulphonic acid, but the behaviour of paradiazotoluene sulphate is like that of the meta-acid. The exceptional behaviour of the two latter compounds is supposed to be due to the influence of the phenol produced in each case. The experiments were made at 64°. H. C.

Flameless Incandescence produced by Coal Gas. By F. Parmentier (*Compt. rend.*, **114**, 744—746).—The author has investigated some of the conditions affecting the well known phenomenon of incandescence produced when a mixture of coal gas and air such as proceeds from an unlighted Bunsen burner is allowed to impinge upon warm platinum. With platinum wire, the incandescence is more intense, and the ignition of the gaseous mixture is more readily produced, the thinner the wire and the brighter and cleaner its surface. The difference is doubtless due to the smaller loss of heat by conduction when the wire is thin, and the smaller loss of heat by radiation when the surface is bright.



If platinum wire gauze is used, a ring of it concentric with the axis of the burner rapidly rises to a red heat, the gas above the gauze next takes fire, and afterwards the gas below the gauze ignites also.

Under similar conditions, spongy platinum becomes dull red, but the gaseous mixture is not ignited.

Platinum crucibles become hotter, and ignite the gaseous mixture more frequently the smaller they are and the brighter their surface. The larger the surface in proportion to the mass in the case of crucibles, dishes, &c., the lower the temperature to which the metal rises. Generally, any cause which tends to increase the loss of heat by conduction, radiation, convection currents of air, &c., reduces the temperature to which the metal is raised, and makes ignition of the gaseous mixture less frequent. C. H. B.

New Laboratory Burner. By N. Teclu (*J. pr. Chem.* [2], **45**, 281—286).—In summing up the points of an effective burner of the

Bunsen type, the author insists on the necessity for (1) a tube which shall be wide enough to admit of the influx of sufficient air, but not wide enough to diminish the pace of the stream of gas; (2) a tube long enough to ensure sufficient time for the complete mixture of the air drawn in with the gas; (3) the substitution of a screw-cock for the usual gas-cock; (4) an air inlet which shall have as large a surface as possible, and be concentric with the ascending column of gas. It is claimed that the burner here depicted combines these qualities, and can be used either as an ordinary Bunsen burner or a "solid flame" burner by regulating the air supply.

The combustion tube *a* is 10 cm. long and 10 mm. in diameter; the mouth of the funnel-shaped portion *b* is 2·5 cm. in diameter; the section of the funnel represented at AB will serve to explain how the tube is fixed on to the gas jet *d* by means of the screw *cc*. The regulating plate *f* is 3 cm. in diameter, and can be screwed up and down on the tube *d*. The screw *k* serves to regulate the gas supply. The gas jet *e* is 4 mm. long and 0·5 mm. wide, and is 2 cm. up the combustion tube. The tube by which the gas enters is 3·5 mm. in diameter. A. G. B.

Inorganic Chemistry.

Solubility of Iodine in Chloroform. By W. Duncan (*Pharm. J. Trans.*, **51**, 544).—Although the statements in the books imply that iodine is freely soluble in chloroform, the author finds that at 10°, 1 part of the iodine requires for solution as much as 56·6 parts of chloroform. R. R.

Action of Sulphur on Metallic Solutions. By J. B. Senderens (*Bull. Soc. Chim.* [3], **6**, 800—807).—Oxides of the alkalis and alkaline earths, when boiled with sulphur and water, react according to the equation:—

$$3M'O + nS + xH_2O = 2M'S_{n-2} + M'S_2O_3 + xH_2O,$$

when the solutions are concentrated; with weaker solutions, a greater amount of thiosulphate is formed from the decomposition of polysulphides, and hydrogen sulphide is liberated; but, under the most favourable conditions, not more than half of the alkaline polysulphides is so converted, even after prolonged boiling. When sulphur is triturated with mercurous oxide, the mixture inflames, and sulphurous anhydride with mercuric sulphate and sulphide are formed; with chromic anhydride, it behaves similarly, and the residue, treated with water, affords chromic chromate and chromic sulphate, although an aqueous solution of the anhydride is hardly affected by sulphur.

Silver oxide and carbonate are slowly decomposed by sulphur in presence of water at the normal temperature, and at 100° the action is complete: silver sulphate being formed, which subsequently decomposes into silver sulphide and hydrogen sulphate; the corresponding cuprous and cupric compounds also suffer decomposition when so treated, cupric sulphide being produced in each case. On boiling the oxides and hydroxides of mercury, lead, bismuth, cadmium, nickel, and cobalt with sulphur in water, their sulphides and sulphates are obtained, the cobalt reacting less readily than the nickel compounds, and yielding in addition some thiosulphate. Manganese and magnesium hydroxides afford their sulphides and thiosulphates, the compound MgS_3 being formed in the latter case.

The oxides of iron, zinc, and tin are not affected by this treatment, neither are the sulphates, nitrates, and chlorides of the alkalis, the alkaline earths, and of nickel, cobalt, cadmium, lead, and mercury; but the corresponding salts of silver and copper are slowly decomposed in the cold, and rapidly on boiling, with formation of argentic and cupric sulphides.

Solutions of acetates of the alkalis and alkaline earths are decomposed on boiling with sulphur; hydrogen sulphide, and acetic acid are liberated, and a thiosulphate is formed, while alkaline carbonate and bicarbonate solutions are decomposed below 100° with evolution of carbonic anhydride and hydrogen sulphide and formation of a thiosulphate.

Sulphur reduces boiling potassium chromate solution; hydrogen sulphide is given off, chromium sesquioxide is precipitated, and potassium thiosulphate is formed. Potassium dichromate solution affords, in like manner, chromium chromate with potassium sulphite and sulphate; argentic and mercuric chromates are also attacked, but the lead salt is unaffected.

Sulphur decomposes boiling solutions of sodium and calcium silicate with formation of polysulphides, of some thiosulphate, and evolution of hydrogen sulphide, while sulphur, boiled with powdered glass, determines a similar reaction which is prevented by a previous addition of hydrochloric acid.

The author is unable to confirm the statement that sulphur and water react at 100° to form hydrogen sulphide and sulphurous anhydride, and he considers the evolution of hydrogen sulphide, under such circumstances, to be due to the action of the sulphur on the glass vessels used. T. G. N.

Preparation of Crystallised Hydroxylamine. By L. Crismer (*Bull. Soc. Chim.* [3], **6**, 793; compare Abstr., 1890, 558).—A mixture of dry hydroxylamine zinc chloride (10 grams), and anhydrous aniline (20 c.c.), is distilled under a pressure of 20 mm. on a water-bath. The distillate of hydroxylamine, which crystallises on cooling, is washed with ether, care being taken to prevent access of moist air. Or dry ammonia gas is passed through absolute ether holding the zinc salt in suspension, and the decanted ethereal solution of hydroxylamine is subsequently distilled under reduced pressure, when crystals are obtained. The author confirms Lobry de Bruyn's observations on the crystals (this vol., p. 402). T. G. N.

Combination of Ammonia with Boron Bromide and Iodide. By A. Besson (*Compt. rend.*, **114**, 542—544).—Ammonia gas combines directly with boron bromide with great development of heat and partial conversion into boron nitride. In order to obtain a definite compound, all rise of temperature must be avoided. If dry ammonia, cooled to 0°, is passed into a solution of boron bromide in dry carbon tetrachloride, cooled to 0°, a white, solid substance separates, and at the end of the reaction the solvent is expelled by means of a current of dry air at 50—60°. The product is amorphous, and has the composition $BBr_3,4NH_3$. At 10° it absorbs more ammonia, but the excess is expelled in a current of dry air. When heated in dry hydrogen, decomposition begins at about 150°, without sublimation, the products being boron nitride and ammonium bromide. The compound is also decomposed by water and alkalis.

Boron iodide, under similar conditions, yields a white, amorphous compound, $BI_3,5NH_3$, which becomes brown when exposed to light, a small quantity of iodine being liberated. It is also decomposed when heated in a current of hydrogen, iodine being liberated, and it is decomposed by water. In a current of dry ammonia, the compound $BI_3,5NH_3$ absorbs the gas rapidly, and yields a liquid approximately of the composition $BI_3,15NH_3$; but even at 0° this compound is unstable, and in a current of dry air it gradually loses ammonia, and is reconverted into the original compound.

Boron iodide forms a crystalline compound with hydrogen phosphide.

In the preparation of boron iodide by the action of hydrogen iodide on amorphous boron obtained by the method of Deville and Wöhler, only a small portion of the boron is attacked, and this portion seems to be a more active variety than the remainder of the boron.

C. H. B.

Carbon Chlorobromides. By A. Besson (*Compt. rend.*, **114**, 222—224).—Bromine and chloroform in molecular proportion are heated in strong, sealed tubes for two hours at 225°; on opening the

tubes, a gas is given off consisting chiefly of hydrogen bromide; the heating is continued for some hours at 250°, after which the gas disengaged is mostly hydrogen chloride; the reaction terminates at 275°.

The three chlorobromides indicated by theory are thus obtained and can be separated by fractionation. The chlorobromide CCl_3Br fuses at −21°. The substance CCl_2Br_2 crystallises in fine needles melting at 22°; it distils at about 135°; its density at 25° is 2·42. Its odour resembles that of chloroform; it volatilises very rapidly at the ordinary temperature, and its vapour tension is 21 mm. at 16°, 31 mm. at 30°, and 268 mm. at 100°.

The chlorobromide $CClBr_3$ crystallises from its ethereal solution in transparent plates which melt at 55°; it distils at 160° with slight decomposition. It has the consistency of wax when melted; its odour recalls that of carbon tetrabromide. It is very soluble in ether, chloroform, carbon tetrachloride, carbon bisulphide, and benzene, less soluble in alcohol. Its density at 15° is 2·71. Attempts to obtain this substance as a brominated derivative of methyl chloride have failed.

The compound $CHBr_2Cl$ is easily obtained, but when this is heated with bromine at 250°, it yields bromoform and carbon tetrabromide; by carrying out the reaction at 200—225°, crystals have been obtained melting at 75°, and apparently consisting of a mixture of the compounds $CClBr_3$ and CBr_4, which are probably isomorphous, and have not been completely separated. W. T.

Action of Ammonium Chloride at its Dissociation Temperature on Silicates. By E. A. Schneider and F. W. Clarke (*Ber.*, **25**, 883—886).—In the course of a research on the constitution of natural silicates (Abstr., 1891, 529, and this vol., p. 125), the authors specially examined the action of dry hydrogen chloride on these compounds. For the sake of convenience, they now employ ammonium chloride. The following is the method of working:—A mixture of the finely-powdered silicate (1 gram) and dry ammonium chloride (10 grams) is heated in a platinum crucible at the temperature at which the ammonium chloride is rapidly volatilised, but below the dehydration temperature of the silicate. When all the ammonium chloride is volatilised, the residue in the crucible is extracted with water and the solution analysed. In some cases the residue is treated two or three times with ammonium chloride before extracting with water.

Olivine and xanthophyllite var. waluewite are scarcely attacked by ammonium chloride or by dry hydrogen chloride, although easily decomposed by the aqueous acid. On the other hand, the action on serpentine, klinochlor, and leuchtenbergite is considerable. The above silicates contain magnesia as a chief constituent. The silicates of the latter group probably contain the radicle –Mg·OH; whilst those of the first group do not. This reaction may possibly be used to determine the presence of the group –Mg·OH.

Of silicates which do not contain magnesia: natrolite,

$$Al_2Si_3O_{12}Na_2H_4,$$

after treatment three times with ammonium chloride, yielded 9·5 per cent. of sodium oxide as sodium chloride; prehnite, $Al_2Si_3O_{12}Ca_2H_2$, gave only 1·72 per cent. of calcium oxide as chloride; wollastonite, $CaSiO_3$, and pectolite, $Ca_2NaHSi_3O_9$, are attacked energetically by ammonium chloride, and gave respectively 36·98 per cent. CaO and 20·5 per cent. CaO, 6·95 per cent. Na_2O, and 0·54 per cent. MnO as chlorides. Here the action of dry hydrogen chloride is not dependent on the presence or absence of hydroxyl groups in these silicates.

The authors have also examined the action of ammonium chloride on various phosphates. Lazulite and turquoise are scarcely attacked; dufrenite is attacked energetically, and a considerable quantity of ferric chloride is formed. E. C. R.

Definite Alloys of Sodium. By Joannis (*Compt. rend.*, **114**, 585—587).—The author has previously shown that when an excess of lead is brought in contact with sodammonium, a compound

$$Pb_4Na,2NH_3$$

is obtained (this vol., p. 275). When the sodammonium is in excess, and the product is repeatedly washed with liquefied ammonia until excess of sodium is removed, the residue is a mixture of sodium amide, NH_2Na, and a perfectly definite alloy, PbNa. The alloy is readily obtained pure by the action of liquefied ammonia on a mixture of lead and sodium in atomic proportions. It is decomposed by water with formation of sodium hydroxide and liberation of lead in black flakes. When exposed to air, it rapidly becomes hot.

The potassium alloy is formed under similar conditions, and is more easily obtained in consequence of the greater solubility of potassium amide in liquefied ammonia. It has the composition Pb_2K.

An alloy of sodium and bismuth, $BiNa_3$, is obtained by the action of sodammonium in excess on pure bismuth. It forms a bluish-black granular mass, takes fire when exposed to air, and is decomposed by water with evolution of practically pure hydrogen. The analogy between the composition of this alloy and that of ammonia, phosphine, and hydrogen arsenide is of considerable interest.

An alloy of sodium and antimony, $SbNa_3$, is obtained in a similar manner. It oxidises very easily, takes fire when exposed to air, and is decomposed by water with evolution of pure hydrogen.

C. H. B.

Salts of Cæsium containing 3 Atoms of Halogen to 1 of Metal. By H. L. Wells and S. L. Penfield (*Amer. J. Sci.*, **43**, 17—32; compare Remsen, this vol., p. 779).—The compounds CsI_3, $CsBrI_2$, $CsBr_2I$, CsClBrI, $CsCl_2I$, $CsBr_3$, $CsClBr_2$, and $CsCl_2Br$ are obtained on dissolving, with the aid of heat, the appropriate normal cæsium halogen salt, and the halogen or halogens indicated by the formulæ, in a convenient quantity of water, or, in the single case of $CsBrI_2$, in dilute alcohol, and cooling until crystallisation occurs. The five compounds containing iodine are much more stable than the others, and will bear long exposure to the air at the ordinary temperature, but with very slight superficial change.

The three compounds containing no iodine usually become white on exposure for a few hours; but the stability of the compounds does not entirely depend on the volatility of the halogens contained in them. All the compounds except $CsBrI_2$ can be recrystallised from alcohol or from a mixture of alcohol and water. They form isomorphous, orthorhombic crystals, and a very remarkable relation exists between those containing iodine, the ratio of the two axes remaining nearly constant throughout, whilst the third varies. Exactly the same relations exist between the compounds containing no iodine, but in this series the ratio between the two constant axes varies slightly from the corresponding ratio in the iodine compounds. If an arrangement according to molecular weights is made with all the compounds containing bromine, or in a like manner with all those containing chlorine, a symmetrical series of axial ratios is not formed. This leads to the conclusion that the two series indicated have a special significance, and that iodine, with the highest atomic weight, plays an important part in the constitution of the first, whilst bromine acts in the same way in the second. Since several of the compounds contain only a single halogen atom of highest atomic weight, it follows that a single atom throughout exerts an influence on the symmetry of the series. This peculiar part, played by an iodine or bromine atom, may be explained by supposing it to be closely united either with cæsium or with one of the other halogen atoms. It seems probable from these considerations that the three halogen atoms in the compounds do not occupy similar positions in the molecules, and consequently that the salts described are not compounds of trivalent cæsium, but have some other structure.

The following table gives the chief properties of the compounds, which are well characterised:—

	Colour.	Melts in open tube.	Melts in closed tube.	Completely decomposes.
Series with iodine—				
CsI_3	Brilliant black	210°	201—208°	330°
$CsBrI_2$.....	Dark reddish-brown..	208	155—190	260
$CsBr_2I$	Deep cherry-red.....	246	243—248	320
$CsClBrI$	Dark yellowish-red ..	238	225—235	290
$CsCl_2I$.....	Deep or pale orange..	238	225—230	290
Series without iodine—				
$CsBr_3$.....	Yellowish-red.....	whitens	180°	160
$CsClBr_2$.....	Pale yellowish-red...	whitens	191	150
$CsCl_2Br$	Bright yellow.....	whitens	205	150

Attempts to prepare the other two possible salts, $CsClI_2$ and $CsCl_3$, were unsuccessful.

The crystallographic properties of the compounds above described harmonise with the view advanced by Remsen (*loc. cit.*) to explain the composition of double halogen salts, namely, that two halogen atoms can behave as bivalent oxygen. G. T. M.

Organosols. By E. A. Schneider (*Ber.*, **25**, 1164—1167).—The author applies the term "organosol" to the solution of a colloïd in an organic liquid, he also adds the formula of the colloïd and, in brackets, the name of the solvent.

Organosol Au_2S_2 (ethyl alcohol) is prepared by mixing an aqueous solution of aurosoauric sulphide (1·514 grams per litre) with 3 vols. of absolute alcohol, and dialysing this solution in absolute alcohol; the organosol closely resembles the hydrosol, but is more stable.

Organosol Au_2S (ethyl alcohol) is obtained in a manner similar to the preceding, but the solution, which is straw-coloured, only contains 0·001 per cent. Au_2S.

Organosol Ag (ethyl alcohol) is formed by the dialysis of the hydrosol in absolute alcohol, or by adding alcohol to the hydrosol, allowing it to coagulate, filtering by means of a Pasteur's tube, and dissolving the silver in absolute alcohol. A solution containing 0·1746 per cent. Ag is opaque, in layers of 2 mm. in thickness; on dilution, the colour is greenish-blue and finally yellowish-green in transmitted light, and violet-brown in reflected light. On distilling off the alcohol, the silver is deposited as a golden-yellow mirror.

The author suggests that it may be possible to explain the variations in colour of silver solutions by known optical laws without assuming the existence of allotropic modifications. J. B. T.

Preparation of Pure Colloïdal Silver. By E. A. Schneider (*Ber.*, **25**, 1281—1284).—Solutions of ferrous sulphate (150 grams of the salt in 500 c.c. of the solution) and of sodium citrate (280 grams of the salt in 700 c.c. of the solution) are mixed, and poured into a 10 per cent. solution of silver nitrate (500 c.c.). Day-light need not be excluded, but it is advisable to divide the mixture into five equal portions, as small quantities can be dealt with more easily than large. At the end of half an hour the supernatant liquid is removed from the precipitated colloïdal silver with a pipette, and the silver is thrown on to a filter (Schleicher and Schüll's No. 590 paper), filtered under diminished pressure, and dissolved on the filter in the minimum quantity of water; solutions may be thus obtained containing 20 grams of silver per litre. To this solution absolute alcohol is added with agitation until coagulation is perceptible, and, after remaining for several days, the colloïd is filtered under a diminished pressure of 10—20 mm. on a Pasteur filter-tube, when it forms a beautiful, iridescent incrustation. Colloïdal silver in this state of purity is soluble in alcohol, and cannot, therefore, be washed with this liquid to remove the last traces of crystalloïds. By this method, a product containing only 0·3—0·5 per cent. of iron salts is obtained.

A. R. L.

Action of Light on Silver Chloride. By A. Béchamp (*Bull. Soc. Chim.* [3], **6**, 836—840).—The author investigated the action of light on silver chloride under water in 1853, and found that after four days' exposure the silver chloride lost nearly 2 per cent. by weight, whilst the water precipitated silver nitrate and decolorised indigo. On fusing the altered silver chloride, it formed a lower horny, yellow,

transparent layer and an upper black, porous mass. (Compare Abstr., 1891, 1420.) T. G. N.

Separation of Barium from Strontium Salts. By Adrian and Bougarel (*J. Pharm.*, **25**, 345—348). If to a solution of a strontium salt containing barium there is added an excess of precipitated calcium sulphate, after a few hours' contact, with occasional stirring, the barium is completely removed from solution. Calcium is substituted for the barium, but can be removed by a couple of crystallisations. On these data, the authors found a commercial process commencing with commercial strontium carbonate or hydroxide, nitric acid, sodium carbonate, and calcium sulphate, and producing pure strontium carbonate, from which other pure strontium salts can be obtained, and commercial sodium nitrate. The process is equally applicable to strontium chloride, acetate, &c. J. T.

Nitrides of Barium and Strontium. By Maquenne (*Compt. rend.*, **114**, 220—222).—A current of nitrogen is passed, at a red heat, over an electrolytic amalgam of barium or strontium contained in an iron or nickel boat, when a product is obtained consisting of barium or strontium nitride, excess of the corresponding metal, finely divided iron or nickel from the boat, a little mercury, and a trace of baryta or strontia formed during the manipulation of the amalgam.

The quantity of hydrogen liberated on treating the mass with water is very variable; it is evidently derived from the action of water on the free barium or strontium present.

Correcting for the impurities found, barium nitride gives from 5·59 to 5·97 per cent. of nitrogen, and strontium nitride similarly gives 9·96 per cent. The formulæ N_2Ba_3 and N_2Sr_3 require 6·38 and 9·64 per cent. respectively.

Barium nitride does not give ethyl bases with alcohol. At a red heat, it reacts energetically with carbonic oxide, with production of baryta and barium cyanide.

Strontium nitride, under similar conditions, gives but a trace of cyanide.

This property of barium nitride explains the synthesis of barium cyanide from nitrogen, carbon, and baryta at a red heat. W. T.

Action of Magnesium on Chlorides. By K. Seubert and A. Schmidt (*Annalen*, **267**, 218—248).—The authors have studied the action of magnesium at various temperatures on the chlorides of a large number of elements; in some cases neutral, acid, and ammoniacal aqueous solutions of the chlorides, containing about 1 per cent. of the metal, were employed; in others the anhydrous chloride was used, and under these conditions a very violent reaction generally took place. It was noticed that, in some cases, the reduction of acid aqueous solutions of chlorides is not so effectively accomplished when the magnesium is employed in the form of filings as when it is used in the shape of small blocks or cubes.

The following is a summary of the results of the investigation:—

Family I: *Group* A.—Aqueous solutions of the chlorides of the

alkalis are not acted on by magnesium under any conditions; at a red heat, especially in an atmosphere of hydrogen, the chlorides are reduced to the corresponding metal, lithium being more readily acted on than sodium chloride, and the latter more readily than potassium chloride. *Group* B.—From neutral aqueous solutions of cupric chloride cuprous oxide is precipitated, from acid solutions copper is precipitated, and from ammoniacal solutions copper is precipitated, whilst cuprous chloride remains in solution; the anhydrous chloride is reduced to metal. The chlorides of silver and gold are readily reduced to metal, both in the dry and in the wet way.

Family II: *Group* A.—The chlorides of calcium, strontium, and barium are not decomposed by magnesium in aqueous solution; at a red heat, and in a stream of hydrogen, they are reduced to the corresponding metal, and the more readily the lower the atomic weight of the metal. *Group* B.—The chlorides of zinc and cadmium give in neutral solution both the metal and the hydroxide, but from acid solutions only the metal is precipitated; in ammoniacal solution, zinc chloride gives both the metal and the hydroxide, but cadmium chloride yields only the metal. Mercuric chloride, in neutral and in acid solution, is first reduced to mercurous chloride and then to the metal. When the anhydrous chlorides are heated with magnesium, they are reduced to the corresponding metals.

Family III: *Group* A.—Anhydrous boron chloride is reduced to boron, with formation of magnesium boride. Aluminium chloride is not acted on in acid solution, but in neutral solution the hydroxide is precipitated; at a red heat it is reduced to metal. *Group* B.—Thallious chloride is reduced to metal both in the dry and in the wet way.

Family IV: *Group* A.—The chlorides of carbon and of silicon are reduced to the corresponding elements, but titanium chloride seems to be converted into the sesquichloride. *Group* B.—From a neutral solution of stannic chloride, stannic acid is precipitated, but both the chlorides of tin are reduced to metal in acid solution. Lead chloride invariably gives the metal.

Family V.—The chlorides of phosphorus, arsenic, antimony, and bismuth are reduced to the corresponding element at a red heat; in acid solution, the chlorides of arsenic and antimony give the corresponding element, and also its hydroxide, but bismuth chloride gives only the metal.

Family VI: *Group* A.—From a neutral solution of chromium chloride the corresponding hydroxide is precipitated, but no reaction occurs in acid solution. The anhydrous chlorides of chromium, molybdenum, tungsten, and uranium are reduced to the corresponding elements at a red heat. *Group* B.—Chloride of sulphur yields sulphur when it is heated with magnesium.

Family VII: *Group* A.—In neutral, and in ammoniacal solution, manganese chloride is converted into manganous hydroxide, but no reaction takes place in acid solution; at a red heat, the anhydrous chloride is reduced to metal.

Family VIII.—From neutral solutions of the chlorides of iron, cobalt, and nickel the lower hydroxides are precipitated; the chlorides of cobalt and nickel show the same behaviour in ammoniacal solution.

Acid solutions of iron and cobalt chloride are reduced to the corresponding metal, but nickel chloride is not acted on. Platinic chloride is always reduced to metal. All the chlorides of this group are reduced at a red heat.

Magnesium can be advantageously employed instead of zinc for the precipitation of antimony and tin from solutions of their chlorides; reduction takes place more quickly than when zinc is used, and no contamination with lead is to be feared. The great purity of magnesium prepared electrolytically and its more rapid action render it very suitable for various other purposes for which zinc is usually employed; as, for example, for the reduction of ferric to ferrous salts in the estimation of iron volumetrically. F. S. K.

Cadmium Sulphides. By G. Buchner (*Chem. Zeit.*, **15**, 329—331).—The author has made several practical experiments with the various modifications of cadmium sulphide. The α-sulphide: A heavy precipitate produced by hydrogen sulphide in neutral, or faintly acid, cadmium solutions. It has a very bright, lemon-yellow colour, and makes a good covering paint. Mixed with white, the colour becomes pure yellow, but never reddish. Its sp. gr. varies from 3·906 to 4·147. It probably crystallises in the same form as greenockite (native cadmium sulphide). Strong heating or rubbing, or treatment with zinc chloride, or nascent hydrogen changes it into the β-modification, whilst fusion with sulphur makes it pass into the δ-state.

Exposed to the influence of light and air, the compound is slowly oxidised to cadmium sulphate, but when made into paint the colour is very permanent. On heating, the sulphide gradually becomes deep-yellow, orange, carmine-red, and finally dark violet-red, but on cooling it slowly regains its original colour, unless the heat has been too strong and partial oxidation to cadmium oxide has taken place.

The β-sulphide: A heavy precipitate produced by hydrogen sulphide in strongly acid solutions. Its colour is very bright, and not unlike red lead. It makes a good covering paint and, when mixed with white, produces a reddish colour. Its sp. gr. is greater than the yellow variety, and varies from 4·492 to 4·513. When heated with acids, it changes into the α- form, before dissolving. Prolonged heating also has that effect. When perfectly free from any α- admixture, it is not oxidised either in the dry or moist state, by the combined influence of light and air. When made into paint, its colour is absolutely permanent, even in strong daylight.

Cadmium sulphide obtained, say, during an analysis, is very often a mixture of the α- and β-modifications. For practical painting purposes, these, or their mixtures are, according to the author, the only admissible ones.

The γ- or soluble sulphide: Colloïdal cadmium sulphide is formed by treating a solution of cadmium iodide with hydrogen sulphide. The liquid becomes deep-yellow without giving a precipitate, which, however, immediately forms on the addition of an acid or even of ammonium chloride.

The same sulphide is also produced when freshly precipitated and washed δ-sulphide is suspended in water and treated with hydrogen

sulphide. The sulphide slowly dissolves, and does not readily re-precipitate, even on boiling. The addition of alum or potassium sulphate causes the sulphide to precipitate as the δ-modification.

The δ-sulphide: A bulky, yellow precipitate produced by treating an ammoniacal solution of cadmium hydroxide with hydrogen sulphide. After being dried, it forms amorphous, resinous lumps of a dark, reddish-brown colour. L. DE K.

Double Halogen Salts. By I. REMSEN (*Amer. Chem. J.*, **14**, 81—89; compare Abstr., 1889, 934).—A further investigation of the double halogen salts of several metals (see next abstract, and pp. 780, 784, 788) confirms the law that "when a halogen salt of any element combines with a halogen salt of an alkali metal to form a double salt, the number of molecules of the alkali salt which are added to 1 mol. of the other halogen salt is never greater, and is generally less, than the number of halogen atoms contained in the latter." To this law, which is in accordance with the hypothesis of the double halogen atom acting as a bivalent group, there are but few exceptions; in fact, only three or four out of over 400 cases; and the author explains these by suggesting that three halogen atoms, in which each halogen atom is trivalent, may possibly form together a trivalent group. Such an assumption makes it possible to regard the double halogen salts as constituted similarly to other compounds, and removes the need of classifying them amongst the so-called molecular compounds. G. T. M.

Double Halogen Salts of Lead. By C. H. HERTY (*Amer. Chem. J.*, **14**, 107—126; compare preceding abstract).—The author finds that of the five double iodides of lead and potassium, PbI_2,KI, $PbI_2,4KI$, $PbI_1,2KI + 4H_2O$, $PbI_2,2KI + 2H_2O$, and $3PbI_2, 4KI + 6H_2O$, described by Boullay, Ditte, and Berthelot, only one exists. This is the salt $KPbI_3,2H_2O$, which loses its water of crystallisation at 110°, and is decomposed, with evolution of iodine, at 310°. The corresponding sodium salt, $NaPbI_3$, crystallises in small needles, and is very deliquescent.

The double bromide of lead and potassium, $KPbBr_3 + H_2O$, crystallises in large, colourless plates; but the corresponding sodium compound could not be separated. The double chloride of lead and potassium, $KPbCl_3$, crystallises in slender, white needles which are anhydrous; the double chloride of lead and sodium does not appear to exist.

All the salts described are decomposed by water, and, in order that they may exist in solution, a certain minimum amount of alkali halogen salt must be present, this amount varying inversely as the atomic weight of the halogen atom present in the compound. The quantity of the halogen salt of lead dissolved by the alkali halogen salt increases with the atomic weight of the halogen. Only a very small quantity of lead fluoride dissolves in a solution of potassium fluoride, a larger quantity of lead chloride in potassium chloride solution, a still larger quantity of lead bromide in potassium bromide solution, and, greatest of all, lead iodide in potassium iodide solution. On the other hand, the number of molecules of water of crystallisa-

tion contained in the double halogen salts decreases with the atomic weight of the halogens, thus: $KPbI_3 + 2H_3O$, $KPbBr_3 + H_2O$, and $KPbCl_3$.

All the double halogen salts of lead and the alkalis admit of their constitution being expressed by formulæ in which two halogen atoms play the part of the so-called linking oxygen atom, and are consequently in harmony with Remsen's law of combination of alkali halogen salts with the halogen salts of other metals. G. T. M.

Mercurous Hypochlorsulphite. By J. E. Gilpin (*Amer. Chem. J.*, **14**, 182—184; compare Remsen, this vol. p. 779).—In connection with the work on double halogen salts, it was considered important to ascertain the molecular weight of one of them by determining the specific gravity of its vapour. To this end the compound SCl_2,Hg_2Cl_2, described by Capitaine (*J. pr. Chem.*, **18**, 422), was employed; but it was found to dissociate on heating, its constituents recombining when the temperature was lowered. G. T. M.

Samarium. By L. de Boisbaudran (*Compt. rend.*, **114**, 575—577), —The author has previously described three lines, λ 466·2, λ 462·7. and λ 459·3, seen when the spark from a coil with a long wire is allowed to play on the surface of solutions containing samarium, and also a band at λ 611—622, seen when the current is reversed.

Some pure samarium, prepared by Cleve, was fractionated with ammonia. The three lines are no longer visible in the tail fractions, are feeble in the middle, but somewhat stronger in the head fractions. The band 611—622 is strongest in the head fractions, but is still visible in the tail; even at the head it is less brilliant than the orange band of samarium. Like the bands of Z_β, the band 611—622 gains in brilliancy when the spark impinges on the centre of the liquid instead of at the side, whilst the orange band becomes somewhat less brilliant. Ferric chloride reduces the intensity of the orange band, but has still more effect on the band 611—622.

The three well known bands of samarium show marked differences in intensity when the point of impact of the spark on the liquid is altered. It is possible that there is a relation between the band 611—622 and the narrow band observed by Crookes in mixtures of basic yttrium and samarium sulphates. The author has observed the same, or an analogous, ray with many products; its position varies distinctly with the nature of the solid solvent employed. It is accompanied by a feebler and more refrangible ray. Lanthanum sulphate, with a little samariferous gadolinite, shows the stronger ray at 612·7, and the weaker at 619·6. Crookes gives 609 for his ray, but the difference in position may be due to the difference in the nature of the solvent. C. H. B.

Double Halogen Salts of Manganese. By C. E. Saunders (*Amer. Chem. J.*, **14**, 127—151; compare Remsen, this vol., p. 779). —In attempting to prepare double chlorides of manganese and lithium, and also of manganese and magnesium, a substance was obtained which proved to be manganous chloride with 2 mols. H_2O instead of

4 mols., which is the normal number. The substance forms slender, monoclinic prisms, and resembles ordinary manganous chloride, except that it does not lose water of crystallisation when dried over calcium chloride.

Manganous chloride combines with the chlorides of potassium, rubidium, and cæsium; but, following the groups of metals according to the periodic system, appears incapable of combining with any of the chlorides between cæsium and magnesium. The latter, however, marks the commencement of a new series, with every member of which manganous chloride can probably combine. The explanation of these facts is simple, if we assume that the acidic and basic powers of manganous chloride are about equal to those of strontium chloride, and that, in its compounds with the chlorides of potassium, rubidium, and cæsium, manganous chloride acts in its acidic capacity, whilst in its compounds with the chlorides of magnesium (zinc?), cadmium, &c., it acts in its basic capacity. Taking this view, it is easy to understand the break occurring between the two series.

The following table gives the double chlorides of manganese and potassium, ammonium, rubidium, and magnesium investigated by the author, and shows that there is a well marked regularity in the series.

$KMnCl_3 + 2H_2O$ (triclinic).	—	—
—	$(NH_4)_2MnCl_4 + 2H_2O$ (monoclinic).	
—	$Rb_2MnCl_4 + 2H_2O$ (triclinic).	
$CsMnCl_3 + 2H_2O$ (orthorhombic).	$Cs_2MnCl_4 + 2H_2O$ (triclinic).	

$Mn_2MgCl_6 + 12H_2O$.
$Mn_2MgBr_6 + 12H_2O$.

Special efforts were made by the author to obtain both the missing compounds from the left-hand series, but without success. The entire dissimilarity in crystalline system and habit between the potassium and cæsium salt is remarkable, and indicates that, although chemically analogous, the compounds are not really very closely related to each other. G. T. M.

Nickel Potassium and Cobalt Potassium Fluorides. By C. Poulenc (*Compt. rend.*, **114**, 746—749).—When nickel chloride is heated with potassium hydrogen fluoride, decomposition takes place with evolution of hydrogen fluoride and considerable intumescence. The mixture is heated for about an hour at 220°, and afterwards is kept in fusion for about 10 minutes, and then cooled very slowly. The product is treated with water in order to remove potassium chloride, and *nickel potassium fluoride*, NiF_2,KF, is obtained in beautiful, green plates of sp. gr. 3·27. The compound is easily soluble in water, very slightly soluble in methyl or ethyl alcohol, insoluble in benzene and terebenthene. It dissolves in cold hydrofluoric acid and also in nitric and hydrochloric acids, the solubility in the latter cases increasing with the temperature. In contact with ammonia, the double fluoride gradually becomes violet-blue; when heated in presence of air,

potassium fluoride volatilises, and crystallised green nickel oxide is left; hydrogen reduces the salt at a red heat; fused alkaline carbonates produce nickel oxide and an alkaline fluoride; fused potassium hydrogen sulphate produces nickel sulphate and potassium fluoride.

Cobalt chloride, under similar conditions, yields *cobalt potassium fluoride*, CoF_2,KF, in garnet-red, crystalline plates of sp. gr. 3·22. In general properties it is strictly analogous to the nickel compound, but in its preparation alcohol must be used instead of water for the extraction of the potassium chloride in consequence of the difficulty of removing the water from the crystals of the double fluoride.

C. H. B.

Rhodosochromium Salts. By S. M. Jörgensen (*J. pr. Chem.* [2], **45**, 260—274; compare Abstr., 1885, 23).—*Rhodosochromium chloride* (roseochromium chloride) $(HO)_3(Cr_2,6NH_3)Cl_3 + 2H_2O$, is formed when a solution of chromammonium chloride in ammonium chloride oxidises spontaneously in sealed flasks; in the author's case, the change was allowed to progress for four years; at the end of this time, the mixture of rhodosochloride and ammonium chloride crystals which had separated were washed by decantation with successive small quantities of cold water acidified with hydrochloric acid, until all the ammonium chloride was dissolved; the rhodosochloride was then dissolved in water, reprecipitated by a saturated solution of ammonium chloride, and washed first with hydrochloric acid diluted with three times its volume of water, and finally with alcohol. The new salt crystallises in crimson, microscopic prisms; it gradually loses 1 mol. H_2O over oil of vitriol, and is slowly decomposed at 100°. One part of the salt dissolves in 10·6 parts of water at 18°; the solution decomposes when heated, becoming first grey, then green, and finally depositing all the chromium as hydroxide. Even at the ordinary temperature, the aqueous solution becomes alkaline and much bluer after 24 hours, and in a longer time deposits chromium hydroxide. The following reactions are obtained with a 4 per cent. cold aqueous solution, freshly prepared; unless otherwise stated, the precipitates are crimson and crystalline. Dilute nitric acid precipitates the nitrate even in very dilute solutions; concentrated hydrochloric acid yields no precipitate; concentrated hydrobromic acid throws down the bromide; solid potassium iodide causes the iodide to separate; dilute sulphuric acid, in the presence of alcohol, precipitates the hydrogen sulphate; ammonium sulphate precipitates the normal sulphate when the solution is stirred; sodium dithionate gives a precipitate which is doubtfully crystalline; hydrofluosilicic acid gives a doubtfully crystalline, bulky precipitate; hydrogen platinochloride gives a buff precipitate; mercuric chloride gives a lilac precipitate; hydrogen aurochloride gives almost immediately a brilliant, red-brown precipitate; potassium chromate precipitates a brilliant, red-brown chromate; potassium dichromate gives a voluminous, orange-yellow precipitate; sodium pyrophosphate gives a precipitate which dissolves in excess; disodium hydrogen phosphate gives no precipitate save in the presence of ammonia; ammonium thiocyanate gives a precipitate in concentrated solution; potassium ferrocyanide gives a lilac-red, and the ferricyanide a chamois-brown precipitate.

Of the salts precipitated as above the *aurochloride*,

$$(HO)_3(Cr_26NH_3)Cl_3,2AuCl_3 + 2H_2O,$$

the *platinochlorides*, $2[(HO)_3(Cr_26NH_3)Cl_3],3PtCl_4 + 6H_2O$ and $(HO)_3(Cr_26NH_3)Cl_3,PtCl_4 + 2H_2O$, the *bromide*, $(HO_3)(Cr_26NH_3)Br_3 + 2H_2O$, the *iodide*, $(HO)_3(Cr_26NH_3)I_3 + 2H_2O$, the *nitrate*, $(HO)_3(Cr_26NH_3)(NO_3)_3 + H_2O$, the *hydrogen sulphate*,

$$2[(HO)_3(Cr_26NH_3)H(SO_4)_2] + 3H_2O,$$

the *normal sulphate*, $2[(HO)_3(Cr_26NH_3)],3SO_4 + 5H_2O$, and the *chromate*, $2[(HO)_3(Cr_26NH_3)],3CrO_4 + 7H_2O$, were analysed and are fully described.

The *persulphide*, $2[(HO)_3(Cr_26NH_3)],S_{11} + 4H_2O$, is precipitated in red-brown, octahedral crystals on adding ordinary ammonium sulphide to a solution of the rhodosochloride and subsequently ammonium sulphide containing much sulphur. The *hydrogen oxalate*, $2[(HO)_3(Cr_26NH_3)],H_4(C_2O_4)_5 + 2H_2O$, is precipitated by adding the rhodosochloride to a cold solution of ammonium oxalate, filtering, and adding oxalic acid and alcohol. It forms crimson-red, rhombohedral prisms and rhombic tables. A. G. B.

Constitution of Cobalt, Chromium, and Rhodium Bases. By S. M. JÖRGENSEN (*J. pr. Chem.* [2], **45**, 274—280; compare Abstr., 1883, 554, *J. pr. Chem.* [2], **42**, 206, and preceding abstract).—Inasmuch as rhodosochromium chloride yields chlorotetramine chromium chloride, $Cl{\cdot}Cr\left\{\begin{matrix}OH_2{\cdot}Cl\\NH_2{\cdot}NH_3{\cdot}NH_3{\cdot}NH_3{\cdot}Cl\end{matrix}\right.$, chromium chloride, ammonium chloride, and water when decomposed by hydrochloric acid, the two chromium atoms cannot be regarded as directly united in the rhodosochloride. The author regards this salt as constituted of the two monovalent residues $-Cr\left\{\begin{matrix}HO\\NH_3{\cdot}NH_3{\cdot}Cl\end{matrix}\right.$ and

$$-Cr\left\{\begin{matrix}OH_2{\cdot}Cl\\NH_3{\cdot}NH_3{\cdot}NH_3{\cdot}NH_3{\cdot}Cl,\end{matrix}\right.$$

united together by an atom of oxygen. So also he regards it as impossible that the chromium atoms in the erythro-salts (Abstr., 1883, 554) should be directly united, and points out that the erythrochloride probably consists of the two residues $-Cr\left\{\begin{matrix}OH_2{\cdot}Cl\\NH_3{\cdot}[NH_3]_3{\cdot}Cl\end{matrix}\right.$ and $-Cr\left\{\begin{matrix}NH_3{\cdot}Cl\\NH_3{\cdot}[NH_3]_3{\cdot}Cl,\end{matrix}\right.$ united by a NH group, in which the N, being unsaturated, readily combines with HCl. General formulæ are deducible from these considerations. A. G. B.

Chromosulphuric Acid and Metallic Chromosulphates. By A. RECOURA (*Compt. rend.*, **114**, 477—479).—The green chromic sulphate, $Cr_2(SO_4)_3$, previously described (this vol., p. 411), combines in aqueous solution with sulphuric acid and various metallic sulphates to form compounds, such as $Cr_2(SO_4)_3,K_2SO_4$, from which the

sulphuric acid is not at once precipitated by barium salts, although the metal introduced with the sulphate may be recognised by means of the usual tests. Hence these compounds may be regarded as salts of a complex acid, chromosulphuric acid, $H_2Cr_2(SO_4)_4$, resembling hydrochromocyanic and chromoxalic acids. The chromosulphates are not, however, very stable substances, as the sulphuric acid is gradually precipitated by barium chloride even in the cold, and at once on heating.

Chromosulphuric acid, $H_2Cr_2(SO_4)_4,11H_2O$, is prepared by reducing chromic acid (50 grams) in the cold with alcohol (15 c.c. of 95 per cent.) and sulphuric acid (50 c.c.) in the presence of a minimum quantity of water (25 c.c.). The green, syrupy liquid thus obtained is evaporated to dryness, and the residue extracted with glacial acetic acid, which yields a solution from which the acid is obtained as a green, hygroscopic powder on evaporating the solvent in a vacuum. Chromosulphuric acid is stable in dry air, but unstable in aqueous solution, in which it gradually changes into the violet chromic sulphate previously described (*loc. cit.*).

Potassium chromosulphate, $K_2Cr_2(SO_4)_4,4H_2O$, is best prepared by heating chrome alum, first to 90°, when it loses half its water of crystallisation (12 mols.), and then to 110°, when it loses a further quantity (8 mols.). It dissolves slowly in cold water to a solution which does not yield a precipitate with barium chloride, but is at once precipitated by platinic chloride or picric acid. The *ammonium* and *sodium* salts are similar green powders.

Another way of preparing these alkali salts consists in reducing the dichromates with alcohol and sulphuric acid as in preparing the chrome alums, but in the presence of a small quantity only of water.

Other compounds similar to chromosulphuric acid, but containing more sulphuric acid, have been prepared. Jn. W.

Note by Abstractor.—Chromosulphates were described by Cross and Higgins in 1882 (Trans., 1882, 113).

New Series of Fluoroxy-compounds of Molybdenum. By A. Piccini (*Real. Accad. Linc.*, 7, i, 267—268).—When potassium fluoroxymolybdate, $MoO_2F_2,2KF + H_2O$, is dissolved in warm hydrogen peroxide solution (4 per cent.) oxidation occurs, and a salt of the composition $MoO_3F_2,2KF + H_2O$ separates out on cooling in splendid yellow laminæ. It is not altered by contact with air, and is very soluble in hot water, sparingly so in cold water. On heating at 100°, it loses water, and at 120° it gives off oxygen, leaving a white residue of $MoO_2F_2,2KF$, which falls to powder on cooling, and on prolonged heating yields potassium molybdate. The new salt reduces potassium permanganate in dilute sulphuric acid solution with evolution of oxygen.

The author proposes to prepare and study salts of analogous composition to the one now described. W. J. P.

Double Halogen Salts of Tin. By G. M. Richardson (*Amer. Chem. J.*, **14**, 89—107; compare Remsen, this vol., p. 779).—The double halogen salts described in this paper were prepared, in most

cases, by mixing the solutions of the constituent halogen salts. The alkali halogen salt was dissolved in water, and the tin solution was prepared by dissolving the metal in hydrochloric acid or hydrobromic acid until the liquid no longer contained free acid.

Potassium stannochloride, $KSnCl_3,H_2O$, is obtained on mixing potassium chloride with a large excess of stannous chloride. It forms white, hair-like crystals, which do not lose water when allowed to remain over sulphuric acid, and dissolves in hot potassium chloride solution, and in hot hydrochloric acid, with formation of *dipotassium stannochloride*, $K_2SnCl_4,2H_2O$, which crystallises out on cooling in large, white, orthorhombic plates [$a : b : c = 0{\cdot}685231 : 1 : 0{\cdot}758634$]. It also crystallises with 1 mol. H_2O.

Stannous chloride unites with ammonium chloride, and stannous bromide with potassium bromide and with ammonium bromide, to form double halogen salts, which are analogous to the potassium salts above described. In the case of the chlorides, the tendency to form the salt with 2 mols. of the alkali chloride is very strong, and is even more marked in the case of ammonium chloride than in that of potassium chloride. With the bromides, on the other hand, the tendency is to form the salt with 1 mol. of the alkali bromide, whilst the one containing 2 mols. of the alkali bromide is obtained with greater difficulty, and in this case also the salt with 2 mols. of ammonium bromide is much more readily obtained than the potassium salt.

No salts of definite composition could be obtained by mixing solutions of stannous bromide and potassium chloride, or of stannous chloride and potassium bromide; and the double halogen salts of tin with lithium and sodium, if formed at all, were so soluble that they refused to crystallise. G. T. M.

Fluoroxyvanadates, Fluoroxyhypovanadates, and Fluorovanadites. By A. Piccini and G. Giorgis (*Gazzetta*, **22**, i, 55—96; compare Abstr., 1889, 214).—The authors have re-examined a number of vanadium fluorine compounds on account of the discrepancies between the results previously obtained by them (Abstr., 1889, 214) and those obtained by Ditte, Petersen, and Baker (Abstr., 1888, 114, 558; 1889, 107; 1890, 15; and Trans., 1879, 760). In analysing these compounds, the fluorine was determined by Penfield's method, the vanadium by Gerland and Gibbs' process, and the alkalis by Roscoe's method (this Journal, 1871, 28); the vanadic anhydride used in the preparations was obtained by carefully calcining pure ammonium metavanadate repeatedly precipitated from its aqueous solution by ammonium chloride; the compounds corresponding with the lower oxides of vanadium were obtained by reducing solutions of pure vanadates by the electric current. For this purpose a battery of about 20 Daniell cells is sufficient.

The solution of pure vanadic anhydride in hydrofluoric acid is not greenish, as stated by Ditte and Petersen, but yellow, the colour being very faint when very strong hydrofluoric acid is used, and becoming more intense on diluting the solution.

Octahedral ammonium fluoroxyvanadate, $VO_2F,3NH_4F$, is prepared by dissolving vanadic acid in excess of hydrofluoric acid and exactly

neutralising the hot solution with ammonia. Baker assigns the formula $12NH_4F,V_2O_5,2VOF_3$ to this substance. It crystallises in octahedra and not in a rhombic form, as stated by Petersen; after pressing between filter-paper, the crystals only lose 0·34 per cent. of their weight at 100°, and finally they may be calcined with care without any loss of vanadium.

Lamellar ammonium fluoroxyvanadate, $2VO_2F,3NH_4F$, may be obtained by heating an aqueous solution of the preceding compound on the water-bath. It is prepared by dissolving vanadic anhydride in a slight excess of hydrofluoric acid, adding ammonium fluoride in the proportion of $1\frac{1}{2}$ mols. per mol. of vanadium, and concentrating the solution. It crystallises in thin, yellowish, nacreous laminæ, and may be recrystallised unaltered from an aqueous solution; it only loses slightly in weight at 100°, but gives off white fumes containing vanadium if rapidly heated to 300°; when gently heated, it may be calcined without loss. Petersen assigns to this compound the formula $HF,7NH_4F,4VO_2F$.

Acicular ammonium fluoroxyvanadate, $2VOF_3,3NH_4F,H_2O$, is obtained by dissolving the octahedral salt in 10 per cent. hydrofluoric acid, and gently evaporating on the water-bath; on cooling, a deposit is formed of pale yellowish, acicular prisms, which have a silky appearance when dry, attack glass, possess an odour of hydrofluoric acid, and are decomposed by sulphuric acid. It is decomposed by crystallisation from water or hydrofluoric acid. It is also decomposed at 100°, but may be calcined with care without loss of vanadium. This compound may possibly be that obtained by Petersen by adding not too large an excess of ammonium fluoride to a hydrofluoric solution of vanadic anhydride and concentrating, a product which was said to have the formula $3HF,9NH_4F,5VOF_3$, but which the author has not succeeded in preparing.

Lamellar potassium fluoroxyvanadate, $2VO_2F,3KF$, obtained by dissolving vanadic anhydride in a hot solution of potassium fluoride, crystallises in yellowish, nacreous plates, dissolves in water, forming an intense yellow solution, attacks glass very slightly, and is only slightly affected by sulphuric acid; it does not lose weight at 100°, or on ignition. Baker assigns the formula $6KF,V_2O_5,2VOF_3 + 2H_2O$ to this compound. The authors have found it impossible to prepare in a state of even approximate purity the compounds $2KF,VOF_3$ and $4KF,VF_5,VF_3$ obtained by Petersen by adding a solution of potassium fluoride to a hydrofluoric solution of vanadic anhydride.

On dissolving the compound $2VO_2F,3KF$ in a hot solution of hydrofluoric acid, and allowing the solution to cool, an acicular salt crystallises out, having approximately the composition

$$HF,3KF,2VOF_3.$$

After standing for a long time, this substance appears to have the composition $2VOF_3,3KF + H_2O$.

Sodium fluoroxyvanadate, $VOF_3,VO_2F,3NaF,H_2O(?)$, is prepared by dissolving sodium carbonate (3 mols.) and vanadic anhydride (2 mols.) in distilled hydrofluoric acid, evaporating on the water-bath until every 100 c.c. of solution contains about 10 grams of

vanadic anhydride, and allowing the solution to remain for a few days. The liquid is then decanted from the crystalline deposit formed and allowed to evaporate spontaneously. After a time yellowish-white, bulky, tabular prisms of the sodium salt are formed, which, however, are very unstable, and turn green and give off an odour of hydrofluoric acid even during drying.

Zinc fluoroxyvanadate, $VO_2F,ZnF_2,7H_2O$, prepared by Baker's method, has the preceding formula. It is very soluble in water, and crystallises in hard, rhombic prisms which rapidly alter on exposure to the atmosphere, becoming coated with a reddish film.

Octahedral ammonium fluoroxyhypovanadate, $VOF_2,3NH_4F$, may be obtained by the electrolytic reduction of a solution of ammonium metavanadate acidified with hydrofluoric acid, and containing ammonium fluoride. The liquid turns blue after a time, and a blue, crystalline deposit is produced. It may also be prepared by reducing vanadic acid with alcohol and adding ammonium fluoride, or by dissolving ammonium metavanadate in dilute hydrofluoric acid, reducing with sulphurous anhydride, neutralising with ammonia, and adding ammonium fluoride. It forms blue, octahedral crystals, soluble in water, but insoluble in a solution of ammonium fluoride. It remains unaltered at 100°, but decomposes on heating strongly. The monoclinic salt, $VOF_2,2NH_4F,H_2O$, may be obtained by dissolving the preceding salt in hot hydrofluoric acid.

Potassium fluoroxyhypovanadate, $VOF_2,2KF$, is obtained in sky-blue crusts by treating a solution of ammonium metavanadate reduced by sulphurous anhydride with potassium fluoride. Petersen's compound, $8NaF,3VOF_2,2H_2O$, could not be isolated in a state of sufficient purity.

Zinc fluoroxyhypovanadate, $VOF_2,ZnF_2,7H_2O$, is prepared by the electrolytic reduction of a hydrofluoric solution of vanadic acid and zinc oxide in molecular proportions. The liquid becomes successively blue and green; a deposit of blue, prismatic crystals is then formed, if the solution is sufficiently concentrated. It is soluble in cold water, but partially decomposes on boiling, except in the presence of hydrofluoric acid. The aqueous solutions are slowly oxidised on standing. When acidified with sulphuric acid, they reduce solutions of potassium permanganate. The salt loses 6 mols. H_2O at 100°, and becomes decolorised, but it regains its colour on re-hydration. On treating it with nitric acid, it is oxidised, and on evaporating to dryness, the residue has the composition $V_2O_5,2ZnO$.

The *cadmium* salt, $VOF_2,CdF_2,7H_2O$, is prepared in a similar manner to the zinc salt, and has similar properties.

Cobalt fluoroxyhypovanadate, $VOF_2,CoF_2,7H_2O$, is obtained by dissolving vanadic anhydride in hydrofluoric acid, adding a little less than a molecular proportion of cobalt carbonate and reducing electrolytically. When the solution becomes of an intense blue colour, it is filtered and concentrated. The salt crystallises in bottle-green prisms which have a violet reflex, and yield a rose-coloured powder. It commences to lose weight at 80°, and becomes anhydrous at 160°.

Nickel fluoroxyhypovanadate, $VOF_2,NiF_2,7H_2O$, is obtained like the preceding compound, and forms green crystals isomorphous with those of the cobalt salt.

Zinc fluorovanadite, $VF_3,ZnF_2,7H_2O$, is obtained by prolonging the action of the electric current in the preparation of zinc fluoroxyhypovanadate until the blue liquid turns green. On concentrating the solution, the zinc salt is deposited in minute, lustrous crystals which lose the greater part of their water of hydration at 100°. It is partially oxidised by the air, and energetically by nitric acid.

The *cadmium* salt, $VF_3,CdF_2,7H_2O$, generally resembles the zinc salt; it is green, sparingly soluble in water, and its solution is oxidised on exposure to the air.

In conclusion, the authors point out that in the elements vanadium, niobium, and tantalum the tendency to form highly fluorinated compounds increases with the atomic weight of the element; thus, whilst VO_2F is not affected by small quantities of hydrofluoric acid, NbO_2F is converted into $NbOF_3$, and $TaOF_3$ into TaF_5. The formation of the three zinc compounds, $VO_2F,ZnF_2,7H_2O$, $VOF_2,ZnF_2,7H_2O$, and $VF_3,ZnF_2,7H_2O$, which all crystallise with the same amount of water, contain the same number of atoms, have similar crystalline habits, and are geometrically isomorphous, seems to indicate that an atom of fluorine may in many cases be substituted for an atom of oxygen without altering the essential character of the compound.

S. B. A. A.

Double Halogen Salts of Antimony. By C. E. Saunders (*Amer. Chem. J.*, **14**, 152—164; compare Remsen, this vol., p. 779).—The double chloride of antimony and cæsium to which Godeffroy (*Zeit. allg. österr. Apotheker-Vereins*, 1874, 161) gave the formula $SbCl_3,6CsCl$, has really the formula $Cs_3Sb_2Cl_9$. It crystallises in elongated, orthorhombic prisms, which are sometimes twinned, giving a rough, pseudo-hexagonal appearance, and is the only compound of cæsium chloride and antimony chloride that can be easily obtained. Similarly, the double chloride of antimony and rubidium, described by that author (*ibid.*, 1875, 21), has, most probably, the formula $Rb_{23}Sb_{10}Cl_{53}$. It crystallises in pseudo-hexagonal, superposed plates, and is so stable that it may be heated to a temperature of nearly 230° without undergoing change. Rubidium chloride and antimony chloride also combine to form the double salts $Rb_5Sb_3Cl_{14}$ and $RbSbCl_4$. The former was obtained as pale-yellow crystals, resembling rhombohedra in general shape; the latter in apparently orthorhombic, colourless crystals, which, when freshly made, had brilliant faces, but soon became opaque on exposure to air.

G. T. M.

Double Halogen Salts of Bismuth. By C. P. Brigham (*Amer. Chem. J.*, **14**, 164—182; compare Remsen, this vol., p. 779).—Of the three previously described double chlorides of bismuth and potassium, only one, namely, that prepared by Jacquelaine (*Ann. Chim. Phys.*, **66**, 113), of the formula $BiK_2Cl_5 + 2H_2O$, really exists. A salt of the composition $BiKCl_4 + H_2O$, which loses half a molecule of water of crystallisation, when dried over calcium chloride, is obtained when bismuth oxide (5 mols.) and potassium chloride (4 mols.) are dissolved in hot hydrochloric acid, and the solution is evaporated until, on cooling, a mass of fibrous needles, radiating from centres, crystallises out.

The salts to which Godeffroy has attributed the formulæ Rb_6BiCl_9 and Cs_6BiCl_9 do not really exist, the latter formula having been given to a mixture of the two compounds Cs_3BiCl_6 and $Cs_3Bi_2Cl_9$. Of these, the former crystallises in thin, transparent plates, and the latter in elongated, yellow prisms.

Bismuth chloride forms, with rubidium chloride, the salts Rb_3BiCl_6, $Rb_{23}Bi_{10}Cl_{53}$, and $RbBiCl_4 + H_2O$, of which the two latter correspond with the double chlorides of antimony and rubidium described by Saunders (preceding abstract).

As the atomic weight of the alkali in combination with bismuth increases, the amount of water of crystallisation decreases, thus:— $BiCl_3,2NaCl + 3H_2O$; $BiCl_3,2KCl + 2H_2O$; $BiCl_3,RbCl + H_2O$; $BiCl_3,3CsCl$. G. T. M.

Preparation and Assaying of Pure Platinum. By F. Mylius and F. Foerster (*Ber.*, **25**, 665—686).—This paper contains first an account of the method for assaying platinum, elaborated by Stas and Deville, in connection with the preparation of the standards for the International Committee of Weights and Measures. An idea of the accuracy of their method is given by the following figures, which represent the results of an analysis of a metre-rod:—

	Deville.	Stas.
Platinum	89·8200	89·8520
Rhodium	0·1300	0·1350
Ruthenium	0·0290	0·0386
Iron	0·0748	0·0506
Iridium	9·8560	9·8652
	99·9098	99·9414

The authors have examined the delicacy of this method by preparing the pure metals, mixing a known small quantity of each with a known weight of platinum, and then estimating this quantity by the Stas-Deville method. To obtain the mixture, a known weight of platinum sponge was impregnated with a solution containing a known weight of the other metal, and the whole was dried, and ignited in a current of hydrogen. The determination of ruthenium and iridium is accurate, and so is that of rhodium, with practice; palladium cannot be so accurately determined. The determination of iron is also accurate; that of copper is less so.

A new method is then proposed for the examination of platinum containing only small quantities of impurities. It is placed in a porcelain boat inside a glass tube, which is heated to about 238° by quinoline vapour, and first chlorine and then a mixture of chlorine with carbonic oxide (and anhydride) is passed over it; the platinum volatilises, and the residue in the boat is examined for impurities. Iridium, however, also volatilises to some extent with the platinum; so do palladium, ruthenium, osmium, gold, and iron; but rhodium, silver, copper, lead, and zinc do not volatilise at all. By combining this method with that of Stas and Deville, the presence of the following quantities of impurities may be detected:—

Iridium	0·003 per cent.
Ruthenium	0·005 „
Rhodium	0·004 „
Palladium	0·01 „
Iron	0·001 „
Copper	0·002 „
Silver	0·002 „
Lead	0·002 „

The following, hitherto unpublished, method of Finkener's for obtaining platinum free from impurities, especially iridium, is then described; it depends on recrystallisation of sodium platinochloride. Commercial purified platinum is dissolved in *aqua regia*, to the solution of the chloride, freed from oxides of nitrogen, the calculated amount of pure sodium chloride is added, the solution is concentrated to a small bulk, and allowed to cool whilst being continuously stirred. The crystals which separate are freed from mother liquor by suction, washed with a concentrated solution of sodium chloride, and dissolved in a 1 per cent. solution of sodium carbonate. The solution is allowed to cool, when the salt again separates out. It is then dried at 120°, reduced in a current of hydrogen at a low temperature, and the platinum sponge thus obtained is washed for a long time with water, and finally dried and ignited. The metal thus obtained was extremely pure; no impurities could be detected in it by the methods mentioned above, and the authors consequently calculate that it contains at least 99·99 per cent. of platinum.

It may be of interest to mention that pure platinum is now prepared in Germany. The method of purification is simpler than the English one, not involving the use of lead, and it yields a very pure product. In a sample of 40 grams, no palladium or rhodium could be detected, and only a trace of iridium. A trace of iron, at most 0·001 per cent., was, however, present.

For further details of the different processes, the original paper must be consulted. C. F. B.

Mineralogical Chemistry.

Breithauptite from Sarrabus, Sardinia. By E. Mattirolo (*Real. Accad. Linc.*, **7**, iii, 98—100).—The mineral is found, together with small quantities of ulmannite, stephanite, discrasite, argentite, and native silver, imbedded in a matrix of calcite. It has the hardness 4·5, the sp. gr. 8·42, and occurs in ill-defined, fragile crystals. From the following analysis, it will be seen to have approximately the theoretical composition NiSb, assigned to breithauptite:—

	Sb.	As.	Ni.	Co.	S, Ag, and Pb.
Per cent.	65·07	0·20	32·94	0·29	traces

W. J. P.

Microscopic Structure of the Oölitic Iron Ore of Lorraine. By BLEICHER (*Compt. rend.*, **114**, 590—592).—Microscopic examination, aided by previous calcination and treatment with acids and alkalis, shows that the ferruginous oölites of Lorraine, Mazenay, Pulnoy, and other oölites of the same horizon, are all constructed on the same type. They consist of a simple or compound inorganic or organic nucleus surrounded by regular concentric layers of a substance rich in silica and organic matter, in which microscopic, hyaline grains of sand and regular, rod-like forms can be recognised. The iron oxide seems to be enclosed between these concentric layers.

C. H. B.

Distribution of Titanic Oxide upon the Surface of the Earth. By F. P. DUNNINGTON (*Amer. J. Sci.*, **42**, 491—495).—In view of the rare mention of titanic oxide as a constituent of rocks, the author has analysed 80 specimens of soil and rocks from points scattered over the earth's surface. Specimens 1 to 17 are from Virginia, the average percentage of titanic oxide found being 1·57. Nos. 18 to 40 are from other portions of the United States; average 0·85 per cent. Nos. 41 to 45 are from Oceania and Asia; average 0·90 per cent. Nos. 46 to 72 are soils from Europe; average 0·54 per cent. These results apply to air-dried soil. The wide distribution of titanic oxide in soils naturally suggested the examination of the rocks themselves. The author has therefore analysed eight typical rocks, the localities of which have previously furnished samples for published analyses. The average percentage of titanium oxide found was 0·56, notwithstanding the fact that in only two cases is titanium oxide noted in the published analyses.

B. H. B.

Heintzite, the New Borate from Leopoldshall. By W. FEIT (*Chem. Zeit.*, **15**, 115).—Luedecke has found, inside a lump of pinnoïte collected near Leopoldshall, crystals of a mineral which he has called heintzite. This mineral has the appearance of clear, transparent gypsum, and is remarkably cleavable. The author has, however, little doubt that it is identical with the one discovered by him in 1889, and which he called kaliborite.

The author's view is supported not only by chemical analysis, but also by Luedecke's crystallographic measurements. The specific gravity and the hardness of the two minerals also agree.

L. DE K.

Heintzite, the New Borate from Leopoldshall. By O. LUEDECKE (*Chem. Zeit.*, **15**, 222).—The author, in reply to Feit (see preceding abstract), admits that the chemical composition of kaliborite and heintzite is practically identical, both containing about the same percentage of boric acid, potash, magnesia, and water. This does not, however, prove them to be the same mineral. Whilst kaliborite occurs in badly-formed, crystalline crusts on the surface of pinnoïte, heintzite, which is found in the inside, forms well-made crystals with shining faces, and is readily cleavable in three directions. The author does not attach much importance to the similarity in specific gravity of the two minerals.

L. DE K.

Ascharite, a New Borate. By W. Feit (*Chem. Zeit.*, **15**, 327).—Boracite and stassfurtite found in the neighbourhood of Aschersleben (Ascharia) occasionally contain a good many white lumps of a remarkably low specific gravity. They are externally covered with kainite and rock-salt, and so incorporated with potassium, sodium, and magnesium chlorides that these can scarcely be recognised with the naked eye. The insoluble residue is, however, quite unlike a similar compound obtained by treating stassfurtite with water. The latter looks like a fine mud and contains about 8 per cent of chlorine, whilst the former is composed of small fragments, easily reducible to an impalpable powder by pressure with the hands, and free from chlorine. A complete analysis proved that the author has come across a new mineral which, although only consisting of crystallised magnesium borate, has a composition different from that of similar known minerals, as its formula was found to be $3Mg_2B_2O_5 + 2H_2O$. The mineral is pure white and practically insoluble in water, to which, however, it communicates an alkaline reaction. Dilute mineral acids gradually dissolve it on warming. Its specific gravity varies between 1·85 and 1·95, according to its freedom from adhering salts. Before the blowpipe, it fuses to a white looking mass, without communicating a green colour to the flame. L. de K.

Barytes from Missouri. By C. Luedeking and H. A. Wheeler (*Amer. J. Sci.*, **42**, 495—498).—A variety of barytes is found in Pettis Co., Missouri, which presents peculiar chemical and crystallographical characteristics. The peculiarity is the occurrence of white to yellowish thin bands in an otherwise normal colourless barytes, and analysis shows that these bands consist of a mixture of barium and strontium sulphates with slight amounts of calcium and ammonium sulphates, the general character of the white barytes being shown by the following analytical results:—

$BaSO_4$.	$SrSO_4$.	$CaSO_4$.	NH_4SO_4.	H_2O.	Total.
87·2	10·9	0·2	0·2	2·4	100·9

The occurrence of ammonium sulphate in barytes has not hitherto been observed. The isomorphism of ammonium sulphate, mascagnite, with barytes, is worthy of notice. B. H. B.

Synthesis of Crocoïte and Phœnicocroïte. By C. Luedeking (*Compt. rend.*, **114**, 544—545).—When a solution of lead chromate in potassium hydroxide is exposed to the air for some months in a vessel with a flat bottom, a mixture of crystals of crocoïte and phœnicocroïte is obtained. With an excess of lead chromate mixed with potassium chromate, crocoïte alone is formed in highly modified, oblique, rhombic prisms, with an adamantine lustre and a hyacinth-red colour; it is stable when exposed to air. With a large excess of concentrated potash solution, phœnicocroïte is the sole product; it forms cochineal-red tables which have a resinous lustre and seems to belong to the rhombic system. When exposed to the air, the crystals alter and form a yellow powder.

If a solution of a caustic alkali saturated with litharge is exposed to the air for several months, crystals of lead hydroxide, $2PbO,H_2O$, are obtained, but no cerussite is formed. C. H. B.

Hübnerite, Hessite, Bismutite, and Natrolite. By F. A. Genth (*Amer. J. Sci.*, **43**, 184—189).—1. *Hübnerite.*—The author gives crystallographical descriptions and analyses of hübnerite from (*a*) the North Star Mine, Silverton, Colorado; (*b*) Cement Creek, near Silverton; (*c*) Bonito Mountain, New Mexico; and (*d*) Monmouth District, Nevada. The analytical results were as follows:—

	WO_3.	FeO.	MnO.	CaO.	MgO.	Total.
a.	74·75	2·91	21·93	0·11	trace	99·70
b.	76·63	1·61	21·78	0·09	trace	100·11
c.	76·33	3·82	19·72	0·13	trace	100·00

2. *Hessite from Mexico.*—A specimen of hessite from the Refugio Mine, Jalisco, contains 62·80 per cent. of Ag_2Te, 1·96 per cent. of PbTe, with 1·40 per cent. of tellurium, probably present as tellurous oxide.

3. *Bismutite.*—Associated with the phenacite of Mount Antero, Colorado, is a greyish or yellowish-green mineral of prismatic form. Of this the author gives the results of two analyses; but the material is too impure to admit of the deduction of a formula.

4. *Natrolite.*—This mineral occurs at Magnet Cove, Arkansas, in association with ægirite, eudialyte, and titanite, in large, colourless, cleavable masses. The sp. gr. is 2·243, and analysis gave:—

H_2O.	SiO_2.	Al_2O_3.	Na_2O.	Total.
9·81	47·97	26·51	15·98	100·27

B. H. B.

Chemical Composition of Iolite. By O. C. Farrington (*Amer. J. Sci.*, **43**, 13—16).—As is well known, the formula of iolite has never been satisfactorily established, chiefly for the reason that the state of oxidation of the iron, in the analyses hitherto published, has not been determined. The exceptional purity of the iolite described by E. O. Hovey (Abstr., 1889, 25) as a rock-forming mineral at Guilford, Connecticut, induced the author to make an analysis of it. The results obtained he tested by comparison with an analysis of iolite from Haddam, Connecticut, and he concludes that the formula of iolite is $H_2O,4(MgFe)O,4Al_2O_3,10SiO_2$. B. H. B.

Chloritoïd, Grünerite, and Riebeckite from Michigan. By A. C. Lane, H. F. Keller, and F. F. Sharpless (*Amer. J. Sci.*, **42**, 499—508).—1. *Chloritoïd* has been known to occur in the upper peninsula of Michigan for some years. Recently it has been found in large, dark-green plates at the Champion iron mine. On analysis, it gave results from which the formula $H_{16}Fe_7Al_{16}Si_8O_{55}$ is deduced, a formula nearly identical with that now generally accepted for sismondine.

2. *Grünerite.*—There is a peculiar amphibole, associated with certain Lake Superior iron ores, which has been described as actinolite and as anthophyllite. In reality, it is a ferro-magnesian monoclinic amphibole, corresponding closely with the description of grünerite given by Lacroix. Analysis shows very clearly, by the absence of calcium, that the mineral is not actinolite.

3. *Riebeckite* or *crocidolite.*—Mr. Lane notes a new occurrence of this group of amphiboles, namely, as a secondary fibrous growth on the primary hornblende of syenite. B. H. B.

Tschermak's Theory of the Chlorite Group and its Alternative. By F. W. Clarke (*Amer. J. Sci.*, **43**, 190—200).—In his latest paper, Tschermak endeavours to explain the chemical structure of the chlorites by dividing this group of minerals into two subgroups, orthochlorites and leptochlorites. The orthochlorites are represented as mixtures of two end products, serpentine and amesite; whilst for the leptochlorite, in addition to the serpentine and amesite molecules, four other fundamental compounds are assumed: strigovite, chloritoïd, and two derivatives of amesite. If this mode of interpretation is the only one possible, the problem of the chlorite group is solved. But if other schemes can be devised representing the facts equally well, further investigation becomes necessary. The known facts, the author believes, are fairly well sustained by his hypothesis that the more complex silicates are merely substitution derivatives of normal salts. The author adduces, at great length, the arguments in favour of his view, and between the two theories, experimental research must be the final arbiter. Until experiment has given grounds for decision, either theory may properly be used as a guide. B. H. B.

Iron Ores of the Marquette District, Michigan. By C. R. Van Hise (*Amer. J. Sci.*, **43**, 116—132).—From the results of a systematic investigation of the entire Marquette district, the author concludes that the original rock of the iron-bearing formation was a cherty iron carbonate, and that the varieties of rock now found in this formation, such as chert, jasper, schists, and ore, were all produced from this original carbonate by various alterations. The form, position, and relation of the ore deposits render it evident that the origin was not eruptive, and it is equally certain that these irregular masses of ore were not produced directly by sedimentation. All the facts bear towards the conclusion that the ore is a secondary concentration produced by the action of water percolating downwards. The same view applies to the other iron-bearing districts of Lake Superior. B. H. B.

New Meteoric Iron from Maryland. By A. E. Foote (*Amer. J. Sci.*, **43**, 64).—Three or four years ago a meteoric iron mass was ploughed up in Garrett Co., Maryland. It contains over 11 per cent. of nickel and cobalt, the proportion of the latter being unusually high. It is one of the best octahedral etching irons known, being even more characteristic than most of those that have been used for printing directly on paper. Besides the octahedral structure, it also shows a

large number of secondary lines regularly disposed with reference to the principal markings, similar to those described by J. Lawrence Smith in a Wisconsin meteorite in 1869, under the name of Laphamite markings. The original weight of the mass was 45 oz., and its present weight is 36½ oz. The paper is illustrated by photographs of the etched surface and of the entire mass. B. H. B.

Aërolite from Kansas. By G. F. Kunz and E. Weinschenk (*Amer. J. Sci.*, **43**, 65—67).—On June 25, 1890, a meteorite was observed travelling from south to north, and the largest portion, weighing 180 lbs., fell at Farmington, Washington Co., on the farm of W. H. January, who witnessed the actual fall. The sound of the explosion was heard throughout a number of counties in Kansas and Nebraska. The approximate composition of the mass is as follows:—

Nickeliferous iron	7·7
Troïlite	5·0
Siliceous part insoluble in HCl....	46·0
Siliceous part soluble in HCl.....	41·5

The iron gave, on analysis, the following results:—

Fe.	Ni.	Co.	Total.
86·76	12·18	0·83	99·77

The siliceous part yielded the following results:—

	SiO_2.	FeO.	Cr_2O_3.	Al_2O_3.	MnO.	NiO.	CaO.	MgO.
I.	38·50	23·54	—	—	0·34	0·69	0·12	36·81
II.	53·80	11·98	1·41	4·32	trace	—	4·08	22·37

	K_2O.	Na_2O.	Total.
I.	—	—	100·00
II.	0·27	1·77	100·00

I Portion soluble (olivine), II portion insoluble, in hydrochloric acid.

As is generally the case in stony meteorites, the nickel-iron shows a higher percentage of nickel and cobalt than is usual in meteoric irons. The meteorite belongs to the black chondrites, and has the greatest resemblance to the meteorite of Sevenkof. B. H. B.

Meteorite of Jelica. By S. M. Losanitsch (*Ber.*, **25**, 876—880).—The Jelica meteorite consists of a soft, grey mass, including several pieces of a brown material which scarcely differs in composition from the grey mass, but contains a slightly larger proportion of metasilicates. The specific gravity of the grey mass = 3·439, that of the brown substance = 3·466 at 18·6° C.

Before analysis, the hard outside crust was removed.

It contains:—

Metals ..	2·49 p. c.	Silicates sol. in HCl	54·00 p. c.
Troïlite..	7·09 ,,	Silicates insol. in HCl...	36·25 ,,
Chromite.	0·15 ,,	Alkali and organic matter	0·12 ,,

The author considers that the last has been absorbed by the meteorite from the damp ground.

The metals, on analysis, gave 66·44 per cent. Fe, 33·47 per cent. Ni, 2·09 per cent. Co, and a trace of copper. It is noteworthy that the percentage of nickel and cobalt is high. The proportion of iron to nickel nearly corresponds with that required by the formula Fe_2Ni.

E. C. R.

"Julianen" and "Georgen" Springs in the Royal Bath at Eilsen. By R. Fresenius (*J. pr. Chem.* [2], **45**, 287—296).—The "Julianen" spring yields 40·6 cub. ft. of water per hour. The water is quite clear and colourless; it smells strongly of hydrogen sulphide; its temperature was 17° on June 20, 1890, the air temperature being 11·45°; its sp. gr. was 1·003087 at 17·5°. The "Georgen" spring yields 196·2 cub. ft. of water per hour; the water is clear and colourless, and smells strongly of hydrogen sulphide; the temperature of the water on 21st of June, 1890, was 20°, the temperature of the air being 12·1°; the specific gravity was 1·002980 at 17·5°. The following table shows the quantity of salts, &c., in grams, per 1000 grams of these waters; the salts are represented as anhydrous, and the carbonates as anhydrous bicarbonates:—

	Julianen.	Georgen.
Calcium sulphate	2·093951	1·948343

Nitrogen	0·027318	0·021298
Total	3·224314	3·036210

Traces of formic acid and other volatile organic acids, of resins, and of "extractive" were detected in both waters. A. G. B.

Organic Chemistry.

Boiling Points of Paraffin Derivatives. By G. Hinrichs (*Compt. rend.*, **114**, 597—599).—The formula previously applied (Abstr., 1891, 1330) to the calculation of the boiling points of the normal paraffins is now shown to hold good for monosubstitution derivatives in which halogen, hydroxyl, amidogen, phenyl, or cyanogen has been substituted for hydrogen in the terminal group of the paraffin chain. C. H. B.

Carbon Chlorobromides. By A. Besson (*Compt. rend.*, **114**, 222—224).—See p. 771.

Pyrogenic Hydrocarbons in Compressed Gas. By A. Brochet (*Compt. rend.*, **114**, 601—603).—The only definite hydrocarbons known to exist in compressed gas prepared by the distillation of Boghead cannel or of shale oils are normal hexylene and erythrene. The author finds that the other olefines present are normal butylene (b. p. 166°), normal amylene $\alpha\beta$ (b. p. 39—40°), and normal amylene $\beta\gamma$ (b. p. 35—36°). He also found piperilene, $CH_2{:}CH{\cdot}CH_2{\cdot}CH{:}CH_2$, boiling at 41—42°, and confirms the presence of erythrene and normal hexylene. It is especially noteworthy that all the olefines formed after the prolonged action of a high temperature are primary, without any lateral chains. C. H. B.

Action of Metals on Salts Dissolved in Organic Liquids. By R. Varet (*Compt. rend.*, **114**, 224—225).—A comparison of the action of metals on salts dissolved in water and in various organic solvents has been made, with the view of determining the part played in the reaction by the water, and by the formation of molecular compounds among the products present.

1. Aluminium reacts with an aqueous solution of mercuric cyanide with the formation of alumina, hydrogen cyanide, hydrogen, and free mercury.

2. A solution of mercuric cyanide in (absolute) alcoholic ammonia yields with aluminium (in absence of all trace of water) a double cyanide of mercury and aluminium, combined with alcohol and ammonia. After treatment with aluminium in small pieces, the solution is filtered in a dry atmosphere, and the filtrate concentrated over a mixture of potash and quicklime; after several days, a thick, soft, transparent, crystalline layer of the complex compound of aluminium mercury cyanide with alcohol and ammonia separates out; it is so unstable that its composition cannot be ascertained with precision. In this reaction, the substitution of aluminium for mercury is never complete, as it only proceeds so far as the formation of the double cyanide.

3. If mercuric cyanide be dissolved in anhydrous pyridine, it does

not react with aluminium. If a small quantity of water be added, the reaction takes place as in 1, till the water is exhausted.

4. Nickel acts on a boiled aqueous solution of mercuric chloride with production of mercurous chloride and nickel chloride.

5. Mercuric chloride dissolved in pyridine is without action on nickel in the cold; when heated, substitution of the nickel occurs.

6. The same solution has no action on iron in the cold, or on heating. An immediate reaction occurs on adding water and heating slightly, with formation of calomel and oxidation of the iron.

The conclusion is drawn that certain metals, capable of precipitating others from their salts dissolved in water, lose this property when certain organic liquids are used as solvents, and that this difference is partly due to the water and partly due to the formation of molecular combinations between the products present.

W. T.

Polymeric Methylthiocarbimide. By A. W. v. Hofmann (*Ber.*, **25**, 876).—Methylthiocarbimide is polymerised when heated with potassium acetate, and by the action of phosphorus pentasulphide on methyl isocyanurate the thio-compounds intermediate between the latter and polymeric methylthiocarbimide are obtained, so that the following series of compounds is known:—$C_3O_3N_3Me_3$, $C_3O_2SN_3Me_3$, $C_3OS_2N_3Me_3$, and $C_3S_3N_3Me_3$. E. C. R.

Derivatives of Chromium Ammonium Thiocyanate. By O. T. Christensen (*J. pr. Chem.* [2], **45**, 213—222).—*Ammonium diaminechromiumthiocyanate*, $Cr(NH_3)_2(SCN)_3,NH_4SCN + H_2O$ (Reinecke's salt, *Annalen*, **126**, 113), is obtained, together with Morland's salt (this Journal, 1861, 252), when ammonium thiocyanate (200 grams) is melted in a porcelain crucible, and powdered potassium dichromate (40 grams) added by degrees; on treating the melt with cold water, the two salts crystallise out together as a red powder, and can be separated by washing with cold water, which dissolves Reinecke's salt; the latter crystallises out on the addition of a saturated solution of ammonium chloride. Morland's salt can be converted into Reinecke's salt by dissolving it in warm ammonia (sp. gr. 0·96), and adding a cold saturated solution of ammonium chloride to the hot liquid.

Reinecke's salt crystallises in rectangular tables; it is insoluble in absolute ether, but dissolves in water to a ruby-red solution and in alcohol. The colour of the salt on Radde's scale is purple 260. Those salts whose metals are precipitated by hydrogen sulphide in acid solution are also precipitated by ammonium diaminechromiumthiocyanate; the precipitates are insoluble in water, with the exception of that of cadmium, which dissolves with difficulty. Those salts whose metals are not precipitated by hydrogen sulphide in acid solution, but are precipitated by ammonium sulphide, give easily soluble precipitates with a concentrated solution of the thiocyanate. The alkali and alkaline earth metals give precipitates in saturated solutions of the thiocyanate. All these precipitates are described in the paper.

With solutions of the salts of most of the ordinary nitrogenous

organic bases, ammonium diaminechromiumthiocyanate gives precipitates consisting of compounds which contain the base in place of the NH_3 of the precipitant. Such compounds containing the alkaloïds are sparingly soluble. Several metallic ammonium derivatives, like the luteo- and purpureo-cobalt salts, are precipitated by the thiocyanate.

The reactions of Morland's salt are so similar to those of Reinecke's salt that the author regards the former as ammonium tetraminechromiumthiocyanate, $Cr(NH_3)_4(SCN)_3,NH_4SCN$. Hot water slowly decomposes Reinecke's salt and its derivatives. A saturated aqueous solution of the salt absorbs all the rays of the spectrum, with the exception of the red, from a little before C nearly up to D.

A. G. B.

Value of the Primary Alcoholic Function. By DE FORCRAND (*Compt. rend.*, **114**, 545—547).—The author extends to glycerol and erythritol the reasoning previously applied to glycol (this vol., p. 576), and shows that the primary alcoholic function has a constant thermal value of 32 Cal., when allowance is made for combination between the monometallic derivative and the excess of the alcohol or polyalcohol, which increases the apparent value of the primary alcoholic function, and for intramolecular combination between the metallic derivatives and the undisplaced hydroxyl groups, which lower the apparent values of the second, third, and fourth alcoholic functions.

C. H. B.

Preparation and Properties of Bunte's Salt (Sodium Ethylthiosulphate). By R. OTTO and A. RÖSSING (*Ber.*, **25**, 988—991).—Sodium ethylthiosulphate, $SEt{\cdot}SO_2{\cdot}ONa$, was first prepared by Bunte (this Journal, 1874, 770) by warming ethyl bromide with an aqueous solution of sodium thiosulphate, and later by Spring (this Journal, 1875, 129) by the action of iodine on a mixture of sodium ethylmercaptan and sodium sulphite. The authors have re-examined both methods, and find that in each case the yield is very small. In Bunte's reaction a considerable quantity of the salt decomposes even in aqueous solution with formation of ethyl bisulphide and sodium dithionate, a change which takes place quantitatively with the dry substance at 100°, as already shown by Bunte. A better yield may be obtained by heating the two compounds in very dilute alcohol at 80° for 2—3 days, allowing the solution to evaporate at the ordinary temperature, and extracting the residue with alcohol.

In Spring's reaction, the iodine largely acts on the two salts separately, and attempts to obtain sodium phenylthiosulphate by the same method led to similar results. Spring also states that the chloride of ethylthiosulphuric acid, prepared by the action of phosphorus pentachloride on the sodium salt, is resolved even in the cold into ethyl bisulphide, sulphurous anhydride, and sulphuryl chloride; the formation of the last-named compound has, however, been disputed by Ramsay (this Journal, 1875, 687), and the authors, on repetition of the experiments, have confirmed Ramsay's results.

H. G. C.

Fluorhydrins from Glycerol. By M. MESLANS (*Compt. rend.*, **114**, 763—766).—Bromine combines energetically with allyl fluoride,

forming a colourless liquid which boils at 162—163° without decomposition and without attacking the glass. No hydrogen fluoride is produced in the reaction. The liquid is *dibromofluorhydrin*, $C_3H_5Br_2F$; it is colourless and mobile, with an odour recalling that of chloroform, and a sweet, burning taste; sp. gr. at 18° = 2·09; vapour density 7·64.

Chlorine likewise combines with allyl fluoride, with development of heat and production of dichlorofluorhydrin, a colourless liquid similar in its properties to the bromine compound; it boils at 122—123°; sp. gr. at 18° = 1·327; vapour density 4·495.

Iodine has no action on allyl fluoride. Fluorine, even at a low temperature, decomposes allyl fluoride with formation of hydrogen fluoride and carbon fluoride, and separation of carbon. C. H. B.

Monosodium Mannitol. By de Forcrand (*Compt. rend.*, **114**, 226—228).—Monosodium mannitol has been prepared by adding finely-divided mannitol (1 mol.) to a solution of sodium ethoxide (1 mol.) in absolute alcohol (4 or 5 mols.), and boiling for 8—10 hours. It has the composition $C_6H_{13}NaO_6$. Its heat of solution in water (204 grams in 4 litres) is 4·86 Cal. at 11°. $C_6H_{14}O_6$ sol. + Na sol. = H gas + $C_6H_{13}NaO_6$ sol. + 34·82 Cal. Its heat of formation is represented by C_6 (diamond) + H_{13} gas + Na sol. + O_6 gas = $C_6H_{13}NaO_6$ sol. + 353·32 Cal. It crystallises with 4 mols. of ethyl alcohol. Attempts to prepare disodium mannitol in the same way resulted in the production of a compound of monosodium mannitol with sodium ethoxide which was stable at 150°. Its heat of formation is $C_6H_{13}NaO_6$ sol. + C_2H_5ONa sol. = $C_6H_{13}NaO_6,C_2H_5ONa$ sol. + 5·95 Cal. In general, the heat of formation of substances of this type is much less, about 1—2 Cal. As in the cases of glycol, glycerol, and erythrol, so with mannitol, we have—

1. The substitution of sodium for the first hydrogen atom in polyatomic alcohols results in a liberation of heat greater than +32 Cal.

2. The displacement of the second hydrogen atom liberates less than +32 Cal. W. T.

Rotatory Power of Compounds of Perseïtol with Sodium Hydrogen and Ammonium Hydrogen Molybdate. By D. Gernez (*Compt. rend.*, **114**, 480—482).—Perseïtol is slightly lævogyrate, but the compounds which it forms with molybdic acid and the alkaline hydrogen molybdates are strongly dextrogyrate, like the analogous compounds of mannitol and sorbitol previously described (Abstr., 1891, 1443; this vol., p. 422).

The molecular rotatory power of perseïtol in supersaturated aqueous solution (0·072 gram per c.c.) is $[\alpha]_D = -1° 12'$. The sign of the rotatory power is changed by the addition of even $\frac{1}{150}$ mol. of sodium hydrogen molybdate, and a maximum ($[\alpha]_D = +7° 11'$) is reached at a point at which the proportion of perseïtol to molybdic acid (calculated as excess over that required to form the normal salt) is as 8 to 9. Almost identical results are obtained with the ammonium salt,

showing that the nature of the alkali has little influence on the optical activity of the compound. Jn. W.

Dextrose from Sulphite-cellulose and from Fir-wood. By T. B. Lindsey and B. Tollens (*Annalen*, **267**, 370—371).—The cellulose obtained by treating wood with calcium hydrogen sulphite dissolves in concentrated sulphuric acid, yielding a very dark solution; after adding water and boiling for a long time, and then proceeding in the usual manner, it is possible to isolate a small quantity of dextrose from the solution; 100 grams of the cellulose gave 3·5 grams of colourless sugar, from which, after recrystallisation, almost 2 grams of dextrose of specific rotatory power $[\alpha]_D = 52{\cdot}65°$ was obtained.

From 18 grams of crude fir-wood, the authors obtained 0·84 gram of dextrose of specific rotatory power $[\alpha]_D = 50{\cdot}4°$. F. S. K.

The Specific Rotatory Power of Cane Sugar in Dilute Solutions. By R. Nasini and V. Villavecchia (*Gazzetta*, **22**, i, 97—104).—The specific rotatory power of cane sugar in dilute solutions has been determined by various observers; the results obtained, however, are very inconsistent. The authors, working with pure cane sugar and using a Landolt-Lippich polaristrobometer with a column of the active liquid about half a metre long, have obtained the following results at 20°:—

Percentage of sugar.	$[\alpha]_D$ observed.	$[\alpha]_D$ calculated.	Percentage of sugar.	$[\alpha]_D$. observed.	$[\alpha]_D$ calculated.
1·2526	66·604	66·783	0·6626	67·370	67·552
1·2191	66·719	66·792	0·5982	67·562	67·715
1·2048	66·855	66·785	0·5877	67·983	67·744
0·9926	67·096	66·963	0·3351	68·241	68·539
0·8243	67·250	67·213	—	—	—

In the table, the first column gives the percentage (p) of sugar present in the aqueous solution, and the second column shows the corresponding specific rotatory powers. The observed rotatory powers can be only approximately expressed as a function of the concentration by an equation containing three constants. The rotatory powers given in the third column are calculated from the equation

$$[\alpha]_D = 69{\cdot}962 - 4{\cdot}8696p + 1{\cdot}86145p^2.$$

The results obtained by the authors do not agree with those of Tollens (Abstr., 1884, 1285) and Pribram (Abstr., 1887, 755).

W. J. P.

Combination of Starch with Iodine. By G. Rouvier (*Compt. rend.*, **114**, 749—750).—According to Mylius, starch only combines with iodine when hydriodic acid or an iodide is also present in the proportion of 1 mol. of the acid or the iodide to 4 atoms of iodine.

The author finds, however, that iodine and starch readily combine in presence of alcohol, when the amount of iodine present in the form of an iodide is not more than 3 per cent. of the total quantity of the iodine. C. H. B.

Wood Sulphite-liquor and Lignin. By J. B. Lindsey and B. Tollens (*Annalen*, **267**, 341—366).—The liquid obtained in the preparation of cellulose for paper making, by heating wood with calcium hydrogen sulphite, gives 9·46 per cent. of residue on evaporation at 100°. When heated with hydrochloric acid, it yields only a small quantity of levulinic acid, a fact which proves the absence of hexoses in any considerable quantity. The absence of dextrose, and of compounds which yield dextrose, is proved by the fact that saccharic acid cannot be isolated from the products of the oxidation of the liquor with nitric acid; galactose, or a derivative of this sugar, on the other hand, is present in the liquor in not inconsiderable quantities, as is shown by the formation of mucic acid. The presence of mannose is proved by the fact that it can be isolated in the form of its hydrazone. The liquor also contains small quantities of pentoses, or of derivatives thereof, as it gives furfuraldehyde on distillation with hydrochloric acid; there is also present in the liquor a trace of vanillin or of a substance having very similar properties. When the liquor is freed from sulphurous acid and then treated with yeast under suitable conditions, fermentation sets in, and a small quantity of alcohol is produced.

When wood sulphite-liquor is freed from sulphuric acid with the aid of barium hydroxide, and then treated with a solution of lead acetate, there is produced a precipitate which contains, in addition to sulphur and other inorganic matter, an organic substance of the composition $C_{26}H_{32}O_{12}$ or $C_{26}H_{30}O_{12}$; this precipitate, on decomposition with dilute sulphuric acid, yields a dark solution, from which, after evaporating to a syrup, a grey, flocculent substance is deposited on the addition of alcohol. Analyses, and methoxy-determinations by Zeisel's method, made with samples of this flocculent substance, and calculated for the ash-free sample, gave results agreeing well, except in the case of the sulphur, with those required by a compound of the composition $C_{24}H_{24}Me_2SO_{12}$. The filtrate from the flocculent precipitate gives, on evaporation at 100°, a dark powder, which is readily soluble in water, and which reduces Fehling's solution; analyses of this product, which contained 3·4 per cent. of ash, gave results from which the composition of the organic matter was calculated to be $C_{24}H_{24}Me_2SO_{12} + 1\frac{1}{2}H_2O$.

A colourless, flocculent precipitate is produced when wood sulphite-liquor is mixed with an equal volume of hydrochloric acid of sp. gr. 1·19; this precipitate, after having been washed with concentrated hydrochloric acid and dried over sulphuric acid, contains 1·99 per cent. of ash; the composition of the ash-free substance can be expressed by the formula $C_{26}H_{30}SO_{10}$. The acid filtrate from this flocculent compound gives, with bromine, an amorphous precipitate which, when dried over sulphuric acid, is obtained in the form of a yellowish-brown powder containing 1·32 per cent. of ash; analyses of this

product, calculated for the ash-free sample, gave results agreeing with those required by a compound of the composition $C_{26}H_{28}Br_4SO_{11}$.

As all the substances described above could only be obtained in an amorphous condition, it is possible that they may be mixtures; if, as is probable, the sulphur is present, in part, at any rate, in the form of a sulphonic acid group, the composition $C_{26}H_{30}O_{10}$ may be assigned to the substance, or substances, from which the above sulphur compounds are formed. The composition $C_{26}H_{30}O_{12}$ is approximately the same as that assigned by Dietrich and König to lignin, and agrees also moderately well with that given to lignon, the ligniu of jute, by Cross and Bevan (Trans., 1889, 213); the composition $C_{26}H_{30}O_{10}$ agrees very closely with that assigned by Lange to lignic acid.

The behaviour of the compound obtained from wood sulphite-liquor resembles, in some respects, that of the tannic acids, but the characteristic reaction of these acids with ferric salts is not given by the compound in question; if, as quite recent experiments seem to show, the sulphur in this compound is really present in the form of a sulphonic acid group, it would resemble rather the substances obtained by Schiff (*Annalen*, **178**, 171) by the action of sulphuric acid on monhydric and polyhydric phenols. F. S. K.

Vegetable Amyloïd. By E. Winterstein (*Ber.*, **25**, 1237—1241). —The substance described under the name "amyloïd" is a constituent of the cell walls of certain plants, and gives the same coloration with iodine as starch does. According to Reiss (*Landw. Jahrb.*, **18**, 733), on hydrolysis with dilute sulphuric acid, it yields considerable quantities of glucose, but as the material used by him also contained cellulose, this statement is open to the objection that the latter was the source from which the glucose was obtained. The author has therefore prepared pure samples of amyloïd, and examined its behaviour on hydrolysis, with results very different from those obtained by Reiss.

To prepare the amyloïd, the seeds of *Tropœolum majus* were extracted successively with ether, cold alcohol, dilute ammonia, dilute soda, and cold water; the residue was boiled with water, filtered, and the solution precipitated with alcohol. The amyloïd separates as a jelly, and is purified by redissolving in water and again precipitating with alcohol. It then forms a colourless, transparent jelly, which dries in the desiccator to an amorphous, vesicular mass, and is coloured blue by starch, the colour disappearing on warming. Its aqueous solution is dextrorotatory ($[\alpha]_D = 93{\cdot}5°$), and it is not converted into sugars by diastase; on oxidation with nitric acid, it yields mucic acid, and with hydrochloric acid gives 15·44 per cent. of furfuraldehyde. On hydrolysis with 2·5 per cent. sulphuric acid, it yields galactose, together with a smaller quantity of another hexose of lower dextrorotatory power, and a pentose which yields trihydroxyglutaric acid on oxidation, and is therefore probably xylose, the second hexose being probably glucose. If the residue, after extracting the seeds with hot water, be boiled with 3 per cent. sulphuric acid, it yields further quantities of galactose and xylose.

The author, therefore, regards amyloïd as a substance corresponding

somewhat with starch or cellulose, but derived from galactose and xylose, instead of from glucose. Whether the substance is really homogeneous is not yet certain, but the fact that the amyloïd prepared from the seeds of *Pæonia officinalis* yields almost the same quantities of mucic acid and furfuraldehyde is in favour of this supposition. H. G. C.

Propylamines and their Derivatives. By F. Chancel (*Compt. rend.*, **114**, 756—758).—When ethyl oxalate is added gradually to a well cooled mixture of equal volumes of monopropylamine and water, a considerable proportion of propyl oxamate and monopropylamine oxalate is formed. When the dipropyloxamide is filtered off and calcium chloride is added to the filtrate, calcium oxalate is precipitated and calcium propyloxamate remains in solution, but separates when the liquid cools. Propyloxamic acid is obtained by decomposing the calcium salt with hydrochloric acid and extracting with ether. It crystallises in long, white needles, very soluble in water, alcohol, and ether; it melts at 109—110°, and sublimes at about the same temperature. Its calcium salt crystallises in small, brilliant prisms with 2 mols. H_2O, when its solution is slowly cooled. If the solution is cooled rapidly, long filaments separate which contain 3 mols. H_2O, but readily lose one of them.

Propylamidoacetic acid is readily obtained by heating monopropylamine with ethyl bromacetate at 100—110°. It is purified by conversion into the copper salt, which is recrystallised and then decomposed by hydrogen sulphide. From alcohol it crystallises in needles. It sublimes easily, and is very readily soluble in water or alcohol, but insoluble in ether. Its platinochloride crystallises in prisms with 1 mol. H_2O, and is very soluble in water. The aurochloride could not be obtained. The copper salt is very soluble in water or alcohol, and crystallises in nodules or crusts.

C. H. B.

Action of Sodium and Potassium Cyanide on Chlorodiamylamine. By A. Berg (*Compt. rend.*, **114**, 483—486).—*Amylamylenamine*, $C_5H_{11}\cdot N{:}C_5H_{10}$, is prepared by treating chlorodiamylamine (1 mol.) with alcoholic soda (1 mol.). Sodium chloride first separates, and the reaction is completed by heating in a reflux apparatus. The alcohol is distilled off, the salt dissolved out with water, and the crude, oily residue dried over potash, and redistilled. The product thus obtained is not pure, however, but a mixture of the amylamylenamine with unchanged diamylamine, the boiling points of which are too near to admit of fractionation. The presence of the former base is shown by the formation of valeraldehyde and amylamine when the mixture is hydrolysed with hydrochloric acid, and the pure base is readily prepared from these substances by simply heating them together in molecular proportions. It is a colourless liquid, which boils at 180—181° under a pressure of 764 mm. It combines with methyl iodide in the cold, and restores the colour to rosaniline which has been decolorised with sulphurous acid.

Diamylcyanamide, $CN\cdot N(C_5H_{11})_2$, is prepared by heating alcoholic chlorodiamylamine (1 mol.) with aqueous potassium cyanide (1 mol.

in minimum quantity of water) in a reflux apparatus for several hours. The alcohol is distilled off, the residue washed with water and dilute sulphuric acid, and then redistilled under diminished pressure. Diamylcyanamide, as thus prepared, is a light, viscous, colourless liquid, which boils at 143—144° under a pressure of 20 mm., dissolves in cold, concentrated hydrochloric acid, and is reprecipitated by water. It is hydrolysed by concentrated hydrochloric acid at 160° into diamylamine, carbonic anhydride, and ammonia. Jn. W.

Preparation of Pure Trimethylamine from Crude Trimethylamine Hydrochloride. By E. Schmidt (*Annalen*, **267**, 254—268).—For the preparation of pure trimethylamine from the commercial hydrochloride, which contains as impurities the hydrochlorides of mono- and di-methylamine, ammonium chloride, and seemingly, also, small quantities of the hydrochlorides of amines richer in carbon, the following method was found, after many experiments, to be the most satisfactory. The crude trimethylamine hydrochloride (250 grams) is placed in a flask of 2 litres capacity, excess of concentrated soda gradually added with the aid of a funnel, and the mixture finally heated to expel the whole of the base; the impure trimethylamine is passed first through a reflux condenser, then through a potash tower, and is finally collected in two wash-bottles, each containing 150 grams of alcohol, and well cooled during the operation. Methyl bromide is then passed into the well-cooled alcoholic solution until the latter no longer shows an alkaline reaction, and the precipitated tetramethylammonium bromide is separated by filtration, washed with alcohol, and dried; this crystalline compound is converted into the corresponding hydroxide by treating it with moist silver oxide in the usual manner, and the anhydrous, crystalline tetramethylammonium hydroxide is then gradually heated in a large flask in a slow stream of hydrogen. The mixed vapours of methyl alcohol and trimethylamine are passed through two condensers, when the former is liquefied and collected in a flask, and the pure trimethylamine, after passing through a potash tower, is finally collected in alcohol. F. S. K.

Action of Isobutyl Iodide on Trimethylamine. By H. Malbot and A. Malbot (*Bull. Soc. Chim.* [3], **6**, 709—711).—A mixture of isobutyl iodide and trimethylamine in molecular proportion is heated with water in sealed tubes at 100° for three days. In addition to trimethylisobutylammonium iodide, which affords a stable platinochloride $(NMe_3{\cdot}C_4H_9)_2,PtCl_6$, a small quantity of butylene is produced. The same products are obtained when the above mixture is frequently agitated during three months in the cold, and the authors think the butylene results from the action of hydrogen iodide on tertiary isobutyl iodide existing as an impurity in the alkyl iodide used.

T. G. N.

Action of Isoamyl Iodide on Trimethylamine. By H. Malbot and A. Malbot (*Bull. Soc. Chim.* [3], **6**, 711).—A mixture of isoamyl iodide with trimethylamine in molecular proportion reacts in the cold when well shaken in presence of water in sealed tubes for six days.

On evaporating the product, white, nacreous crystals of trimethylisoamylammonium iodide are obtained, which yield a platinochloride, $(NMe_3{\cdot}C_5H_{11})_2PtCl_6$. The chemical activity of isoamyl iodide and of tri-isoamyline in respect to amines and alkyl iodides respectively is greater than that of the corresponding butyl derivatives.

T. G. N.

Action of Capryl Iodide on Trimethylamine. By H. Malbot and A. Malbot (*Bull. Soc. Chim.* [3], **6**, 845).—A mixture of capryl iodide with trimethylamine in molecular proportion is heated with water in sealed tubes for successive periods of 48 hours at 100° and 155°. The lower of the two layers contains tetramethylammonium iodide, which crystallises out, and some trimethylamine iodide, and in the supernatant layer dimethylamine and some caprylene occur.

T. G. N.

Derivatives of Neurine and Choline. By J. Bode (*Annalen*, **267**, 268—299).—Trimethylamine ethylene bromide, $NMe_3Br{\cdot}C_2H_4Br$, prepared according to Hofmann's method, by treating the base with ethylene bromide in alcoholic solution, crystallises from alcohol in lustrous plates melting at 230°, and from cold water in large, monoclinic plates, $a : b : c = 0{\cdot}8478 : 1 : 0{\cdot}86958$, $\beta = 71° 2' 7''$; on prolonged boiling with an aqueous solution of silver nitrate (2 mols.) it is converted into trimethylethoxyammonium hydroxide (choline). When treated with excess of bromine in alcoholic solution, a perbromide of the composition $NMe_3Br{\cdot}C_2H_4Br,Br_2$ is deposited in golden crystals melting at 147—148°; this compound is insoluble in cold, and is decomposed by boiling alcohol and by boiling water.

Trimethylvinylammonium bromide, $NMe_3Br{\cdot}C_2H_3$, can be obtained by treating trimethylamine ethylene bromide with silver oxide and then saturating the filtered solution with hydrogen bromide; it is a colourless, very hygroscopic compound, melts at 193°, and is readily soluble in water and alcohol, but insoluble in ether. The corresponding *iodide*, $NMe_3I{\cdot}C_2H_3$, prepared in like manner, crystallises from hot alcohol in colourless needles, turns yellow at about 180°, melts at 196°, and is readily soluble in water and hot alcohol.

Dibromethyltrimethylammonium bromide, $NMe_3Br{\cdot}CHBr{\cdot}CH_2Br$, is formed when bromine is added to an alcoholic solution of trimethylvinylammonium bromide, or of the corresponding chloride; it crystallises from hot alcohol in colourless needles, and from cold water in plates, turns brown when heated, and melts at 165°; it combines with bromine, yielding a crystalline, unstable perbromide,

$$NMe_3Br{\cdot}C_2H_3Br_2,Br_2,$$

which melts at 73°.

Dibromethyltrimethylammonium chloride, $NMe_3Cl{\cdot}CHBr{\cdot}CH_2Br$, can be obtained by treating a cold aqueous solution of the corresponding bromide with excess of silver chloride; it separates from alcoholic ether in colourless needles, and is very readily soluble in water, but rather more sparingly in alcohol. The *platinochloride*,

$$(C_5H_{12}NBr_2Cl)_2,PtCl_4,$$

crystallises from hot, dilute hydrochloric acid in orange needles,

melts at 220°, and is only sparingly soluble in cold water. The *aurochloride*, $C_5H_{12}NBr_2Cl,AuCl_3$, crystallises in golden plates, melts at 216°, and is only sparingly soluble in cold, but more readily in hot water.

Bromovinyltrimethylammonium bromide, $NMe_3Br{\cdot}CH{:}CHBr$, is formed when dibromethyltrimethylammonium bromide is treated with alcoholic potash (1 mol.); it separates from alcoholic ether in colourless, lustrous plates, melts at 146—147°, and dissolves freely in alcohol and water. The *aurochloride*, $C_5H_{11}NBrCl,AuCl_3$, crystallises from dilute hydrochloric acid in golden prisms melting at 223°. The *platinochloride*, $(C_5H_{11}NBrCl)_2,PtCl_4$, forms well-defined prisms and melts at 202°.

Tribromethyltrimethylammonium bromide, $NMe_3Br{\cdot}CHBr{\cdot}CHBr_2$, can be prepared by treating the preceding compound with bromine in chloroform solution; it crystallises from hot alcohol in colourless needles, melts at 152°, and is readily soluble in water and hot alcohol.

Acetenyltrimethylammonium platinochloride, $(NMe_3Cl{\cdot}C{:}CH)_2,PtCl_4$, is precipitated when bromovinyltrimethylammonium bromide is treated with alcoholic potash (2 mols.), the filtered solution acidified with hydrochloric acid, and then mixed with platinic chloride; it separates from dilute hydrochloric acid in orange crystals, melts at 218° after previously turning brown, and is readily soluble in water. The corresponding *aurochloride*, $NMe_3Cl{\cdot}C{:}CH,AuCl_3$, crystallises in golden needles, melts at 245°, and is only sparingly soluble in cold water. When a solution of the corresponding chloride is treated with bromine, there is formed a *bromo*-derivative of the composition $NMe_3Br{\cdot}C_2HBr_4$; this substance separates from alcoholic ether in colourless crystals melting at 146°. The physiological action of the acetenyl base has been examined by Schmidt (compare this vol., p. 905).

Chlorethoxytrimethylammonium platinochloride,

$$(NMe_3Cl{\cdot}C_2H_3Cl{\cdot}OH)_2,PtCl_4,$$

is obtained when trimethylvinylammonium chloride is treated with hypochlorous acid, the alcoholic solution of the product acidified with hydrochloric acid, and mixed with platinic chloride; it separates from dilute hydrochloric acid in long, orange, prismatic crystals melting at 205—207°.

Trimethylchlorethylammonium platinochloride,

$$(NMe_3Cl{\cdot}C_2H_4Cl)_2,PtCl_4,$$

can be prepared by decomposing the platinochloride just described with hydrogen sulphide, treating the hot solution of the product with tin and hydrochloric acid, and, after precipitating the tin, adding a solution of platinic chloride; it separates from dilute hydrochloric acid in small, yellow, octahedral crystals, melts at 260°, and is only very sparingly soluble in cold water.

Trimethyldihydroxyethylammonium platinochloride,

$$[NMe_3Cl{\cdot}CH(OH){\cdot}CH_2{\cdot}OH]_2,PtCl_4,$$

is obtained when chlorethoxytrimethylammonium chloride is treated with moist silver oxide, and the hydrochloric acid solution of the product precipitated with platinic chloride; it forms small, yellow crystals, melts at 264°, and is only sparingly soluble in cold water.

The *aurochloride*, $NMe_3Cl{\cdot}CH(OH){\cdot}CH_2{\cdot}OH,AuCl_3$, crystallises in long, golden needles, melts at 237°, and is only sparingly soluble in cold water. The physiological action of trimethyldihydroxyethyl ammonium chloride (isomuscarine chloride, or hydroxycholine chloride) has been previously referred to (compare Schmidt, *loc. cit.*).

A compound of the composition $NMe_3,C_8H_8Br_2$ is deposited in colourless, nodular crystals when a 33 per cent. alcoholic solution of trimethylamine is warmed with cinnamene dibromide at 50—60°; it crystallises from alcoholic ether in colourless plates, melts at 202°, and is very readily soluble in water, and moderately easily in alcohol; on keeping, it decomposes with liberation of trimethylamine.

F. S. K.

Action of Hydriodic and of Hydrobromic Acid on Neurine and Choline. By E. Schmidt (*Annalen*, **267**, 300—318).—*Trimethylamine ethylene iodide*, $NMe_3I{\cdot}CH_2{\cdot}CH_2I$, is formed when neurine iodide is heated with concentrated hydriodic acid at 100° for several hours; it separates from hot water in colourless crystals, melts at 230—231°, and is only very sparingly soluble in boiling alcohol; when heated for a long time with a slight excess of silver nitrate in aqueous solution, it yields choline and only a very small quantity of neurine.

The *platinochloride* of β-iodethyltrimethylammonium chloride, $(NMe_3Cl{\cdot}C_2H_4I)_2,PtCl_4$, is obtained when a cold aqueous solution of the preceding compound is digested with silver chloride, the filtrate acidified with hydrochloric acid, and treated with platinic chloride; it separates from hot dilute hydrochloric acid in small, orange-yellow crystals, melts at 234° with decomposition, and is only very sparingly soluble in cold water. The corresponding *aurochloride*,

$$NMe_3Cl{\cdot}C_2H_4I,AuCl_3,$$

forms lustrous, golden plates, melts at 193·5° with decomposition, and is very sparingly soluble in cold water.

The trimethylamine ethylene iodide (β-iodethyltrimethylammonium iodide) prepared from neurine is identical with the compound obtained by Baeyer (*Annalen*, **140**, 306) by heating neurine hydrochloride (choline chloride) with hydriodic acid. The same compound is formed, but only in small quantities, when an alcoholic solution of trimethylamine is heated at 50° with ethylene iodide; when an aqueous solution of the compound is treated with moist silver oxide, the filtered solution acidified with hydrochloric acid and mixed with platinic chloride, neurine platinochloride is precipitated; it is possible, therefore, to convert choline into neurine, and *vice versâ*, in a comparatively simple manner.

When neurine iodide is heated for six hours at 100° with concentrated hydrobromic acid, it seems to give a mixture of trimethylamine ethylene bromide (compare this vol., p. 806) and trimethylamine ethylidene bromide, in which the former is present in the larger quantity; when this mixture is treated with silver nitrate in aqueous solution, choline and smaller quantities of neurine are obtained.

F. S K.

Formation of Bromaldehydes and Bromoketones by the Action of Bromine on Alcohols of the Ethyl Series. By A. ETARD (*Compt. rend.*, **114**, 753—755).—The author is unable to confirm the usual statement that the action of bromine on normal propyl alcohol yields propyl bromal. The action of 1 mol. of bromine (Br_2) on 1 mol. of propyl alcohol develops a considerable quantity of heat, but the liquid afterwards requires to be heated in order to make the reaction complete. Dibromopropaldehyde, $C_3H_4Br_2O$, is formed together with propyl bromide and some propyl bromopropionate.

Dibromopropaldehyde obtained in this way is a colourless liquid which boils without decomposition at 137°; sp. gr. at 15° = 1·899. Its vapour is intensely irritating to the eyes. It combines with sodium hydrogen sulphite to form a compound crystallising in nacreous scales, and with water it forms a very soluble hydrate, $C_3H_4Br_2O + 2H_2O$, which crystallises in beautiful prisms. The constitution of the derivative is, probably, $CMeBr_2{\cdot}COH$.

Isopropyl alcohol, under the same conditions, is very rapidly attacked by bromine, and yields isopropyl bromide boiling at 61°, and acetyl bromoform, $COMe{\cdot}CBr_3$, which forms phenylcarbylamine in presence of aniline, and yields bromoform when treated with ammonia. Acetyl bromoform boils, with decomposition, at 255°, and unites with difficulty with hydrogen sulphites.

Normal butyl alcohol is not readily attacked by bromine; it yields monobrombutaldehyde, boiling at 235°.

Isobutyl alcohol is attacked more easily; the products are isobutyl bromide, isobutyl isobutyrate, and bromisobutaldehyde. The latter boils at 197° with some decomposition.

Trimethylcarbinol explodes feebly in contact with bromine, and isobutylene bromide, $CMe_2Br{\cdot}CH_2Br$, boiling at 148°, is formed.

Fermentation amyl alcohol reacts readily with bromine, and yields amyl bromide, bromovaleral boiling at 125° under a pressure of 80 mm., dibromovaleral, and dibromovaleraldehyde, which boils at 155—160° under a pressure of 80 mm., and oxidises to dibromovaleric acid when exposed to the air.

The amyl alcohol $OH{\cdot}CMe_2{\cdot}CH_2Me$, when treated with bromine, loses water and yields amylene dibromide, $CMe_2Br{\cdot}CHBrMe$, boiling at 172°.

When bromine acts on isobutyl and amyl alcohols in presence of an alkali, it produces carbon tetrabromide and alkaline butyrates or valerates. C. H. B.

Preparation of Crotonaldehyde. By J. A. MÜLLER (*Bull. Soc. Chim.* [3], **6**, 795—796).—Crotonaldehyde is best prepared by heating 100 grams of acetaldehyde with 0·7 c.c. of zinc chloride solution (containing 150 grams per 100 c.c.), in sealed tubes at 100° for 48 hours. The product is distilled on a water-bath, and the residue, after treatment with saturated sodium carbonate solution, is filtered, dehydrated by potassium carbonate, and subjected to repeated fractionations from fused calcium chloride in an atmosphere of carbonic anhydride. A yield amounting to 16·7 per cent. of the acetaldehyde actually used is obtained. T. G. N.

Occurrence of a Tetracarbon Aldehyde in a Brandy. By J. A. Muller (*Bull. Soc. Chim.* [3], **6**, 796—800).—A badly tasting brandy, distilled from a "piquette" wine resulting from the fermentation of grape marc washings yielded, on treatment with moist silver hydroxide, silver γ-oxybutyrate, from which the corresponding calcium and barium salts were prepared. A further portion of the spirit afforded a yellow, oily oxime, C_4H_7NO, which probably results from the presence therein of an isocrotonaldehyde, $CH_2{:}CH{\cdot}CH_2{\cdot}CHO$.

T. G. N.

Action of Chlorine on some Fatty Ketones. By Démètre-Vladesco (*Bull. Soc. Chim.* [3], **6**, 807—836; compare Abstr., 1890, 956; 1891, 1183; this vol., 424).—Chlorethyl methyl ketone, when heated with water in sealed tubes at 150° for eight hours, affords *methylacetylcarbinol*, which boils at 140—150°. Sodium reacts on a dry ethereal solution of the chloroketone to yield a liquid diketone, $(COMe{\cdot}CHMe)_2$, soluble in ether and in alcohol, boiling at 210°, and forming crystalline compounds with phenylhydrazine and sodium hydrogen sulphite. Chlorethyl methyl ketone and sodium (equal mols.) react in alcoholic solution, yielding a ketonic alcohol, $C_4H_8O_2$, which boils at 140—145°, and reduces cold Fehling's solution and warm ammoniacal argentic nitrate. It dissolves in the ordinary solvents and combines with phenylhydrazine to yield a diacetylosazone (m. p. 2·420) identical with that obtained by v. Pechmann (Abstr., 1891, 738).

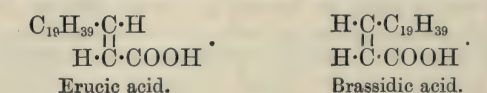
Potassium acetate and chlorethyl methyl ketone, when heated at 150° for 12 hours, afford *methylacetylcarbinyl acetate*, $CHMeAc{\cdot}OAc$, an acetous liquid boiling at 160° under a pressure of 760 mm., which is but slightly soluble in the ordinary solvents. It combines with phenylhydrazine, and by the action of potassium hydroxide affords methylethylcarbinol. By this general reaction, the author prepared *methylacetylcarbinyl butyrate*. Alcoholic solutions of the chloroketone and potassium cyanide (equal mols.) are heated in sealed tubes at 120° for three hours, and a liquid ketonic nitrile, *methylacetylacetonitrile*, $CN{\cdot}CHMe{\cdot}COMe$, is formed, which boils at 156° under a pressure of 755 mm., and is a lower homologue of the compound obtained by Hanriot and Bouveault (Abstr., 1889, 841). This compound is insoluble in water, but dissolves in the ordinary solvents, and has a sp. gr. at 0° of 0·9934 and a vapour density of 3·35. With ammoniacal silver nitrate solution, it forms a crystalline compound $CN{\cdot}CMeAg{\cdot}COMe$, and on treatment with potassium hydroxide, it evolves ammonia, a potassium salt, $COMe{\cdot}CHMe{\cdot}COOH$, being formed; this is decomposed by sulphuric acid with formation of carbonic anhydride and methyl ethyl ketone, and when heated with ethyl iodide and alcohol in sealed tubes at 150° yields ethyl methylacetoacetate. The nitrile itself forms a yellow, oily compound with phenylhydrazine, $C_{11}H_{13}N_3$, which distils at 305—315°, and is, perhaps, by a molecular transformation converted into phenyldimethylamidopyrazole [1 : 3 : 4 : 5], as in the case of the β-ketonic nitriles (Bouveault, Abstr., 1891, 51).

Chlorethyl methyl ketone reacts in the cold with a solution of sodium in phenol, and the oily, insoluble product, after washing with alkaline hydroxide solution and drying over potassium carbonate, affords on fractionation at 235—240°, *αα-acetylphenoxyethane*, $OH{\cdot}CMePh{\cdot}COMe$, which is insoluble in water, but dissolves in the ordinary solvents, and on treatment with dilute sulphuric acid loses a molecule of water, and forms *αβ*-dimethylcoumarone, which distils at 260°.

The author was unable to isolate an amido-ketone from the product of the action of ammonia gas on an alcoholic solution of chlorethyl methyl ketone, but evaporation of the alcoholic solution affords a viscid liquid from which hot water extracts long needles of tetramethylpyrazole, $C_8H_{12}N_2$, melting at 86°; the constitution and formation of the pyrazoles is discussed, and in this case the author thinks it results from a condensation of 2 mols. of the amidoethyl methyl ketone with subsequent elimination of a molecule of water and of hydrogen.

Chlorethyl methyl ketone combines with aniline at 100°, and with methylaniline at 200°, to yield 2′ : 3′-dimethylindole and 1′ : 2′ : 3′-trimethylindole respectively (Abstr., 1890, 1421).

Chlorethyl methyl ketone forms crystalline compounds with trimethylamine, with dimethylamine, and with carbamide. Sodium ethoxide reacts with it to yield an ether-like compound, but the investigation of these substances is incomplete owing to the death of the author. The chlorination of methyl propyl ketone, diethyl ketone, and dipropyl ketone afforded similarly constituted monochloroketones, boiling at 130—133°, 145°, and 167° respectively, and which, so far as they were investigated, more especially in respect to the formation of pyrazoles, gave reactions similar to those of chlorethyl methyl ketone. T. G. N.



Chlorinated Diacetylacetone. By F. Feist (*Ber.*, **25**, 1067—1070).—When dehydracetic chloride is heated with water for several hours at 200°, a gas is evolved, and a small quantity of dehydracetic acid is formed; the principal product is, however, a crystalline compound, which melts at 83—85°, and is identical with the substance obtained by Collie (Trans., 1891, 619) by boiling dehydracetic acid with concentrated hydrochloric acid. The compound in question has the composition $C_7H_9O_2Cl + 2H_2O$, not $C_7H_{11}O_3Cl$, as stated by Collie, and is hydrochlorodimethylpyrone containing water of crystallisation; it loses 2 mols. H_2O over sulphuric acid under reduced pressure, the anhydrous substance being very hygroscopic, and melting at 154°. F. S. K.

Dry Distillation of Silver Salts of Organic Acids. By A. Lieben (*Ber.*, **25**, 1188—1189).—The author points out that the results obtained by Kachler (this vol., p. 37) have been previously obtained by Iwig and Hecht (Abstr., 1886, 439). He also discusses the observations of Koenig's (this vol., p. 293) in relation to those of Kachler. E. C. R.

Stereoisomerism of Oleïc and Elaïdic Acids. By A. Saytzeff (*J. pr. Chem.* [2], **45**, 300—302).—This is a preliminary notice. An isoerucic acid has been isolated (compare Abstr., 1888, 815).

A. G. B.

Stereometric Relations of Erucic Acid and Brassidic Acid. By A. Holt (*Ber.*, **25**, 961—965).—In a previous paper (this vol., p. 429), the author has shown that the relations between erucic acid and brassidic acid are best explained by the stereometric formulæ:—

Erucic acid. Brassidic acid.

In order to obtain further evidence on this point, the author has investigated the action of reducing agents on behenolic acid, $C_{19}H_{39}\cdot C{:}C\cdot COOH$, which should, according to Wislicenus' hypothesis, yield as first product an acid having the stereometric formula above assigned to brassidic acid, and which should therefore, if the author's views are correct, be identical with that acid. The results obtained show that brassidic acid is formed without any admixture of erucic acid.

Alkaline reducing agents are without action on behenolic acid, but it is readily attacked by zinc dust and acetic acid if a few drops of hydrochloric acid be added to the liquid. The product is pure brassidic acid, and combines with bromine forming the known dibromide. It was also found that zinc and acetic acid do not convert erucic acid into brassidic acid, and the latter must therefore be regarded as the sole product of the action of reducing agents on behenolic acid.

Hydrobromic acid saturated at 0° also acts on behenolic acid at 100° with formation of bromobrassidic acid, which, on reduction with sodium in alcoholic solution, yields brassidic acid. The action of hydrochloric acid does not proceed so smoothly, a hydroxy-acid, $OH\cdot C_{22}H_{41}O_2$, being obtained together with oily substances; the acid melts at 80°, and forms a heavy, crystalline silver salt, stable towards light.

The dibrom-additive product of behenolic acid (dibromobrassidic acid) and also di-iodobrassidic acid, when treated with sodium in alcoholic solution, re-form behenolic acid; the tetrabromide of behenolic acid behaves in the same manner, and does not, as stated by Haussknecht (*Annalen*, **143**, 40), yield erucic acid.

For the preparation of behenolic acid, the author employs a modification of v. Grossmann's method (*Inaug. Diss., Leipsic*, 1890), which consists in boiling 1 part of the dibromide of erucic acid with 2 parts of potash and 8—9 parts of 96 per cent. alcohol. The yield is 80 per cent. of the theoretical. H. G. C.

Lactonic Acids, Lactones, and Unsaturated Acids. By R. Fittig (*Annalen*, **267**, 186—191).—General remarks on the papers by Fittig and Ström (next abstract), and by Fittig and Parker (this vol., p. 814). F. S. K.

Action of Sodium Ethoxide on Butyrolactone. By R. Fittig and K. T. Ström (*Annalen*, **267**, 191—203; compare Abstr., 1890, 866—869). — *Dibutolactone*, $\begin{matrix}CH_2\cdot CH_2\\ |\\ CH_2-O\end{matrix}>C:C<\begin{matrix}CO\cdot O\\ |\\ CH_2\cdot CH_2\end{matrix}$, is formed, together with γ-ethoxybutyric acid (see below), when butyrolactone (1 mol.), prepared by the method described by Chanlaroff (*Annalen*, **226**, 325), is heated on the water-bath for about three hours with an alcoholic solution of sodium ethoxide (1 mol.); after distilling off the alcohol, the residue is washed with ether, dissolved in water, the ice-cold solution mixed with 15 per cent. hydrochloric acid, and the products then extracted by repeatedly shaking with ether; the acid is separated from the lactone by agitating the ethereal extract with soda. Dibutolactone separates from hot ether in small, rosette-like aggregates, and from water in larger, scaly crystals; it melts and turns slightly yellow at 86·5°, and is readily soluble in chloroform, hot water, benzene, and alcohol, but only sparingly in carbon bisulphide and cold ether.

Oxetonecarboxylic acid, $\begin{matrix}CH_2\cdot CH_2\\ |\\ CH_2-O\end{matrix}>C<\begin{matrix}CH(COOH)\cdot CH_2\\ |\\ O\text{————}CH_2\end{matrix}$, is precipitated when concentrated soda is gradually added to dibutolactone, suspended in a small quantity of warm water, and the solution then acidified. It crystallises from cold water in needles, melts at 156°, and is readily soluble in alcohol and moderately easily in hot water, but only sparingly in cold ether and chloroform, and insoluble in carbon bisulphide. The *calcium* salt, $(C_8H_{11}O_4)_2Ca$, and the *barium* salt, $(C_8H_{11}O_4)_2Ba$, are colourless, amorphous compounds, readily soluble in water, but more sparingly in alcohol. The *silver* salt, $C_8H_{11}O_4Ag$, crystallises from warm water in small needles, is only moderately stable in the light, and is decomposed by boiling water, with separation of silver and carbonic anhydride and formation of oxetone.

Oxetone, $\begin{matrix}CH_2\cdot CH_2\\ |\\ CH_2-O\end{matrix}>C<\begin{matrix}CH_2\cdot CH_2\\ |\\ O-CH_2\end{matrix}$, is formed when its carboxylic acid is heated above its melting point, or is boiled with water or dilute mineral acids; it is most easily prepared by boiling dibutolactone with dilute acids. It is a colourless, mobile, highly refractive liquid, specifically lighter than water, and readily volatile with steam; it has a strong, peppermint-like odour, boils at 159·4°, and is soluble in 10 to 15 parts of water at the ordinary temperature, the solution becoming turbid when treated with potassium carbonate, or when gently warmed, but clear again when heated at about 90°; it is miscible with alcohol, ether, chloroform, and benzene in all proportions. It is not acted on by boiling dilute acids, or by alkalis, but it immediately reduces warm ammoniacal silver solutions. When treated with concentrated hydrobromic acid at 0°, it yields a crystalline compound of the composition $C_7H_{12}OBr_2$; this substance melts at 34·5°, and is very readily soluble in alcohol, chloroform, carbon bisulphide, ether, and benzene, but insoluble in cold water; it is decomposed by boiling water and by alkalis, being reconverted into the oxetone.

γ-Ethoxybutyric acid, $OEt\cdot[CH_2]_3\cdot COOH$, is obtained as a brown

oil when the alkaline solution referred to above is acidified and then extracted with ether; it is a thick liquid boiling at 231°. The *calcium* salt $(C_6H_{11}O_3)_2Ca + 2H_2O$, separates from water in rosette-shaped crystals, loses its water at 115°, and melts at 140°; it is readily soluble in alcohol. The *silver* salt, $C_6H_{11}O_3Ag$, is a colourless, amorphous compound, readily soluble in boiling water, and very stable in the light. When γ-ethoxybutyric acid is heated with concentrated hydrochloric acid at 140°, it is converted into γ-chlorobutyric acid; this compound is decomposed by boiling water, yielding butyrolactone, from which γ-hydroxybutyric acid is easily obtained as a thick oil, boiling at 231°, and miscible with water in all proportions. F. S. K.

Divalolactone. By R. Fittig and W. D. Hoeffken (*Annalen*, **267**, 203—204).—Divalolactone (compare Fittig and Rasch, Abstr., 1890, 867), when purified by distillation, solidifies in a freezing mixture, and, after having been pressed between blotting paper, can be recrystallised from warm light petroleum, from which it is deposited in slender needles melting at 39°; it boils at 309° with slight decomposition. F. S. K.

Condensation of Pyruvic Acid with Dicarboxylic Acids. By R. Fittig and G. Parker (*Annalen*, **267**, 204—218).—Pyrocinchonic anhydride can be very easily and cheaply prepared by gradually heating a mixture of anhydrous sodium succinate, pyruvic acid, and acetic anhydride, in molecular proportion, to 110°, and then keeping the mixture at that temperature until the evolution of carbonic anhydride ceases, which is usually the case in from 20—30 hours; after cooling, the mixture is treated with warm water, and steam-distilled as long as the distillate shows an acid reaction. The distillate is mixed with excess of sodium carbonate, concentrated, acidified with hydrochloric acid, the crystalline precipitate extracted by shaking with ether, and finally recrystallised from hot water; the anhydride is obtained in this way in large, transparent plates melting at 95°.

Barium pyrocinchonate, $C_6H_6O_4Ba$, is deposited in small, nacreous, anhydrous plates when its solution in cold water is warmed; the *calcium* salt, $C_6H_6O_4Ca$, is also more readily soluble in cold than in hot water, and crystallises in lustrous, anhydrous plates. The *silver* salt, $C_6H_6O_4Ag_2$, is sparingly soluble in water. When the mixture of sodium succinate, pyruvic acid, and acetic anhydride referred to above is carefully heated at a temperature below 80°, the principal product is an acid which could not be obtained in a pure condition, but which is, in all probability, identical with the valerolactonedicarboxylic acid described by Rasch (*Annalen*, **234**, 35).

Uvic acid (pyrotritartaric acid), $C_7H_8O_3$, is obtained when a mixture of anhydrous sodium succinate and pyruvic acid is heated at 110° for about 36 hours; the product is isolated by distillation with steam.

Ethylmethylmaleïc acid, $C_7H_{10}O_4$, is formed by the mutual action of sodium glutarate, pyruvic acid, and acetic anhydride, in molecular

proportion, under the conditions described in the preparation of pyrocinchonic anhydride; the product is distilled with steam, and isolated by means of its crystalline *barium* salt, $C_7H_8O_4Ba$. The *calcium* salt, $C_7H_8O_4Ca + H_2O$, like the barium salt, is much more readily soluble in cold than in warm water, and is deposited in colourless plates when a cold, saturated solution is warmed. The *silver* salt, $C_7H_8O_4Ag_2$, crystallises from hot water in plates. When the barium salt is treated with hydrochloric acid, ethylmethylmaleïc anhydride is precipitated as an oil, which is moderately easily soluble in hot water, and miscible with alcohol, ether, &c., in all proportions (compare Bischoff, Abstr., 1891, 291); the yield is comparatively small. The solution of the original product, from which ethylmethylmaleïc acid has been separated, contains a syrupy acid which is in all probability dimethylbutyrolactonedicarboxylic acid; when this substance is distilled, it is converted into ethylmethylmaleïc anhydride (b. p. 232—233°) with evolution of carbonic anhydride; the quantity of anhydride obtained in this way is much larger than that prepared directly from the crude product in the manner described above. F. S. K.

Action of Hydroxylamine on Dibromopyruvic Acid. By H. G. Söderbaum (*Ber.*, **25**, 904—916).—*Primary dihydroximidopropionic acid*, $C_3H_4N_2O_4$, is obtained by cautiously mixing aqueous solutions of dibromopyruvic acid (60 grams), hydroxylamine hydrochloride (48 grams), and anhydrous sodium carbonate (80—90 grams), at a low temperature; after remaining at 10—15° for 1—2 days, the precipitated crystals are collected, dissolved in dilute sulphuric acid, and the solution extracted with ether. The pure compound crystallises in tufts of small, white needles containing 1 mol. H_2O, sinters at 80° with the loss of water, melts at 141—143°, and is readily soluble in water, alcohol, and ether, but almost insoluble in benzene. Its aqueous solution has an acid reaction, gives a blood-red colour with ferric chloride, a dark-violet with ferrous sulphate and sodium hydroxide, and an amorphous, olive-green precipitate with copper acetate. The *sodium* salt, $C_3H_3N_2O_4Na + 3H_2O$, crystallises in large, four-sided tables; the *silver* salt, the *ammonium* salt, the *calcium* salt, with $2H_2O$, and the barium salt, with $5H_2O$, were also prepared. The *diacetyl* derivative, obtained by treating the anhydrous acid at the ordinary temperature, or at 90—100°, with acetic anhydride, and allowing the solution to evaporate in a vacuum over potash, forms six-sided tables, and melts at 135° with the evolution of gas; it also crystallises from a small quantity of water in monhydrated, four-sided tables melting at 90—92° with the evolution of gas; it dissolves in ether, alcohol, and chloroform, but is insoluble in benzene, and when treated with a large quantity of water, or with alkali, it is hydrolysed with the formation of secondary dihydroximidopropionic acid (see below). When the diacetyl derivative is heated at 130—140°, it is decomposed into carbonic anhydride, acetic acid, and acetylhydroximidoacetonitrile melting at 46° (see below). When primary dihydroximidopropionic acid is dissolved in water, and hydrogen chloride is passed through the solution, it decomposes into the secondary acid, cyanogen, carbonic anhydride, and water; whilst if the acid is boiled in a

reflux apparatus with concentrated aqueous alkali, a salt of isonitrosomalonic acid is obtained.

Secondary dihydroximidopropionic acid is prepared by heating the mother liquor from the primary acid at 50—60°, or by treating the primary acid with hydrogen chloride, as above described; the anhydrous acid forms a white, crystalline powder, and melts at 172° with decomposition, but it crystallises from dilute sulphuric acid in long, delicate needles containing water of crystallisation, and melting at 156°; it resembles the primary acid in its reactions. The *sodium salt*, with $2H_2O$, crystallises in white needles, the *ammonium salt*, the *silver salt*, with $2H_2O$, the *calcium salt*, with $4H_2O$, and the *barium salt*, with $2H_2O$, are also described. When treated with acetic anhydride at temperatures ranging between 15° and 100°, *acetylhydroximidoacetonitrile*, CN·CH:NOAc, which crystallises in jagged needles, and melts at 46°, is obtained. The *acetyl derivative* is obtained in small quantity by digesting the acid for several days with acetic chloride, and is separated from unattacked acid by means of ether; it crystallises with 1 mol. H_2O in colourless needles or prisms, and melts at 90°; whilst, after remaining in the desiccator, it is dehydrated, and then melts at 133°; the secondary acid is obtained by hydrolysing it, and it gives isonitromalonic acid when boiled with concentrated alkali. Taking the above described facts into account, the author assigns the configuration  (*carboxysynglyoxime*) to the primary acid, and the configuration  (*syncarboxyamphiglyoxime*) to the secondary acid. A. R. L.

Constitution of Ethyl Acetoacetate and of the so-called Ethyl Formylacetate. By H. v. Pechmann (*Ber.*, **25**, 1040—1054; compare this vol., p. 696).—When ethyl acetoacetate is shaken with soda and benzoic chloride, it yields a mono- and a di-benzoyl derivative, whereas Wislicenus' "ethyl formylacetate" gives only a monobenzoyl derivative. The monobenzoyl derivative of ethyl acetoacetate has still the properties of ethyl acetoacetate, in so far as it has an acid character, which it loses, however, on the introduction of a second benzoyl group; "ethyl formylacetate," on the other hand, loses its acid character on the introduction of a single benzoyl group. It follows, therefore, that ethyl acetoacetate contains two, "ethyl formylacetate" only one hydrogen atom replaceable by acid radicles; in the former, the benzoyl group combines directly with carbon, but the latter gives a benzoate, as will be shown below, the benzoyl group replacing the hydrogen atom of a hydroxyl radicle.

These facts, and other experiments described below, prove that ethyl acetoacetate and "ethyl formylacetate" are quite differently constituted; the latter contains a hydroxy-group, and is ethyl β-hydroxyacrylate, OH·CH:CH·COOEt, whereas ethyl acetoacetate, both in the free condition and in its metallic derivatives, has the ketone constitution, otherwise it must behave like ethyl hydroxyacrylate (compare Brühl, this vol., p. 583). Although this conclusion

is directly opposed to that arrived at by Nef (this vol., p. 147), the author agrees with Nef that it is unnecessary to assume that ethyl acetoacetate exists in tautomeric forms, not, however, because the existence of tautomeric forms should be denied in all cases, but for the simple reason that all the reactions of ethyl acetoacetate can be explained on the basis of the ketone formula.

The author then describes the preparation and the manner of separating the two acetyl and the two benzoyl derivatives of ethyl acetoacetate; the syrupy dibenzoyl derivative and the diacetyl derivative (ethyl triacetylacetate) were found to be identical with the compounds described by Nef (*loc. cit.*); the monobenzoyl derivative boils at 202° under a pressure of 50 mm., and its copper derivative melts at 224°, not at 180—190°, as stated by James (*Annalen*, **226**, 220). When an alkaline solution of ethyl acetoacetate is treated with ethyl chloroformate, a large quantity of a neutral substance, probably the dicarboxethyl derivative, and a trace of a substance which is soluble in soda, and which is probably ethyl acetylmalonate, are formed. Ethyl β-hydroxyacrylate ("ethyl formylacetate"), prepared by the method described by Wislicenus (Abstr., 1888, 129), gives, with copper acetate and a few drops of ammonia, a crystalline copper derivative, which separates from dilute alcohol in yellowish-green needles, and from benzene in plates, melting at 168°. The *benzoyl* derivative, OBz·CH:CH·COOEt, prepared by shaking a cold alkaline solution of the sodium derivative with benzoic chloride, melts at 5°, boils at 208—209°, under a pressure of 50 mm., and is insoluble in alkalis; its alcoholic solution gives no coloration with ferric chloride and no precipitate with copper acetate; when the benzoyl derivative is treated with bromine in well-cooled chloroform solution, it yields a colourless, oily dibromo-additive product, which decomposes on keeping, seemingly into benzoic bromide and ethyl hydroxybromacrylate. The *acetyl* derivative, OAc·CH:CH·COOEt, prepared in like manner, or better, by gradually adding acetic chloride to ether containing the sodium derivative of ethyl β-hydroxyacrylate in suspension, is a colourless liquid boiling at 126° under a pressure of 46 mm.; it is insoluble in water and alkalis, and gives no reaction with ferric chloride or with copper acetate, but it is very readily hydrolysed even by cold sodium carbonate.

Ethyl β-acetoxy-αβ-dibromopropionate,

OAc·CHBr·CHBr·COOEt,

is formed when the acetyl derivative of ethyl hydroxyacrylate is treated with bromine in well-cooled chloroform solution; it is a thick, colourless oil, boils at 154° with slight decomposition under a pressure of 34 mm., and decomposes on keeping.

Ethyl β-acetoxymethylacrylate, OAc·CH:CMe·COOEt, prepared by heating ethyl β-hydroxymethylacrylate ("ethyl formylpropionate") with acetic anhydride at 140°, is a colourless liquid boiling at 132° under a pressure of 48 mm.; it is insoluble in alkalis, and gives no reaction with ferric chloride. The corresponding *benzoyl* derivative, OBz·CH:CMe·COOEt, crystallises from dilute alcohol in long, lustrous needles, melts at 55°, and dissolves freely in all ordinary solvents.

except water and light petroleum; it is insoluble in soda, and gives no colour reaction with ferric chloride.

Ethyl β-anilidoacrylate, NHPh·CH:CH·COOEt, is precipitated when an aqueous solution of the sodium derivative of ethyl hydroxyacrylate is gradually added to a solution of aniline in dilute acetic acid; it separates from alcohol in almost colourless plates, melts at 106°, and is insoluble in water and light petroleum, but very readily soluble in other ordinary solvents. It is insoluble in soda, but it dissolves in concentrated hydrochloric acid, yielding a solution from which water precipitates a colourless, flocculent substance, which is soluble in alkalis; its alcoholic solution gives a reddish-yellow coloration with ferric chloride. When dissolved in alcoholic potash, and precipitated with water, it is converted into a crystalline compound melting at 136°. Although this ethereal salt has, doubtless, the constitution assigned to it above, it is not identical with the ethyl β-anilidoacrylate prepared by Reissert (Abstr., 1888, 276) from the product of the action of aniline on dibromosuccinic acid.

Ethyl β-paratoluidoacrylate, C_6H_4Me·NH·CH:CH·COOEt, prepared in like manner, crystallises in yellowish plates, melts at 116°, and resembles the preceding compound in its behaviour with solvents; when treated with alcoholic potash, it is converted into a crystalline compound melting at 144°, and when warmed with acetic anhydride, it yields acetotoluidide.

Ethyl β-paratoluidodiacrylate, $C_6H_4Me·N(CH:CH·COOEt)_2$, can be prepared by heating an ethereal solution of ethyl hydroxyacrylate with ethyl toluidoacrylate, or by treating paratoluidine with ethyl hydroxyacrylate, ethyl β-chloracrylate, or ethyl β-benzoylhydroxyacrylate under the same conditions; it crystallises from alcohol in well-defined, lemon-yellow, transparent prisms, from dilute alcohol in lustrous, yellow needles, and melts at 73°.

When ethyl α-phenyl-β-hydroxyacrylate (ethyl formylphenylacetate) is oxidised with potassium permanganate in alkaline solution, it yields benzoylformic acid; ethyl β-hydroxyacrylate gives glyoxylic acid. F. S. K.

Ethyl Bromacetoacetates and Cyanacetoacetates. By A. Haller and A. Held (*Compt. rend.*, **114**, 452—455).—The authors have observed that ethyl bromacetoacetate, prepared according to Schönbrodt's method (Abstr., 1890, 27) is invariably accompanied by a small proportion of an isomeric liquid, which gives off hydrogen bromide and partially decomposes when boiled, and, like the similar compound prepared by Duisberg, yields ethyl succinosuccinate when treated with potassium cyanide.

In order to ascertain the structure of the isomeride, some bromacetoacetate, prepared and purified according to Schönbrodt's directions, was treated with dry potassium cyanide in ethereal solution, with the result that only 5 per cent. of the potassium and ethyl salts of the α-cyano-derivative, but 40 per cent. of the ethyl salt of the γ-cyano-derivative, was obtained. The identity of the latter was proved by treating it with a methyl alcohol solution of hydrogen chloride, when, in addition to the hydrochloride of the imido-com-

pound already described (Abstr., 1891, 171), an acetonedicarboxylic acid was obtained which, on further treatment with hydrocyanic acid and hydrochloric acid, was converted into citric acid. *Ethyl γ-cyanaceto-acetate*, $CN\cdot CH_2\cdot CO\cdot CH_2\cdot COOEt$, is a colourless liquid, which boils at 135—140° under a pressure of 40 mm., and is insoluble in aqueous sodium carbonate.

That Schönbrodt's bromacetoacetate was really a mixture was further shown by treating it with thiocarbamide after Hantzsch's method, by which means the condensation products, ethyl μ-amido-methylthiazolcarboxylate and μ-amidothiazylacetate were obtained, which were described by that author as resulting from ethyl γ- and α-bromacetoacetates. The relative quantities of the products, however, seemed to show that the α-bromo-derivative was present in the greater proportion. JN. W.

So-called Ethyl Carbacetoacetate. By A. HANTZSCH (*Ber.*, **25**, 1310).—Genvresse (*Ann. Chim. Phys.* [6], **24**, 46) regards the chlorination product of ethyl acetoacetate as a γ-derivative; whereas Hantzsch and Schiffer (this vol., p. 697) have pronounced it to be an α-derivative. Genvresse further describes a large number of derivatives of the so-called ethyl carbacetoacetate, and proposes a constitutional formula for this substance; the author points out that the latter has already been shown by Polonoffska (Abstr., 1886, 1011) to be impure ethyl isodehydracetate. A. R. L.

Turkey-red Oil. By P. JUILLARD (*Bull. Soc. Chim.* [3], **6**, 638—656).—By methods similar to those described by Scheurer-Kestner (Abstr., 1891, 542, 665), the author has isolated several derivatives of ricinoleïc acid which result from the action of strong sulphuric acid on it and on castor oil. He states that, although the composition of the oil varies greatly with the conditions of its formation, the main products of the reaction are ricinoleïc and ricinoleosulphonic acids and their polymerides, the higher terms of which are but slightly soluble in water, whilst the special solvent action of the oil is due to the presence of diricinoleïc and diricinoleosulphonic acids, and perhaps to the presence of an easily-decomposable diricinoleosulphonic anhydride. The washed product of the primary reaction, when kept for some weeks at 20—30°, undergoes almost complete conversion into polyricinoleïc acids, and both ricinoleïc acid and castor oil, when treated with hydrochloric acid, behave similarly, the action being hastened at a temperature of 100°. The author has prepared acetylricinic, butyroricinic, and oleoricinic acids, which are oily liquids soluble in alcohol. T. G. N.

Amido- and Anilido-derivatives of Succinic Acid. By C. HELL and R. POLIAKOFF (*Ber.*, **25**, 640—652).—The action of ammonia on ethyl mono- and di-bromosuccinate has been again studied, previous observers having obtained discordant results. When ethyl monobromosuccinate is treated with a considerable excess of

10 per cent. aqueous ammonia, no reaction occurs at 0°, but at the atmospheric temperature, flakes of fumaric diamide,

$$CONH_2{\cdot}CH{:}CH{\cdot}CONH_2,$$

are deposited, and resinous products are also formed. If alcoholic ammonia is used, the same reaction takes place, but much more slowly. Curiously enough, the same substance is obtained from the dibromosuccinate, together with large quantities of resinous products. If, however, the dibromosuccinate be heated with alcoholic ammonia at 60—70°, ethyl imidosuccinamate, $NH<\begin{matrix}CH{\cdot}CONH_2\\ |\\ CH{\cdot}COOEt\end{matrix}$, is formed, together with resinous products. The same substance is obtained, although in much smaller quantity, from the monobromosuccinate under similar circumstances. At higher temperatures, ranging from 80° to 150°, nothing but resinous products were, as a rule, obtained; once only, when the dibromosuccinate was heated at 120—130° with alcoholic ammonia, was a crystalline product, *imidosuccinic diamide*,

$$NH<\begin{matrix}CH{\cdot}CONH_2\\ |\\ CH{\cdot}CONH_2\end{matrix},$$

obtained. This forms yellowish plates melting at 175—176°, dissolves in hot water, alcohol, ether, and acids, and is decomposed by alkalis, even in the cold, with liberation of ammonia.

If ethyl monobromosuccinate (1 mol.) is heated for 4 hours at 140—160° with aniline (4—5 mols.), some ethyl anilidosuccinate, $COOEt{\cdot}CH(NHPh){\cdot}CH_2{\cdot}COOEt$, is formed, together with some *ethyl anilidophenylsuccinamate*, $NHPh{\cdot}CO{\cdot}CH(NHPh){\cdot}CH_2{\cdot}COOEt$, and much anilidosuccinic dianilide,

$$NHPh{\cdot}CO{\cdot}CH(NHPh){\cdot}CH_2{\cdot}CONHPh.$$

The second substance may be obtained by extracting the product of the reaction successively with cold ether and acetic acid, and crystallising the residue from hot absolute alcohol. It forms fine, yellow prisms, melts at 144°, turning brown and evolving gas, dissolves but sparingly or is insoluble in the usual solvents, and is decomposed by alkalis, with formation of aniline and the anilido-acid. If, instead of 4—5, only about 3 mols. of aniline are used in the reaction, and the temperature is kept somewhat lower, anilidosuccinanil, $\begin{matrix}CH(NHPh){\cdot}CO\\ |\\ CH_2\text{———}CO\end{matrix}>NPh$, is also formed, and in greater quantity, as the reaction lasts longer. C. F. B.

Fermentation. By E. Buchner (*Ber.*, **25**, 1161—1163).—Hydrogen ammonium fumarate and ammonium fumarate are acted on by *Penicillium glaucum* at ordinary temperatures, and by *Aspergillus niger* at 30—35°, whilst the corresponding maleïc salts are unaffected by these organisms. For experimental details, the original paper should be consulted. J. B. T.

Action of Heat on the Hydrogen Malates of Methylamine and Benzylamine. By E. Giustiniani (*Gazzetta*, **22**, i, 169—176).

—On heating ethylamine hydrogen malate, Piutti (Abstr., 1889, 590) obtained ethylfumarimide and an amorphous condensation product which could not be converted into inactive aspartic acid.

The author finds that, on heating methylamine hydrogen malate at 200°, it gives a large quantity of an amorphous condensation product which does not yield methylaspartic acid when heated with hydrochloric acid in a sealed tube at 150°. A small quantity of *methylfumarimide*, $\begin{matrix}CH\cdot CO\\ \|\\ CH\cdot CO\end{matrix}>NMe$, is also formed and distils over. It crystallises in long, white prisms, melts at 90—92°, and is soluble in alcohol, less so in water and ether, and only very sparingly in benzene. It readily volatilises, and provokes tears. It yields a bromo-compound melting at 97°, and, when fused with caustic potash, gives off methylamine, leaving potassium fumarate in the residue. It dissolves in cold caustic potash, forming a reddish solution which deposits *methylfumaramic acid*, NHMe·CO·CH:CH·COOH, when hydrochloric acid is added. This substance forms small, white crystals melting at 149°, and combines with bromine in the cold. It is soluble in water and alcohol, sparingly so in ether. The *silver* salt is a white, amorphous powder not altered by light.

On heating benzylamine hydrogen malate at 200°, benzylfumarimide and two isomeric benzylmalimides are obtained, together with an amorphous condensation product which is not altered by heating with hydrochloric acid at 200° in a sealed tube. *Benzylfumarimide*, $\begin{matrix}CH\cdot CO\\ \|\\ CH\cdot CO\end{matrix}>N\cdot CH_2Ph$, separates from its alcoholic solution in splendid prisms melting at 67·5°. It is very soluble in hot alcohol and ether, sparingly so in water; it has a pungent taste, and its boiling ethereal solution takes up bromine, giving a liquid bromo-compound. On dissolving it in a mixture of sulphuric and nitric acids, a nitro-derivative is obtained which crystallises from alcohol in yellow needles, and melts at 173°. It dissolves in cold caustic potash forming *benzylfumaramic acid*, $CH_2Ph\cdot NH\cdot CO\cdot CH{:}CH\cdot COOH$, which separates, on adding hydrochloric acid, in small, white crystals melting at 183°. It is soluble in water, alcohol, and ether, but only very sparingly in benzene. It yields a white, amorphous *silver salt* which is rapidly changed by light, and explodes on heating. Both benzylfumarimide and benzylfumaramic acid give benzylamine on fusion with caustic potash. When the residue obtained on heating benzylamine hydrogen malate is extracted with hot water, two isomerides are dissolved. The less soluble one crystallises in square tablets melting at 114°, and is *α-benzylmalimide*, $C_{11}H_{11}NO_3$; it is soluble in acetic acid, hot water, alcohol, and ether, less so in benzene. The more soluble compound is *β-benzylmalimide;* it crystallises in acicular prisms, melts at 105°, and is soluble in acetic acid, alcohol, and ether, very sparingly so in benzene. On heating at 200—210° it is partly polymerised and partly decomposed into water and benzylfumarimide; the α-modification, when similarly treated, merely sublimes unchanged. Both α- and β-imides dissolve in caustic potash (20 per cent.) with formation of benzylmalamic acid. On treating them with

hot concentrated potash, benzylamine and potassium malate are produced. They both dissolve unaltered in acetic anhydride. On treatment with acetic chloride, the α-compound yields an *acetyl* derivative which melts at 90°, and is very sparingly soluble in water; the β-imide gives an *acetyl* derivative which melts at 102°, and is very soluble in alcohol and ether. The *benzoyl* derivative of α-benzylmalimide crystallises in small needles and melts at about 100°. The *benzoyl* derivative of the β-imide crystallises in needles melting at 122°.

Benzylmalamic acid, $CH_2Ph{\cdot}NH{\cdot}CO{\cdot}CH(OH){\cdot}CH_2{\cdot}COOH$, obtained by dissolving the benzylmalimides in cold aqueous potash (20 per cent.), and treating the solution with hydrochloric acid, forms small, white crystals melting at 130—132°. It is very soluble in alcohol, ether, and boiling water, sparingly so in cold water. Its *silver* salt is a white, crystalline powder, slowly altered by light. The *monacetyl* derivative forms a whitish, crystalline powder, soluble in alcohol and ether, sparingly so in water, and melts at 87°. The *benzoyl* derivative is obtained as very minute, white crystals melting at 117°. It is very soluble in alcohol and ether, sparingly so in water, and on boiling with water gives benzoic acid. W. J. P.

Synthesis of Tartaric Acid. By P. Genvresse (*Compt. rend.*, **114**, 555—557).—Glyoxylic acid was treated with zinc powder in presence of acetic acid diluted with its own weight of water, first at the ordinary temperature, and afterwards on the water-bath. The zinc is added gradually to the mixture of the two acids, the proportions of the molecules being, glyoxylic acid, 1; acetic acid, 3; zinc 2. Under these conditions glyoxylic acid is converted into tartaric (racemic) acid, the reaction being analogous to the conversion of acetone into pinacone, or benzaldehyde into hydrobenzoïn. The racemic acid was identified by the behaviour of the calcium salt, the reduction of ammoniacal silver nitrate, and the isolation of the free acid and measurement and analysis of the crystals. C. H. B.

Optically Isomeric Gulonic Acids. By E. Fischer and R. S. Curtiss (*Ber.*, **25**, 1025—1031).—The compound (m. p. 160°) previously described as *i*-gulonolactone (Abstr., 1891, 668) is simply a mechanical mixture of the *d*- and *l*-lactones; when a solution of equal quantities of the two optically active lactones is allowed to evaporate slowly, such large crystals of the two compounds are formed that they can be separated mechanically. The fact that the racemic modification of gulolactone cannot be obtained by crystallisation from water is of general interest, but not without analogy. A further examination of the two active lactones has shown that they are crystallographical antipodes.

i-Gulonic acid is obtained in the form of its *calcium* salt,

$$(C_6H_{11}O_7)_2Ca,$$

when an aqueous solution of equal quantities of the two optically active lactones is boiled with calcium carbonate. This salt crystallises from hot water in very slender needles, and contains water

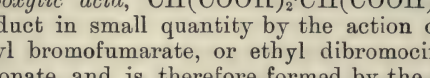
of crystallisation, which is slowly given up on keeping over sulphuric acid; 100 parts of water at 15° dissolve only 1·6 parts of the anhydrous salt, whereas the same quantity of water at the same temperature dissolves 5·8 grams of the anhydrous calcium salt of *l*-gulonic acid. A solution of the acid, prepared by heating a solution of the calcium salt with 10 per cent. hydrochloric acid, is optically inactive.

i-Gulonic acid phenylhydrazide, $C_6H_{11}O_6{\cdot}N_2H_2Ph$, is deposited in yellow crystals when a concentrated, optically inactive solution of the two lactones is heated at 100° with phenylhydrazine for an hour, and then allowed to cool. It crystallises from hot alcohol in slender needles, melts and slowly decomposes at 153—155°, and is very readily soluble in hot, but only moderately easily in cold, water. A 10 per cent. aqueous solution of the hydrazide is optically inactive, whereas a 9 per cent. solution of the corresponding derivative of *l*-gulonic acid is feebly dextrorotatory; as the two compounds differ also in melting point, and in the readiness with which they crystallise from alcohol, it is very probable that the inactive hydrazide just described is really the racemic modification, and not simply a mechanical mixture.

i-Gulose can be obtained as a colourless syrup by reducing a mixture of the two lactones with sodium amalgam in the usual manner. The *phenylhydrazone*, $C_6H_{12}O_5{\cdot}N_2HPh$, crystallises from alcohol in slender, colourless needles, melts at 143°, and is sparingly soluble in cold water; a 7 per cent. aqueous solution of this compound, examined at 50° in a tube 1 dm. in length, was found to be optically inactive, but in other respects the hydrazone resembles the corresponding derivative of *l*-gulose so closely that it is impossible to say with certainty whether it is the racemic modification or a mechanical mixture.

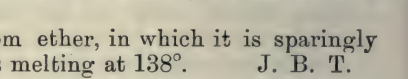
i-Phenylgulosazone, $C_6H_{10}O_4(N_2HPh)_2$, crystallises from warm ethyl acetate in slender, yellow needles, melts at 157—159°, and is much more sparingly soluble in hot water than *l*-phenylgulosazone, from which it also differs in its manner of crystallising; as, moreover, the new compound is optically inactive, it is doubtless the racemic modification.

i-Phenylgulosazone resembles phenyl-β-acrosazone so closely in melting point, crystalline form, solubility in water, and in optical behaviour, that the two compounds might be considered to be identical, were it not that the former requires for solution about four times as much ethyl acetate as the latter. That the two compounds are not identical was also proved by a comparison of their bromo-derivatives. *Parabromophenylgulosazone*, prepared by heating gulose with a dilute alcoholic solution of bromophenylhydrazine acetate at 100°, crystallises from ethyl acetate in slender, yellow needles, melts at 180—183° when quickly heated, and decomposes at a slightly higher temperature. The corresponding derivative of β-acrose, obtained by warming a dilute aqueous solution of β-acrosone with bromophenylhydrazine and acetic acid, melts at 180—183°, and is much more readily soluble in ethyl acetate than the isomeride just described. The conjecture that β-acrosazone might be inactive gulosazone consequently falls to the ground. F. S. K.



Citric Acid. By E. Buchner and H. Witter (*Ber.*, **25**, 1159—1160).—H. Kämmerer's "isomalic acid" appears to be anhydrous citric acid; it is readily prepared by heating citric acid in aqueous solution until the temperature rises to 130°; on cooling, the anhydrous acid is deposited in colourless crystals which melt at 153°, and are unacted on by water. On adding a crystal of the hydrated acid to a concentrated aqueous solution of the anhydrous acid at the ordinary temperature, the hydrated acid separates in crystals, but the converse does not apply. Both acids yield identical methyl salts, but the lead salts are not identical; for, on treatment of these compounds with hydrogen sulphide, the original anhydrous or hydrated acid is regenerated.

Hydrated citric acid melts between 135° and 152°, not at 100° as stated in text-books. J. B. T.



Symmetrical Ethanetetracarboxylic Acid. By E. Buchner and H. Witter (*Ber.*, **25**, 1157—1158).—Symmetrical *ethanetetracarboxylic acid*, $CH(COOH)_2 \cdot CH(COOH)_2$, is obtained as a bye-product in small quantity by the action of ethyl dibromosuccinate, ethyl bromofumarate, or ethyl dibromocinnamate on ethyl sodiomalonate, and is therefore formed by the condensation of 2 mols. of malonic acid. It is prepared by boiling the methyl salt (1 gram) with soda (4·5 c.c.) of sp. gr. 1·2, and water (4·5 c.c.), for 1·5 hours, and crystallises from ether in small needles which melt at 167—169° with evolution of gas; on heating for some time at 180°, succinic acid is formed.

The *methyl salt* is deposited from ether, in which it is sparingly soluble, in small, colourless crystals melting at 138°. J. B. T.

Reduction of Mucic Acid. By E. Fischer and J. Hertz (*Ber.*, **25**, 1247—1261).—According to theory, two optically inactive bibasic acids are capable of existence, having the configurations:—

and

Van't Hoff (*Die Lagerung der Atome in Raume*, S. 39) regarded mucic acid as one of them, and the so-called paramucic acid, which has been shown to be mucic acid lactone (Abstr., 1891, 1193), as the other. Later, Van't Hoff altered his views (*Dix années dans l'histoire d'une théorie*, p. 60) in accordance with Bouchardat's observation that dulcitol yields optically active derivatives; and, therefore, in spite of their apparent inactivity, both dulcitol and mucic acid must be represented as optically active systems. Dulcitol and mucic acid have also been regarded as "racemic" compounds by Carlet (*Jahresber.*, 1860, 250). If mucic acid is an optically inactive com-

pound in virtue of the spacial symmetry of its molecule, it might be expected that on reduction both carboxyl groups would be equally attacked, and that the resulting inactive monobasic acid would be separable into two oppositely active components, both of which would yield mucic acid on oxidation. The experiments described below show this to be the case.

Reduction of Mucic Acid Lactone.—Commercial mucic acid, which contains unknown optically active impurities, is purified by dissolving it in the smallest possible quantity of hot dilute sodium hydroxide solution, treating with animal charcoal, and adding hydrochloric acid to the filtrate, when the pure acid separates and is washed with cold water; that portion which is converted into the lactone is reconverted into the acid by evaporating the filtrate with an excess of hydrochloric acid, and recovered. The purified acid (150 grams) is boiled with water (60 parts) until it dissolves, and the solution is evaporated to $1\frac{1}{2}$ litres; the mucic acid which separates on cooling is removed, and the filtrate containing the lactone is cooled to 0°, and treated with $2\frac{1}{2}$ per cent. sodium amalgam with frequent shaking. At a certain stage in the reduction it is necessary to keep the solution acid by the frequent addition of dilute sulphuric acid, but after its cupric reducing power has attained its maximum, that is, when all the lactone is converted into aldehyde acid, it is kept faintly alkaline during the addition of the remaining portion of the amalgam. The operation, which usually lasts about seven hours, is stopped when 12 parts of the solution do not completely reduce 1 part of Fehling's solution; 2—$2\frac{1}{2}$ kilos. of amalgam are generally required. The solution is decanted from mercury and the filtrate evaporated to the crystallising point of sodium sulphate; concentrated sulphuric acid (50 grams) and hot 96 per cent. alcohol are then added. After cooling, the filtrate is evaporated with addition of water until the alcohol is removed; when the aqueous liquid is boiled with barium carbonate for half an hour, a barium salt, amounting to 45 per cent. of the lactone employed, is obtained in delicate, white needles on evaporating the filtrate. Details are also given of the reduction of diethyl mucate by sodium amalgam, but by this method i.-galactonic acid hydrazide corresponding only with 2 per cent. of the ethyl salt is obtained. *i.-Galactonic acid*, $C_6H_{12}O_7$:—The last-mentioned barium salt is dissolved in water, exactly precipitated by sulphuric acid, and the filtrate evaporated, when an optically inactive mixture of the acid and lactone separates. To obtain the *lactone*, $C_6H_{10}O_6$, the last product is dissolved in about $\frac{1}{3}$ its weight of warm water, and the crystals which separate after some days are collected, washed with alcohol, and later with acetone, and finally crystallised from boiling acetone. It is thus obtained in delicate prisms; it melts at 122—125°, exhibits no appreciable optical rotation in 10 per cent. aqueous solution, dissolves readily in water, somewhat sparingly in alcohol and pure acetone, and very sparingly in ethyl acetate, and is easily converted into mucic acid by nitric acid. The *barium* and *calcium* salts both crystallise with $2\frac{1}{2}$ mols. H_2O, the latter being very sparingly soluble in boiling water; the *cadmium* salt crystallises with 1 mol H_2O; whilst the *phenylhydrazide*, $C_{12}H_{18}N_2O_6$, obtained by heating a 20 per cent.

aqueous solution of the lactone with an equal quantity of phenylhydrazine on the water-bath for an hour, crystallises from water or dilute alcohol in stellate groups of colourless needles, and melts at about 205° with decomposition. *i.-Galactose*, $C_6H_{12}O_6$, is prepared by reducing a 10 per cent. cold aqueous solution of the lactone in the usual manner with nine times its weight of sodium amalgam. The solution decanted from mercury is rendered alkaline and boiled, exactly neutralised with sulphuric acid, and sufficient absolute alcohol added until it contains 85 per cent. of the latter. The sodium salt which separates is again treated with alcohol in the same way until it is free from the sugar, and the united alcoholic solutions are evaporated to a syrup, when crystallisation commences after some days. It is then triturated with methyl alcohol, and the collected crystals washed with the same liquid, dissolved in boiling absolute alcohol, filtered from insoluble matter, evaporated in a vacuum, and the syrup placed over concentrated sulphuric acid; the sugar which separates is then washed with alcohol and ether. It melts not quite constantly between 140° and 142°, and is optically inactive; it does not exhibit a characteristic crystalline form, but the question whether it is a "racemic" compound or a mechanical mixture of the two isomerides is not decided. Its derivatives are optically inactive. The *phenylhydrazone* forms colourless leaflets, and melts at 158—160°; the phenylosazone melts at 195°, and is undoubtedly identical with that obtained from dulcitol (Abstr., 1888, 358).

i.-Galactonic acid may be separated into its optically active components by the method employed for the separation of i.-mannonic acid (Abstr., 1890, 467). The lactone (20 grams) is dissolved in 70 per cent. alcohol (600 c.c.), and the solution boiled for an hour with finely pulverised strychnine (50 grams); the filtrate is evaporated with the addition of water until all the alcohol is removed, when the excess of strychnine separates, and after evaporating this filtrate to a thin syrup, white needles consisting chiefly of the d.-salt separate; it is recrystallised from alcohol, converted into the barium salt, and thence into the calcium salt. The latter is boiled with twice its weight of water, when only the d.-salt passes into solution, and separates from the filtrate in the pure state on cooling; it has all the properties of calcium d.-galactonate, and gives the lævorotatory lactone described by Tollens and others (Abstr., 1891, 43). l.-Galactonic acid is obtained by boiling the mother liquor from strychnine d.-galactonate with barium hydroxide, exactly precipitating the solution of the barium salt with sulphuric acid, boiling the filtrate with calcium carbonate, and evaporating this filtrate to a syrup, when a mixture of the l.- and i.-calcium salts separates. It is boiled with twice its weight of water, when the l.-salt dissolves, and separates from the filtrate in five-sided plates, closely resembling the d.-salt. When it is heated at 100°, it loses 15 per cent. of its weight, and when 0·2 gram is heated at 100° in a sealed tube with 0·91 per cent. hydrochloric acid (4 c.c.), the solution shows an optical activity of 2·71° in a 100-mm. tube, due to the formation of a dextrorotatory lactone.

l.-Galactose, $C_6H_{12}O_6$, is obtained by the fermentation of i.-galactose; the crude syrup obtained by reducing i.-galactonic lactone is dissolved

in water (10 parts), fresh, washed, active beer yeast added, and the mixture placed in an incubator at 30°. Fermentation commences after two hours, and is generally complete at the end of 5—6 days. The filtered solution is boiled with animal charcoal, evaporated, and the crystals washed with methyl alcohol, again treated in dilute aqueous solution with animal charcoal, and evaporated; the syrup is then triturated with methyl alcohol, and the crystals boiled with absolute alcohol, the resulting solution evaporated to incipient turbidity, and the crystals obtained from the filtrate repeatedly recrystallised from alcohol. The compound melts at 162—163°; whereas, according to v. Lippmann (*Ber.*, **18**, 3335), d.-galactose melts at 168°. The l.-galactose possessed a specific rotatory power in 10 per cent. aqueous solution eight minutes after preparation, $[\alpha]_D = -120$, and this ultimately became $[\alpha]_D = -73{\cdot}6$ to $-73{\cdot}7$ on remaining. The *phenylhydrazone* is dextrorotatory, and melts at 158—160°; the *phenylosazone* melts at 192—195°; l.-galactose yields mucic acid on oxidation with nitric acid and dulcitol on reduction with sodium amalgam. A. R. L.

So-called Artificial Pectic Acid from Fir-wood. (Oxycellulose.) By J. B. Lindsey and B. Tollens (*Annalen*, **267**, 366—370). The authors have made a number of analyses of the compound, obtained by the action of nitric acid on fir-wood, which Sacc considered to be pectic acid, but which, according to Porter, is a totally different substance. This product was found to contain 1·72—1·76 per cent. of ash, and the composition of the organic matter may be expressed by the formula $(C_6H_{10}O_5)_n$, or better still, by the formula $6C_6H_{10}O_5 + O$; the properties and reactions of the substance agree to some extent with those of the preparations described by Sacc and by Porter, and also with those of Cross and Bevan's oxycellulose (Trans., 1883, 22). When freed from nitric acid, it has a gelatinous character, and swells up when treated with water, so that it cannot be separated by filtration; when it is washed with a mixture of nitric acid and 60 per cent. alcohol, then repeatedly with 93 per cent. alcohol and ether successively, and dried over sulphuric acid, it is obtained in the form of a colourless powder, which dissolves completely in dilute ammonia, and in very dilute soda, being reprecipitated as a jelly on the addition of more concentrated soda or nitric acid. From a study of its properties, the authors conclude that it is not to be classed with the true pectin substances, as it does not contain pentoses, but that it is closely related to cellulose. F. S. K.

Bromacetamide. By E. Buchner and A. Papendieck (*Ber.*, **25**, 1160—1161).—Bromacetamide is prepared by treating ethyl bromacetate with two volumes of 10 per cent. aqueous ammonia at −10°; the product is deposited after some time, and crystallises from alcohol in colourless, flat needles which melt at 91°, not 165° as usually stated. J. B. T.

γ-Substituted Hydantoïns and Carbamido-acids. By I. Guareschi (*Chem. Centr.*, 1892, i, 140; from *Gior. R. Accad. Med.*,

1891).—The author has prepared γ-substituted hydantoïns and carbamido-acids by the action of mono-substituted carbamides on amido-acids. *γ-Methylhydantoïn*, $CO<\begin{matrix}NH—CH_2\\ NMe\cdot CO\end{matrix}$, is obtained from methylcarbamide and glycocine; *γ-phenylhydantoïn*, $CO<\begin{matrix}NH—CH_2\\ NPh\cdot CO\end{matrix}$ is obtained from phenylcarbamide and glycocine; *methylparaphenylglycoluric acid*, $NHMe\cdot CO\cdot NH\cdot C_6H_4\cdot COOH$, from methylcarbamide and paramidobenzoic acid; *phenylparaphenylglycoluric acid*,

$$NHPh\cdot CO\cdot NH\cdot C_6H_4\cdot COOH,$$

from phenylcarbamide and paramidobenzoic acid. J. W. L.

γ-Substituted Hydantoïns. By E. Quenda (*Chem. Centr.*, 1892, i, 140; from *Gior. R. Accad. Med.*, 1891).—From paratolylcarbamide and glycocine, the author has prepared *γ-paratolylhydantoïn*,

$$CO<\begin{matrix}NH———CH_2\\ N(C_6H_4Me)CO\end{matrix}.$$

Some ditolylcarbamide was formed at the same time. From the orthotolylcarbamide, the corresponding hydantoïn was obtained.

J. W. L.

Formation of Hydroxamic Acids of the Fatty Acids by means of Acid Anhydrides. By L. Crismer (*Ber.*, **25**, 1244; compare Miolati, this vol., p. 698).—A claim of priority. H. G. C.

Compounds of Thiophen and of its Homologues, and of some Ketones, with Mercuric Chloride. By J. Volhard (*Annalen*, **267**, 172—185).—When thiophen is shaken with a cold, saturated, aqueous solution of mercuric chloride, a voluminous, colourless precipitate is produced, and the solution acquires an acid reaction; a little alcohol is added in order to prevent the precipitate caking together, and the free hydrochloric acid produced in the reaction is got rid of by the addition of sodium acetate; the colourless precipitate is separated by filtration, washed with cold water, and then repeatedly extracted with boiling alcohol.

Thiophen mercuric chloride, $C_4SH_3\cdot HgCl$, separates from the alcoholic extract on cooling in colourless plates; it melts at 183°, sublimes at temperatures above 100°, and is almost insoluble in cold, and only moderately easily soluble in boiling, water; it is readily decomposed by hydrochloric acid, yielding thiophen and mercuric chloride. The portion of the precipitate which is insoluble in alcohol is a colourless powder of the composition $C_4SH_2{:}Hg_2Cl_2$; it is insoluble in all neutral solvents, is not acted on by alkalis, and is only slowly decomposed even by concentrated nitric acid.

When thiophen mercuric chloride, $C_4SH_3\cdot HgCl$, is boiled for some time with acetic chloride, it yields acetothienone, or thienyl methyl ketone, C_4SH_3Ac, identical with the compound previously described by Peter (Abstr., 1885, 141); the yield is 77 per cent. of the theoretical. When treated with benzoic chloride in like manner, it gives

phenyl thienyl ketone (m. p. 56°), identical with the compound prepared by Comey (Abstr., 1884, 1168). It is also readily acted on by iodine in presence of warm water, being converted into diiodothiophen (m. p. 40°).

α-Methylthiophen mercuric chloride, $C_5SH_5{\cdot}HgCl$, is formed, practically as sole product, when α-methylthiophen is shaken with an aqueous solution of mercuric chloride and sodium acetate; it crystallises from boiling alcohol in short, transparent needles, melts at 197°, and is insoluble in water and ether. When warmed with benzoic chloride for a long time, it yields phenyl thiotolyl ketone, a compound which has been previously described by Ernst (Abstr., 1887, 238) as an oil, but which the author obtained in lustrous needles melting at 124°.

β-Thiotolene mercuric chloride, $C_5SH_5{\cdot}HgCl$, prepared from thiotolene in like manner, crystallises from hot alcohol in slender, lustrous needles. The *dimercuric chloride*, $C_5SH_4{:}Hg_2Cl_2$, is a colourless, granular powder, insoluble in all neutral solvents, and only slowly acted on even by concentrated nitric acid.

β-Isopropylthiophen mercuric chloride, $C_7SH_9{\cdot}HgCl$, crystallises from hot alcohol in long, colourless needles, melts at 137°, and is soluble in ether, but insoluble in water; the *dimercuric chloride*, $C_7SH_8{:}Hg_2Cl_2$, is a colourless, granular compound, insoluble in all neutral solvents, and only slowly decomposed by concentrated nitric acid.

Acetothienone combines with mercuric chloride under the conditions already described yielding a compound of the composition $C_6H_6OS,HgCl_2$; this substance crystallises in long, colourless needles, melts at 68°, and is soluble in ether. Acetophenone, under the same conditions, gives a compound of the composition $C_8H_8O,HgCl_2$, which crystallises in large, colourless needles, melts at 59°, and is soluble in water, ether, and alcohol. The compound obtained with benzophenone crystallises in long, colourless needles, melts at 81°, and is readily soluble in water, alcohol, and ether; it has the composition $C_{13}H_{10}O,HgCl_2$. All these additive compounds are very readily decomposed, and on exposure to the air, the ketone contained in them gradually volatilises. F. S. K.

β-Ethylthiophen and Thiophen-αβ-dicarboxylic Acid. By M. Gerlach (*Annalen*, **267**, 145—172).—β-Ethylthiophen, $\begin{matrix}CEt{:}CH\\ |\\ CH{:}CH\end{matrix}\!>\!S$, was prepared by distilling a mixture of anhydrous sodium ethylsuccinate and phosphorus trisulphide (compare Damsky, Abstr., 1887, 237). It is a colourless, mobile, highly refractive liquid of sp. gr. 1·0012 at 16°; it boils at 135—136°, has an odour like that of benzene, and is miscible with alcohol, ether, benzene, light petroleum, and chloroform, but insoluble in water. It burns with a very smoky flame, gives a greenish-blue coloration with sulphuric acid and isatin, and is gradually decomposed by concentrated sulphuric acid at the ordinary temperature; it is decomposed by hot dilute nitric acid, and with very concentrated acid an explosively violent reaction takes place. The *bromo*-derivative, C_6H_7BrS, is obtained when the

theoretical quantity of bromine is gradually added to water containing ethylthiophen in suspension; it is a colourless liquid, boils at 180—190°, and dissolves freely in alcohol, ether, chloroform, and light petroleum. The *dibromo*-derivative, $C_6H_6Br_2S$, prepared in like manner, is a yellow oil boiling at 215—225°. The *tribromo*-derivative, $C_6H_5Br_3S$, is formed when ethylthiophen is treated with three times the theoretical quantity of bromine at the ordinary temperature; it is a heavy, yellow oil, boils at 272—280°, and is only slightly volatile with steam. The *pentabromo*-derivative, $C_5H_3Br_5S$, can be obtained by treating ethylthiophen with bromine at 100°; it crystallises from alcohol in yellowish, lustrous needles, melts at 86°, and is insoluble in water, and only sparingly soluble in cold alcohol, but more readily in hot alcohol, ether, chloroform, and light petroleum.

Acetyl-β-ethylthiophen, $\begin{matrix}CEt:CAc\\ |\\ CH:CH\end{matrix}\!\!>S$, prepared by treating a solution of ethylthiophen in light petroleum with acetic chloride and aluminium chloride, is a colourless liquid, boils at 227°, is volatile with steam, and darkens in colour on exposure to the air; on oxidation with potassium permanganate in well-cooled alkaline solution, it yields only very small quantities of a dicarboxylic acid. Its *oxime*, $C_8H_{11}NOS$, separates from alcohol in lustrous, prismatic crystals, melts at 56°, and is readily soluble in alcohol, ether, light petroleum, chloroform, and benzene, but insoluble in water.

When acetyl-β-methylthiophen (b. p. 218°), prepared by the method described by Demuth (Abstr., 1886, 228), is oxidised with potassium permanganate in alkaline solution, it is converted into β-methylthiophencarboxylic acid and αβ-thiophendicarboxylic acid; the mixture of the two acids is treated with sufficient soda to convert the dicarboxylic acid into its sodium hydrogen salt, and the monocarboxylic acid is then extracted with ether.

β-Methylthiophen-α-carboxylic acid melts at 140°; Demuth (*loc. cit.*) gives 144° as the melting point of this compound. The *silver* salt, $C_6H_5AgO_2S$, separates from hot water in small, colourless, lustrous crystals. The *lead* salt, $(C_6H_5O_2S)_2Pb$, is a colourless powder.

αβ-Thiophendicarboxylic acid, $C_6H_4O_4S$, crystallises from water in long, colourless, lustrous needles, melts at 270° with decomposition, and is only sparingly soluble in cold water, but very readily in ether; it is identical with the acid prepared by Grünewald (Abstr., 1888, 48) by the oxidation of αβ-dimethylthiophen. The *sodium hydrogen* salt, $C_6H_3O_4SNa + 3H_2O$, separates from water in colourless, star-like forms.

Dibromo-β-methylthiophen, $C_5H_4Br_2S$, prepared as described in the case of the corresponding β-ethyl derivative, is a heavy, yellow oil boiling at 220—230°.

Bromacetyl-β-methylthiophen, C_7H_7OBrS, is formed when a light petroleum solution of the dibromo-derivative is treated with acetic chloride (2 mols.) and aluminium chloride; in this reaction some of the acetic chloride seems to be converted into bromacetic chloride. It is a yellow liquid, darkens in colour on exposure to the air, and is readily soluble in alcohol and ether. Its *oxime*, C_7H_8NOBrS, forms

yellowish crystals, melts at 105°, and is readily soluble in alcohol and ether, but only sparingly in light petroleum, and insoluble in water.

Bromothiophendicarboxylic acid, $C_6H_3O_4BrS$, is obtained when the preceding compound is oxidised with an alkaline solution of potassium permanganate. It separates from hot water in colourless, microscopic, hair-like crystals, sinters together and decomposes at 240°, and is only sparingly soluble in boiling water; when heated with resorcinol, it gives a brown mass, the solution of which in soda is yellowish-red, and shows a green fluorescence. The *lead* salt, C_6HBrO_4SPb, is a colourless powder, insoluble in water. The *silver* salt, $C_6HBrO_4SAg_2$, is very sparingly soluble in water. F. S. K.

Nitrogenous Derivatives of Thiophen and Furfuran. By P. Douglas (*Ber.*, **25**, 1311—1314).—*Thiophen nitrile*, $C_4SH_3{\cdot}CN$, is obtained when crude thiënylglyoxylic acid is boiled with an excess of a concentrated solution of hydroxylamine hydrochloride; it boils at 192°, and is converted into ethoximidothiophen hydrochloride when dry hydrogen chloride is passed through its alcoholic solution.

Ethylthiophenhydroximic acid is produced when ethoximidothiophen is heated with $1\frac{1}{2}$ times its weight of hydroxylamine hydrochloride in aqueous alcoholic solution; when crystallised from water, it melts at 67°, and appears to exist in one modification only, which is probably the anti-compound, $C_4SH_3{\cdot}\overset{\displaystyle N{\cdot}OH}{\overset{\|}{C}}OEt$.

Furfuronitrile, $C_4OH_3{\cdot}CN$, is formed when furfuraldehyde is gently heated with neutral hydroxylamine solution, and the crystalline product obtained by extraction with ether is warmed with acetic anhydride, neutralised, and driven over with steam; it boils at 147° as stated by Wallach (Abstr., 1881, 715).

When the last compound is dissolved in alcohol, and the cooled solution treated cautiously with dry hydrogen chloride, the residue remaining, after treatment with aqueous sodium carbonate, yields on crystallisation from alcohol a white compound which is perhaps ethoximidofurfuran.

Thiopyromucamide, $C_4OH_3{\cdot}CS{\cdot}NH_2$, is produced when furfuronitrile is dissolved in an equal quantity of alcohol and twice its volume of dry ether, and dry hydrogen sulphide passed through. On gently heating, and adding 25 per cent. ammonia, yellowish crystals separate; the pure compound melts at 127°, and is only slightly soluble in cold water, but readily so in alcohol. Furfuronitrile gives with hydroxylamine a crystalline amidoxime melting at about 70°. A. R. L.

Silver Phenylacetylide. By C. Liebermann and F. Damerow (*Ber.*, **25**, 1096—1098).—It is shown that the formula $2(CPh{:}CAg) + Ag_2O$ for this substance given in the text-books is based on an error in Glaser's calculations. Properly calculated, his analytical data correspond with the formula $CPh{:}CAg$. Reason is also given for supposing that silver and copper acetylides have respectively the constitution C_2Ag_2 and C_2Cu_2, the low results obtained on analysing these compounds being due to the presence of moisture.

A compound of silver phenylacetylide with silver nitrate, $CPh{:}CAg + AgNO_3$, was prepared by adding an alcoholic solution of silver nitrate to an alcoholic solution of phenylacetylene. At first an amorphous precipitate of Glaser's silver phenylacetylide is formed, but this soon changes into pretty, white needles of the silver nitrate compound. This substance was thus obtained in a neutral solution, whereas Glaser obtained silver phenylacetylide in an ammoniacal solution. The silver nitrate compound is actually decomposed by ammonia into silver nitrate and silver phenylacetylide.

C. F. B.

Aromatic Isocyanates. By L. Gattermann and A. Cantzler (*Ber.*, **25**, 1086—1091; compare Abstr., 1890, 970).—When a concentrated aqueous solution of potassium cyanate, and then finely-divided copper, are added to a solution of diazotised aniline, phenyl cyanate is formed, but only in small quantity; it may be extracted with chloroform. Orthotolyl cyanate, boiling at 184—187°, can be made in the same way, and the yield is much better. It reacts like phenyl cyanate, yielding di-substituted carbamides with aniline, toluidine, &c.; whilst if warmed with orthocresol, it yields *orthotolyl orthotolylcarbamate*, $C_6H_4Me{\cdot}NH{\cdot}COO{\cdot}C_6H_4Me$, which crystallises from acetic acid in colourless needles, melts at 126°, and is decomposed into its constituents when heated. Heated at 160° with β-naphthol in a sealed tube, orthotolyl cyanate yields *β-naphthyl orthotolylcarbamate*, $C_6H_4Me{\cdot}NH{\cdot}COO{\cdot}C_{10}H_7$, which crystallises from acetic acid in colourless plates melting at 149°. Heated on the water-bath with benzyl alcohol, orthotolyl cyanate yields *benzyl orthotolylcarbamate*, $C_6H_4Me{\cdot}NH{\cdot}COO{\cdot}CH_2Ph$, which crystallises from light petroleum in colourless needles, and melts at 83—84°. Heated with resorcinol at 120°, *metaphenylene orthotolylcarbamate*, $(C_6H_4Me{\cdot}NH{\cdot}COO)_2C_6H_4$, is formed; this crystallises from alcohol in colourless plates melting at 153—154°. Heated with quinol at 150°, *β-phenylene orthotolylcarbamate*, $(C_6H_4Me{\cdot}NH{\cdot}COO)_2C_6H_4$, is formed; it crystallises from acetic acid in long needles melting at 206·5°. Heated at 125° with benzoïn, a substance $C_6H_4Me{\cdot}NH{\cdot}COO{\cdot}CHPh{\cdot}COPh$ is obtained which crystallises from dilute alcohol in colourless prisms melting at 125°, and is decomposed by heat into its constituents. Heated at 125° with benzamide, *benzoylorthotolylcarbamide*, $C_6H_4Me{\cdot}NH{\cdot}CO{\cdot}NHBz$, is formed; it crystallises from acetic acid in long needles melting at 210°.

Metatolyl cyanate, boiling at 195—198°, can be obtained in the same way as the ortho-compound, but the yield is smaller. With metatoluidine, it yields *dimetatolylcarbamide*, $CO(NH{\cdot}C_6H_4Me)_2$, melting at 203°, and crystallising from acetic acid in colourless needles.

Metaxylyl cyanate, boiling at 205°, was prepared in a similar manner from symmetrical metaxylidine [1 : 3 : 5]. With xylidine, it yields *dixylylcarbamide*, $CO(NH{\cdot}C_6H_3Me_2)_2$, melting at 250—251°, and crystallising from acetic acid in long, colourless needles.

Pseudocumyl cyanate, boiling at 225—230°, yields, with pseudocumidine, *dipseudocumylcarbamide*, $CO(NH{\cdot}C_6H_2Me_3)_2$, melting at 274°.

Parabromophenyl cyanate, boiling at 215—220°, can be obtained from parabromaniline, but the yield is small. With aniline, it yields *bromodiphenylcarbamide*, $NHPh{\cdot}CO{\cdot}NH{\cdot}C_6H_4Br$, crystallising from acetic acid in silvery plates which begin to sublime at 180°.

When diazotised metanitroparatoluidine reacts with potassium cyanate and copper powder, an oil is formed which explodes when distilled. It is, doubtless, nitrotolyl cyanate, for with nitrotoluidine it yields dinitrotolylcarbamide melting at 235°.

Parethoxyphenyl cyanate, boiling at 230—235°, is obtained from paraphenetidine, and unites with it to form *diethoxydiphenylcarbamide*, $CO(NH{\cdot}C_6H_4{\cdot}OEt)_2$, which crystallises from acetic acid in long needles melting at 225—226°. The substance described as this cyanate by Köhler (Abstr., 1884, 1159) was probably not a cyanate at all, and was possibly the carbamide.

The method of obtaining cyanates from the diazotised amine, potassium cyanate, and copper powder does not give a yield of more than 20—30 per cent. of the theoretical, except in the case of orthotolyl compounds, when the yield is much greater. C. F. B.

Composition of Betel Oil. By Schimmel (*Chem. Centr.*, 1892, i, 92; from *Schweiz. Wochenschr. Pharm.*, **29**, 402—403).—The oil has a golden-yellow colour and the peculiar odour of betelphenol (Abstr., 1889, 863), and has a density of 1·044 at 15°. The phenol boils at 128—129° under a pressure of 11 mm. The oil, as obtained from different sources, has been found to contain betelphenol in every case, and, in addition, that from Java contained terpenes and chavicol, that from the dried leaf from Siam, a sesquiterpene, whilst that from Manilla contained no other phenol. J. W. L.

Quinitol, the Simplest Sugar of the Inositol Group. By A. v. Baeyer (*Ber.*, **25**, 1036—1040).—Paradiketohexamethylene can be easily prepared in almost any quantity by hydrolysing ethyl succinosuccinate with dilute sulphuric acid; on reduction with sodium amalgam in carbonic acid solution, it is converted into a glycol, which seems to consist of the two theoretically possible geometric forms. The more sparingly soluble portion of this glycol gives a crystalline diacetyl derivative, $OAc{\cdot}CH<\begin{matrix}CH_2{\cdot}CH_2\\CH_2{\cdot}CH_2\end{matrix}>CH{\cdot}OAc$, melting at 105—106°, from which, by hydrolysing with barium hydroxide, the glycol can be obtained in a pure condition. The compound prepared in this way is probably *cistransparadihydroxyhexamethylene*, and in its appearance and behaviour it resembles a sugar of the mannitol group; its solution is stable towards potassium permanganate in the cold, and does not reduce Fehling's solution even on warming; it crystallises from alcohol in crusts, melts at 143—145°, sublimes and distils without decomposition, and is readily soluble in alcohol and water. The taste of the solid glycol is sweet at first, afterwards bitter; when warmed with potassium dichromate and sulphuric acid, it yields quinone. The author names the compound *quinitol*.

Phloroglucinol is reduced by sodium amalgam, although more slowly than paradiketohexamethylene.

When quinitol is warmed with concentrated hydrobromic or hydriodic acid, it is converted into a crystalline bromide, or iodide, which, on treatment with alcoholic potash, yields a peculiarly-smelling hydrocarbon—in all probability dihydrobenzene—and, on boiling with dilute sulphuric acid, gives a substance having an odour recalling that of oil of turpentine; by the reduction of these halogen compounds, hexamethylene will doubtless be obtained. From the chlorhydrin, or from the hydroxyketone formed as an intermediate product in the reduction of the diketone, it will doubtless be possible to prepare hydroxy- and keto-hexamethylene, compounds corresponding with menthol and menthone, and tetrahydrobenzene, the parent substance of menthene, is also attainable in this way.

Of particular interest, because of their relationship to the terpenes, are the paralkyl derivatives of quinitol, which can, no doubt, be obtained without much difficulty; it is only necessary to prepare ethyl dimethylsuccinosuccinate from ethyl glutarate, in order to obtain dimethylquinitol. From a mixture of ethyl methylsuccinate and ethyl isopropylsuccinate, it will, presumably, be possible to prepare ethyl methylisopropylsuccinosuccinate, and from the latter, methylisopropylquinitol and dihydrocymene.

The nitrile of dihydroterephthalic acid has been prepared from the additive product of the diketone and hydrogen cyanide; it is decomposed by alcoholic potash, yielding benzonitrile and hydrogen cyanide, just as pinylamine gives cymene and ammonia.

Experiments are in progress with the object of preparing all the theoretically possible paradialkyldihydrobenzene derivatives. The methyl ketone of terephthalic acid (paracetylacetophenone), for example, can be easily obtained from the product of the interaction of terephthalic chloride and ethyl sodiomalonate, and this compound must, on reduction, yield paradiethylbenzene; it may be presumed, therefore, that, starting from the five isomeric dihydroterephthalic acids, the five theoretically possible paradiethyldihydrobenzenes can be prepared in like manner.

The hexahydroisophthalic acid, prepared by reducing isophthalic acid, is identical with the compound obtained by Perkin (Trans., 1891, 798) from ethyl pentantetracarboxylate. F. S. K.

Decomposition Products of Anilic Acid. By A. Hantzsch (*Ber.*, **25**, 827—841).—This paper is an answer to Nef's criticisms on the author's work, and contains a theoretical consideration of the experiments described in the following paper. The electrical conductivity of some of the compounds prepared is also given. E. C. R.

Action of Halogens on Chloranilic and Bromanilic Acids. By H. Landolt, Jun. (*Ber.*, **25**, 842—859).—The silver salt of chloranilic acid, when treated with chlorine in the absence of water, yields tetrachlorotetraketohexamethylene; treated with aqueous hypochlorous acid, it yields trichlorotetraketohexamethylene. The tetrachlorketone yields with alkali, tetrachlorodiketopentamethylenehydroxycarboxylic acid; the trichlorketone yields trichlorodiketopentamethylenehydroxycarboxylic acid. The latter is also formed by the

action of sodium hypochlorite (1 mol.) on chloranilic acid; the former from sodium hypochlorite (2 mols.) and chloranilic acid. The trichlorinated acid is converted by salts of hypochlorous acid into tetrachlorodiketopentamethylenehydroxycarboxylic acid, and by chlorine into trichlorotriketopentamethylene, which is also obtained by the direct action of chlorine on chloranilic acid in aqueous solution.

The action of bromine on bromanilic acid is somewhat different. The compounds obtained are less stable, and the brominated hydroxycarboxylic acids of pentamethylene are not stable, but split up into carbonic anhydride, hydrogen bromide, and the brominated ketone of the pentamethylene ring. Instead of tetrabromodiketopentamethylenehydroxycarboxylic acid, there is formed tribromotriketopentamethylene, and, instead of tribromodiketopentamethylenehydroxycarboxylic acid, there is formed dibromotriketopentamethylene. Silver bromanilate, in the absence of water, yields tetrabromotetraketohexamethylene; in the presence of water, it yields tribromotetraketohexamethylene. From the tetrabromotetraketone, there is formed tribromotriketopentamethylene, and from the tribromotetraketone, there is formed dibromotriketopentamethylene. Tribromotriketopentamethylene is also formed by the direct action of bromine on bromanilic acid, and from dibromotriketopentamethylene by the action of bromine-water.

Trichlorotetraketohexamethylene hydrate, $C(OH)_2<\begin{matrix}C(OH):CCl\\CCl_2 - CO\end{matrix}>CO$ or $C(OH)_2<\begin{matrix}CO\cdot CHCl\\CCl_2-CO\end{matrix}>CO$, is obtained by treating chloranilic acid with an aqueous solution of hypochlorous acid. The aqueous solution is extracted with ether, the ethereal extract dried with anhydrous copper sulphate, evaporated in a vacuum, and the residue washed with benzene and crystallised from a mixture of benzene and ether. It is easily soluble in ether and alcohol, somewhat easily so in water, melts at 158° with decomposition, is acid to litmus, and is insoluble in concentrated sulphuric acid. When reduced by warming with sulphurous acid or sodium thiosulphate, it is converted into chloranilic acid. The *azine*, $C_6(OH)_3Cl_3{:}N_2{:}C_6H_4$, is obtained as a metallic, orange precipitate, by adding orthophenylenediamine hydrochloride to a dilute solution of the trichlorketone. It quickly turns red in the air, and melts at 117°.

Trichlorodiketopentamethylenehydroxycarboxylic acid is obtained by treating the above trichlorketone with cold concentrated sodium carbonate, and, after some time, acidifying with sulphuric acid, and extracting with ether. It melts at 170°, and contains ether of crystallisation. It may also be obtained from the trichlorketone by the action of dilute sodium hydroxide or ammonia. When treated with hypochlorous acid (1 mol.), it is converted into trichlorotriketopentamethylene, which, on treatment with alcoholic ammonia, yields a characteristic ammonium salt melting at 207°.

Trichlorotriketopentamethylene is also obtained by the action of chlorine-water on chloranilic acid, and, in small quantities, by the action of 1 mol. of hypochlorous acid. It is the final product of the action of chlorine or hypochlorous acid on chloranilic acid in the

absence of alkali. When treated with twice the theoretical quantity of phenylhydrazine acetate, it yields a *trihydrazine*,

$$C_5H_2Cl_2(N_2HPh)_3 + 2H_2O,$$

with evolution of hydrogen chloride.

Tetrachlorotetraketohexamethylene, $CCl_2<^{CO\cdot CO}_{CO\cdot CO}>CCl_2$, is obtained by the action of dry chlorine on silver chloranilate suspended in carbon bisulphide. It melts about 60°, and is easily decomposed by water, yielding carbonic anhydride, hydrogen chloride, and trichlorotriketopentamethylene. When the freshly-prepared tetrachlorotetraketone is treated with cold concentrated soda, it yields a colourless solution, from which, by acidifying and extracting with ether, the hydrate of *tetrachlorodiketopentamethylenehydroxycarboxylic acid* is obtained. The latter crystallises in beautiful, white needles, melts at 217°, and yields an ammonium salt melting at 145°.

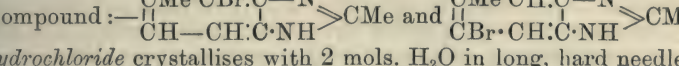
Tribromotetraketohexamethylene is obtained by the action of bromine vapour on an aqueous solution of the acid sodium salt of bromanilic acid. It is separated by acidifying with sulphuric acid and extracting with ether, and is identical with the substance formerly described by Hantzsch as bromanilic acid bromide (*Ber.*, **21**, 2438). It is very easily converted into equivalent quantities of bromanilic acid and tribromotriketopentamethylene. With excess of bromine, it yields tribromotriketopentamethylene, and with sulphurous acid it gives a quantitative yield of bromanilic acid. The *azine*, $OH\cdot C_6Br_2O\cdot N_2\cdot C_6H_4$, is obtained as a reddish-brown precipitate on adding phenylenediamine hydrochloride and sodium acetate to a concentrated aqueous solution of the tribromide. The *hydrazone*, $C_6OBr_2(N_2HPh)_3 + 2H_2O$, is obtained as an amorphous, brownish-red precipitate.

Dibromotriketopentamethylene hydrate is obtained by dissolving tribromotetraketohexamethylene in soda, acidifying with sulphuric acid, and extracting with ether. It crystallises with $\frac{1}{2}$ mol. of ether in beautiful prisms; when exposed to the air, it loses its ether and forms a colourless oil, which cannot be obtained crystalline except from ether. It has an acid reaction, but easily loses hydrogen bromide in aqueous or alkaline solution. When treated with excess of hypochlorous acid in the presence of hydrochloric acid for some hours at the ordinary temperature, it yields dichlorobromacetone, $CO(CCl_2Br)_2$ (m. p. 53°), and oxalic acid.

Tribromotriketopentamethylene is obtained by adding an excess of bromine to an aqueous solution of dibromotriketopentamethylene, then at once adding sulphurous acid until the mixture is colourless and extracting with ether. It melts at 189°, yields an ammonium salt melting at 183°, and can be sublimed undecomposed by careful heating. With phenylhydrazine, it yields a compound of the formula $C_5H_2Br_2(N_2HPh)_3 + 2H_2O$.

If an excess of bromine is allowed to act for some time on dibromotriketopentamethylene, perbromacetone, $CO(CBr_3)_2$, and oxalic acid are formed.

Tribromotriketopentamethylene is also formed by treating tetrabromotetraketohexamethylene with well-cooled soda solution.



E. C. R.

Preparation of Orthonitraniline. By C. Turner (*Ber.*, **25**, 985—987).—Orthonitraniline may be readily prepared according to the following method:—50 grams of acetanilide is heated on the water-bath with 150 grams of fuming sulphuric acid containing 20 per cent. of SO_3 until the whole is soluble in alkalis, 100 grams of concentrated sulphuric acid added to the cooled mixture, and afterwards the theoretical quantity of nitric acid mixed with an equal volume of sulphuric acid, the temperature not being allowed to rise above 0°. After nitration, 140 c.c. of water is added, so that a sulphuric acid of about 67 per cent. strength is formed, and the whole heated to the boiling point; the boiling is continued for half an hour after complete solution has taken place, and the nitraniline separated from the cooled liquid by fractional precipitation with water. The first portions are somewhat impure, but the subsequent fractions are sufficiently pure for most purposes; they may, however, be further purified by recrystallisation or distillation in a current of superheated steam. The yield is about 70 per cent. of the theoretical.

Orthonitraniline is not affected by boiling with ammonium sulphide for several hours, but is readily reduced by tin and hydrochloric acid; from the product, orthodiamidobenzene may be isolated in the usual manner. H. G. C.

Anhydro-compounds. By S. Niementowski (*Ber.*, **25**, 860—875).—Ethenyldiamidotoluene is best prepared by reducing metanitroparacetotoluidide with the theoretical quantity of tin and hydrochloric acid (1 concentrated acid to 1 water); the tin is precipitated with hydrogen sulphide, the filtrate evaporated, and the hydrochloride of the base decomposed with ammonia or soda. It crystallises from dilute spirit, and melts at 203°.

Bromethenyldiamidotoluene is obtained by brominating ethenyldiamidotoluene dissolved in acetic acid or carbon bisulphide and decomposing with alkali the hydrobromide thus obtained. It crystallises from dilute spirit in white needles, melts at 216°, is easily soluble in alcohol and acetone, less so in ethyl acetate, sparingly in benzene and chloroform, and almost insoluble in hot water and carbon bisulphide. It is not attacked by potassium hydroxide, sodium and amyl alcohol, or tin and hydrochloric acid. Its alcoholic solution, when boiled with silver nitrate, gives no precipitate of silver bromide. The author puts forward the following formulæ for this compound:—

The *hydrochloride* crystallises with 2 mols. H_2O in long, hard needles, and has no sharp melting point. The *hydrobromide* is similar to the hydrochloride, but is less soluble. The *nitrate* crystallises without water, and decomposes at 228°.

Nitrobromethenyldiamidotoluene is obtained by gradually adding bromethenyldiamidotoluene (12 grams) to fuming nitric acid (50 grams sp. gr. = 1·53); the mixture is boiled for 20 minutes, poured into 15 times the quantity of water, and the nitrate thus obtained hydrolysed with potash. It crystallises from alcohol in yellow needles, melts at 219°, is soluble in ethyl acetate, alcohol, chloroform,

and acetone, less so in boiling benzene and ether, and only very sparingly soluble in boiling water. The *nitrate* melts at 207°, and crystallises in white needles. The *hydrochloride* and *sulphate* are also crystalline.

Metabromorthoacetotoluidide is best prepared by passing a current of air saturated with bromine vapour through a solution of acetotoluidide. (200 grams) in glacial acetic acid (1300 grams) until the solution solidifies. It is obtained pure after one crystallisation from alcohol, and melts at 156—157°. The acetic acid mother liquors contain metabromorthotoluidine hydrobromide. The latter blackens at 260°, decomposes at 280°, and is easily hydrolysed by cold potash.

Metanitrometabromorthoacetotoluidide [Me : NHAc : NO_2 : Br = 1 : 2 : 3 : 5] is obtained by adding finely powdered bromacetotoluidide to four times its weight of nitric acid (1·48), taking care that the temperature does not rise above 25°. After an hour, the product is poured into water, washed, dried, and crystallised from acetic acid. It forms yellowish-white needles, melts at 205°, is soluble in acetic acid, alcohol, acetone, and chloroform, and sparingly so in benzene or hot water. On hydrolysis with potash, it yields nitrobromotoluidine, which may be purified by steam distillation, forms orange-yellow leaflets or needles, and melts at 145°.

Dinitrometabromorthoacetotoluidide is obtained by adding finely-powdered bromacetotoluidide (1 part) to a mixture of sodium nitrate (1 part) and concentrated sulphuric acid (20 parts), and allowing the mixture to remain some time at the ordinary temperature. It crystallises in slender, white needles, melts at 244° with frothing, and is soluble in boiling alcohol, acetic acid, acetone, and ethyl acetate, sparingly so in benzene, toluene, and chloroform, and almost insoluble in water.

Metabromisoethenyldiamidotoluene, $C_6H_2MeBr<\overset{NH}{\underset{N}{>}}CMe$, is obtained, together with *metabromoxyisoethenyldiamidotoluene*,

$$C_6H_2MeBr<\overset{NH\cdot CMe}{\underset{N}{\quad}}>O,$$

by the reduction of metabromometanitrorthoacetotoluidide with tin and hydrochloric acid. The hydrochloride of bromoxyisoethenyldiamidotoluene crystallises out in long, white needles, whilst the stannochloride of bromisoethenyldiamidotoluene remains in solution. The latter is decomposed by hydrogen sulphide, and the hydrochloride thus obtained is hydrolysed by suspending it in absolute alcohol, and adding sodium or solid potassium hydroxide.

Bromisoethenyldiamidotoluene melts at 244—246°, crystallises in well-formed, colourless tablets, and is sparingly soluble in organic solvents, and very sparingly so in water. The *hydrochloride* crystallises with 1 mol. of water in needles. The *nitrate* crystallises in slender, white needles, and melts at 217—219° with decomposition.

Metacetotoluidide is nitrated much less readily than its isomeride. The product consists of orthonitrometacetotoluidide (m. p. 102°), a large quantity of oily products, and orthonitrometacresol (m. p. 56°).

E. C. R.

Synthesis of Dehydrothiotoluidine. By L. Gattermann and O. Neuberg (*Ber.*, **25**, 1081—1085).—*Paranitrobenzotoluidide*, $NO_2{\cdot}C_6H_4{\cdot}CO{\cdot}NH{\cdot}C_6H_4Me$, was obtained by mixing ethereal solutions of paranitrobenzoic chloride and paratoluidine. It crystallises from alcohol in yellowish needles melting at 197°. When gently warmed with phosphoric chloride, it yields an *amide chloride*,

$$NO_2{\cdot}C_6H_4{\cdot}CCl_2{\cdot}NH{\cdot}C_6H_4Me,$$

which crystallises from ether in large, golden needles, melts at 119°, and decomposes in moist air. When a benzene solution of this substance is treated with dry hydrogen sulphide, or an ethereal solution with alcoholic sodium sulphide, and finally acidified, small quantities of *thionitrobenzotoluidide* are formed, and when this substance is allowed to remain with alkaline potassium ferricyanide, it is oxidised to a compound which crystallises from acetic acid in yellowish-red needles, and is reduced by tin or stannous chloride and hydrochloric acid to dehydrothiotoluidine. A slight variation of this method was attained by converting the amide chloride into an amidine, and this, by the action of carbon bisulphide into the thioamide. The amide chloride, when heated with aniline at 150°, yields an amidine, $NO_2{\cdot}C_6H_4{\cdot}C(NPh){\cdot}NH{\cdot}C_6H_4Me$, which crystallises from alcohol in colourless needles, melting at 260°. With paratoluidine, it yields the amidine $NO_2{\cdot}C_6H_4{\cdot}C(N{\cdot}C_6H_4Me){\cdot}NH{\cdot}C_6H_4Me$, which crystallises from alcohol in lustrous crystals melting at 300° with decomposition, and very sparingly soluble in most solvents. When heated with carbon bisulphide at 200°, it yields the thioamide, and this, as described above, can be converted into dehydrothiotoluidine.

The constitution previously assigned (Abstr., 1889, 867) to dehydrothiotoluidine is thus confirmed. C. F. B.

Reduction Products of Azo-compounds. By P. Jacobsen and W. Fischer (*Ber.*, **25**, 992—1012).—In view of the discussion now being carried on as to whether the compounds obtained by the action of diazobenzene chloride on phenols are to be regarded as hydroxyazo-compounds or as quinonehydrazones (compare Abstr., 1890, 614; 1891, 1209), the authors examined the action of reducing agents on an ether of the simplest of such compounds, namely, the ethyl ether of parahydroxyazobenzene, the two possible formulæ of which are as follows:—

$$EtO{\cdot}C_6H_4{\cdot}N{:}N{\cdot}C_6H_5, \qquad O{:}C_6H_4{:}N{\cdot}NH{\cdot}C_6H_5.$$

They have been able to show that aniline and paraphenetidine are among the products of reduction, thus proving the first formula to be correct; these, however, only form a small portion of the products of the reaction, two other substances being obtained, the examination of which has led to very interesting results.

Parethoxyazobenzene was prepared by dissolving hydroxyazobenzene and the requisite quantity of sodium in alcohol, boiling with ethyl bromide for three hours, and subsequently adding a little more sodium and ethyl bromide, and boiling again for two hours; it separates out on pouring the liquid into water, and, after recrystal-

lisation from alcohol, melts at 77—78°, as given also by Bohn (*Inaug. Diss., Zürich*, 1883). The reduction was carried out with stannous chloride and hydrochloric acid; a resinous stannochloride quickly separates out, more of which may be obtained by the addition of small quantities of water, and if the mother liquors are allowed to remain for some time, another stannochloride separates as a thick, white, crystalline precipitate; the filtrate from this salt contains the aniline and paraphenetidine, which were isolated and identified by their boiling points and conversion into their acetyl derivatives.

The two stannochlorides may be converted into the corresponding bases in the usual manner; the first has the composition $C_{14}H_{16}N_2O$, crystallises from dilute alcohol in long, pale-violet needles, and melts after repeated crystallisation at 95°; the second is isomeric with the first, and will be described later, the first-named base only being discussed in the present paper. This had been previously prepared by the action of ammonium sulphide on parethoxyazobenzene by Bohn (*loc. cit.*), who regarded it as a diphenyl derivative obtained by the usual intramolecular change from the hydrazo-compound first formed; Nölting and Werner take the same view (Abstr., 1891, 211), and the authors at first adopted the same supposition, according to which it would be an ethoxydiphenylene, $C_{12}H_7(NH_2)_2{\cdot}OEt$ [OEt : $(NH_2)_2$ = 3 : 6 : 4′]. They therefore endeavoured to convert it into the corresponding dihydroxy-derivative by the action of nitrous acid and subsequent treatment with water, but, instead of the diazo-compounds, they obtained an azimido-derivative, which, after purification, forms colourless crystals having the composition $C_{14}H_{13}N_3O$ and melting at 107—108°; it has feebly basic properties, is readily soluble in alcohol, ether, and benzene, less readily in light petroleum, and crystallises from acetic acid in lustrous, rectangular tablets. The formation of this compound shows that the above constitution of the base cannot be correct, but that it behaves in a manner similar to the orthodiamido-compounds. This is confirmed by the action of formic acid and acetic anhydride, which yield the *methenyl* and *ethenyl* derivatives characteristic of orthodiamido-compounds; the former, $C_{15}H_{14}N_2O$, forms colourless, compact crystals, melts at 77—78°, and yields a crystalline nitrate, and the latter, $C_{16}H_{16}N_2O$, is an oil, but also yields a crystalline nitrate. The base further combines with carbon bisulphide, forming a well crystallised derivative, $C_{14}H_{14}\ll^{N}_{N}>CS$, or $C_{14}H_{13}\ll^{N}_{N}>C{\cdot}SH$, which separates from alcohol in silky, asbestos-like needles, and melts at 229°.

The formation of these anhydro-compounds may be explained on the supposition that the base is an orthodiamido-compound, or that it is a peridiamidodiphenyl derivative, which might, like diphenic acid (in which the carboxyl groups occupy the peri-position), yield anhydro-derivatives. Peridiamidodiphenyl itself has, however, been prepared by Täuber (Abstr., 1891, 570), and behaves towards nitrous acid and acetic anhydride in the usual manner, yielding diazo- and acetyl compounds and not anhydro-derivatives; the supposition that

in Bohn's base the amido-groups occupy the peri-position is therefore very improbable. It has been shown to be impossible in the following manner:—If the base consists of a diamidodiphenyl, $OEt\cdot C_{12}H_7(NH_2)_2$, it must yield an azimido-compound, and have one of the two following formulæ:—

$$OEt\cdot C_{12}H_7<\begin{matrix}NH\\ -N\end{matrix}>N, \qquad OEt\cdot C_{12}H_7<\begin{matrix}N\\ |\\ N\end{matrix}>NH;$$

in either case the compound would contain a replaceable hydrogen atom, but all attempts to replace it by a methyl or acetyl group have been without success. With methyl iodide, it combines to form a quaternary compound, $C_{14}H_{13}N_3O,CH_3I$, which yields a caustic hydroxide, and on heating at 190°, splits up into methyl iodide and the original azimide, and not its methyl derivative. The azimide can therefore contain no replaceable hydrogen, and must be a tertiary compound containing the group:—

$$\begin{matrix}-NR\\ -N\end{matrix}>N,$$

and the base from which it is formed must contain one imido- and one amido-group.

The formation of a compound containing these two groups from a hydrazo-compound may be imagined as taking place in the following manner:—In the formation of benzidine from hydrazobenzene, a hydrogen atom from each benzene nucleus migrates to the nitrogen atom attached to it, the two benzene residues then uniting together; this may be represented as follows:—

$$\begin{matrix}H\cdot C_6H_4\cdot NH\\ |\\ H\cdot C_6H_4\cdot NH\end{matrix} = \begin{matrix}C_6H_4\cdot NH_2\\ |\\ C_6H_4\cdot NH_2\end{matrix}.$$

If, however, the migration of the hydrogen atom were only to take place in one benzene nucleus, the nitrogen atom in connection with that nucleus would be then separated from the second imido-group, leaving the latter free to unite with the benzene nucleus in the position previously occupied by the hydrogen atom, the change being represented as follows:—

$$\begin{matrix}H\cdot C_6H_4\cdot NH\\ |\\ C_6H_5\cdot NH\end{matrix} = \begin{matrix}C_6H_4\cdot NH_2\\ |\\ C_6H_5\cdot NH\end{matrix}.$$

Such a change has not hitherto been observed with hydrazobenzene itself, but in that case both halves of the molecule are similar, and there is no apparent reason for one half showing any special behaviour; in the case of ethoxyhydrazobenzene, however, the two halves of the molecule are dissimilar, and it is quite possible that such an intramolecular change as represented above might take place; this may occur in two different ways according to the half of the molecule in which the migration of the hydrogen atom takes place:—

$$\begin{array}{rcl} H\cdot C_6H_4\cdot NH & & C_6H_4\cdot NH_2 \\ | & = & | \\ OEt\cdot C_6H_4\cdot NH & & OEt\cdot C_6H_4\cdot NH \end{array},$$

$$\begin{array}{rcl} C_6H_5\cdot NH & & C_6H_5\cdot NH \\ | & = & | \\ H\cdot OEt\cdot C_6H_3\cdot NH & & OEt\cdot C_6H_3\cdot NH_2 \end{array}.$$

Either of these formulæ would explain the reactions of the base, so far as they are at present known, both formulæ representing a mono-substituted orthodiamidobenzene, which would from analogy yield a methenyl and ethenyl derivative and a tertiary azoimide. In order, however, to obtain more definite evidence on this point, the base was subjected to other reactions in which mono-substituted ortho-diamidobenzene plays a characteristic part. When heated with benzaldehyde and alcohol, it behaves in exactly the same manner as orthamidoditolylamine (Fischer and Lieder, Abstr., 1891, 434), yielding a dihydro-anhydro-compound containing the group $\begin{matrix} NR \\ NH \end{matrix}>CHPh$, which crystallises in needles, and melts at 152°. It likewise combines with benzoïn to form a dihydroquinoxaline derivative (compare O. Fischer, Abstr., 1891, 747), which crystallises in stellate groups of prisms, melts at 126—128°, and shows a yellowish-green fluorescence in dilute alcoholic solution; with benzil, it behaves like orthamidodiphenylamine (Abstr., 1891, 945, 1109), yielding a fluorescent *azonium* base, which melts at 145°, then quickly solidifies, and remelts on further heating at 162—163°, and on oxidation, like the azonium bases of Fischer and Busch (Abstr., 1891, 1109, 1514), yields the dihydroquinoxaline obtained with benzoïn.

The above reactions characterise the base definitely as a mono-substituted orthodiamido-derivative, and by means of further reactions, which will be described in a subsequent paper, it has been shown that the second of the formulæ given above is correct. These results show conclusively that, besides their conversion into benzidine derivatives, hydrazo-compounds are capable of undergoing another kind of intramolecular change in which bases of the type of amido-diphenylamine are produced. This change probably occurs in other hydrazo-derivatives than the one discussed in this paper, and it is not unlikely that some of the substance hitherto supposed to be benzidine derivatives are in reality derivatives of amidodiphenyl-amine (compare Täuber, this vol., p. 853, and Witt and Schmidt, this vol., p. 862). H. G. C.

Displacement of the Hydrazine Residue by Halogens. By L. Gattermann and R. Hölzle (*Ber.*, **25**, 1074—1075).—It is well known that hydrazines are oxidised by copper sulphate to hydrocarbons; for example, phenylhydrazine to benzene. But if, instead of the free hydrazine, a hot solution of phenylhydrazine in hydrochloric acid is allowed to drop into a boiling aqueous solution of copper sulphate, nitrogen is evolved, metallic copper is deposited, and chlorobenzene distils over with the steam. The yield is 86·4 of the theoretical. Diazobenzene chloride is probably formed as an inter-

mediate product. Bromo-, iodo-, and cyano-benzene may be prepared in a similar manner; the yield is respectively 60, 20, and 10 per cent. of the theoretical. The tolylhydrazines exhibit the same reaction.

C. F. B.

Acid Hydrazides. By L. Gattermann, E. S. Johnson, and R. Hölzle (*Ber.*, **25**, 1075—1081).—Various hydrazides were oxidised by boiling them with a solution of copper sulphate in aqueous ammonia, and the products which separated were purified by boiling out with alcohol.

Formylphenylhydrazine, prepared from formamide and phenylhydrazine, yields *formyldiphenylhydrazine*, $NPh_2{\cdot}NH{\cdot}CHO$, which yields diphenylamine when distilled, and can be synthesised from diphenylhydrazine and formic acid. It melts at 116·5°, crystallises from alcohol in colourless needles, dissolves sparingly in hot water and light petroleum, readily in other solvents. Like all the secondary hydrazides mentioned below, it yields, with strong sulphuric acid, a blue solution which turns green when warmed.

Acetylphenylhydrazine yields *acetyldiphenylhydrazine*, $NPh_2{\cdot}NHAc$, also prepared from diphenylhydrazine and acetic chloride. It crystallises from dilute alcohol in colourless needles melting at 185° (uncorr.).

Propionylphenylhydrazine yields *propionyldiphenylhydrazine*,

$$NPh_2{\cdot}NH{\cdot}COEt,$$

which crystallises from dilute alcohol in colourless needles melting at 178°.

Benzoylphenylhydrazine yields benzoyldiphenylhydrazine,

$$NPh_2{\cdot}NHBz,$$

identical with the substance obtained from diphenylhydrazine and benzoic chloride. It forms colourless needles melting at 189°.

Formylorthotolylhydrazine, $C_6H_4Me{\cdot}NH{\cdot}NH{\cdot}CHO$, was obtained from formamide and orthotolylhydrazine. It crystallises from alcohol in flat, colourless needles, melts at 121°, and, when oxidised, yields *formyldiorthotolylhydrazine*, $N(C_6H_4Me)_2{\cdot}NH{\cdot}CHO$; this crystallises from alcohol in colourless plates melting at 139°.

Acetylorthotolylhydrazine, $C_6H_4Me{\cdot}NH{\cdot}NHAc$, from acetic acid and orthotolylhydrazine, crystallises from water in colourless plates melting at 104°. It yields *acetyldiorthotolylhydrazine*, $N(C_6H_4Me)_2{\cdot}NHAc$, which crystallises from alcohol in lustrous plates melting at 191°.

Propionylorthotolylhydrazine, $C_6H_4Me{\cdot}NH{\cdot}NH{\cdot}COEt$, from propionic acid and orthotolylhydrazine, crystallises from water in colourless tables melting at 83—84°. It yields *propionyldiorthotolylhydrazine*, $N(C_6H_4Me)_2{\cdot}NH{\cdot}COEt$, which crystallises from dilute alcohol in colourless needles melting at 167°.

Benzoylorthotolylhydrazine, $C_6H_4Me{\cdot}NH{\cdot}NHBz$, from benzoic chloride and orthotolylhydrazine, forms long, lustrous needles melting at 180°. It yields *benzoyldiorthotolylhydrazine*, $N(C_6H_4Me)_2{\cdot}NHBz$, which crystallises in flat needles melting at 209°.

Formylparatolylhydrazine yields *formyldiparatolylhydrazine*,

$$N(C_6H_4Me)_2{\cdot}NH{\cdot}CHO,$$

which crystallises from dilute alcohol in thin, silky plates, and melts at 146°.

Acetylparatolylhydrazine, $C_6H_4Me{\cdot}NH{\cdot}NHAc$, from acetic acid and paratolylhydrazine, forms plates melting at 121°. It yields *acetyldiparatolylhydrazine*, $N(C_6H_4Me)_2{\cdot}NHAc$, which crystallises from alcohol in silvery needles melting at 176°.

Propionylparatolylhydrazine, $C_6H_4Me{\cdot}NH{\cdot}NH{\cdot}COEt$, crystallises from water in flat needles melting at 170°. It yields *propionyldiparatolylhydrazine*, $(C_6H_4Me)_2N{\cdot}NH{\cdot}COEt$, which crystallises from dilute alcohol in small needles melting at 171·5°.

Benzoylparatolylhydrazine yields benzoyldiparatolylhydrazine, already prepared from diparatolylhydrazine and benzoic chloride.

Chloracetylphenylhydrazine, $NHPh{\cdot}NH{\cdot}CO{\cdot}CH_2Cl$, is obtained from chloracetic chloride and phenylhydrazine. It crystallises from ether in ill-defined crystals melting at 115°. It is decomposed by water, and consequently does not suffer oxidation in the normal manner.

When the product obtained from ethyl chloroformate and phenylhydrazine is oxidised, it yields a substance, $NPh_2{\cdot}NH{\cdot}COOEt$, which crystallises from alcohol in long, colourless needles melting at 140°.

C. F. B.

Phenyldithiobiuret. By E. Fromm (*Ber.*, **25**, 1277—1281).—The compounds obtained by the interaction of ketones with thiobiurets, in molecular proportion, in the presence of hydrogen chloride are named by the author *thioketurets*. *α-Phenyldithiodimethylketuret*, $C_{11}H_{13}N_3S_2$, is produced from acetone and α-phenyldithiobiuret; it melts at 239°, contains 2 atoms of hydrogen displaceable by metal, and therefore dissolves in alkalis; the *dibenzyl* derivative, $C_{25}H_{25}N_3S_2$, melts at 128°, and when boiled with concentrated hydrochloric acid decomposes into ammonia, aniline, acetone, and *benzyl imidodicarbothioxylate*, $HN(COSCH_2Ph)_2$; the last-mentioned compound melts at 146°, and, when treated with alkalis, decomposes into benzyl mercaptan and ammonia. These facts are most easily explained by assigning to α-phenyldithiodimethylketuret the constitution $NPh{:}C(SH){\cdot}N{<}\begin{matrix}CMe_2\\C(SH)\end{matrix}{>}N$.

A. R. L.

Orthohydroxyacetophenone. By Y. Tahara (*Ber.*, **25**, 1306—1310).—*Ethyl orthomethoxybenzoylacetate*, $OMe{\cdot}C_6H_4{\cdot}CO{\cdot}CH_2{\cdot}COOEt$ [= 1 : 2], is obtained when methyl ethylsalicylate (50 grams) is mixed with ethyl acetate (24·5 grams) and sodium wire (6·4 grams) added; after adding alcohol (about 2 grams), the reaction becomes brisk, and the mixture is heated on the water-bath for 18 hours. The mass, after cooling, is treated with water, and the aqueous solution extracted with ether, the crude product being fractionally distilled under diminished pressure, and further purified by means of its sodium hydrogen sulphite compound. It is a colourless oil of an aromatic odour, and is sparingly soluble in water, readily in ether; its alcoholic solution gives a red colour with ferric chloride.

Orthomethoxyphenylphenylpyrazolone, $OMe{\cdot}C_6H_4{\cdot}C{<}\begin{matrix}CH_2{\cdot}CO\\N-NPh\end{matrix}$, separates when the last compound and phenylhydrazine are dissolved in

acetic acid and the solutions mixed; it melts at 114°, and is very little soluble in water; its alcoholic solution is coloured reddish-brown by ferric chloride,

Orthomethoxybenzoylacetic acid is obtained by allowing a solution of the above ethyl salt in dilute sodium hydroxide to remain for three days. It is precipitated by sulphuric acid, purified by redissolving in sodium carbonate and reprecipitating with acid, and finally crystallised from dilute alcohol; it crystallises in tables, melts at 68° with decomposition, and is sparingly soluble in water; it gives a red colour with ferric chloride; the silver salt crystallises in prisms.

Orthomethoxyacetophenone, $OMe{\cdot}C_6H_4{\cdot}COMe$, is produced by boiling ethyl orthomethoxybenzoylacetate with dilute sulphuric acid for 10 hours; it is an oil having a faint odour, boils at 240° (712 mm.), and is insoluble in alkalis; the phenylhydrazine compound crystallises in colourless leaflets, and melts at 86°.

Orthohydroxyacetophenone is prepared by heating the last compound with concentrated hydrochloric acid in a sealed tube at 130°. It is a colourless oil having a strong phenolic odour, boils at 213° (717 mm.), is sparingly soluble in water, but miscible in all proportions with ether, alcohol, and glacial acetic acid, and is coloured violet-red by ferric chloride. The *phenylhydrazone* crystallises from alcohol in delicate needles, and melts at 107°; whilst the *acetyl* derivative forms colourless leaflets, and melts at 89°. A. R. L.

Derivatives of Cyanacetophenone. By F. Garelli (*Gazzetta*, **22**, i, 140—146).—Claisen (Abstr., 1892, 506), by distilling phenylisoxazolic acid, obtained small quantities only of cyanacetophenone. Salvatori, however (Abstr., 1892, 304), found the yield to be satisfactory, and this is confirmed by the author, who obtained about 66 per cent. of the theoretical.

Cyanacetophenone (4 grams) dissolved in absolute alcohol (300 c.c.) is reduced by sodium with production of phenylpropylamine. The alcohol is distilled off, and the crude base purified by steam distillation and conversion into its hydrochloride. Small quantities of acetic and benzoic acids are also formed during the reduction. Phenylpropylamine oxalate melts at about 190° with decomposition; the low melting point observed by Tafel (Abstr., 1886, 939; 1889, 975) is probably due to the presence of dioxalate as an impurity in the normal salt. The *picrate* crystallises in long, yellow needles, and melts at 152—153° without decomposition; it is soluble in boiling water, sparingly so in cold water. W. J. P.

Dehydrodiacetylpæonol. By W. N. Nagai (*Ber.*, **25**, 1284—1291; compare this vol., p. 58).—When pæonol (20 grams) is boiled in a reflux apparatus for 16 hours with acetic anhydride (40 grams) and fused sodium acetate (20 grams), the product triturated with ether, repeatedly boiled with 18 per cent. acetic acid, which extracts an *acetylpæonol* (m. p. 130°), and crystallised from alcohol, yellowish leaflets of a compound melting at 160° are obtained. It has the composition $C_{13}H_{12}O_4$, and may be provisionally named dehydrodiacetylpæonol; it is readily soluble in chloroform, sparingly in hot benzene,

and insoluble in alkalis and ammonia. When the new compound is heated on the water-bath for a short time with half its weight of potassium hydroxide and a little alcohol, potassium acetate and the salt $C_{11}H_{11}O_4K$ are formed; the latter, when treated in aqueous solution with dilute mineral acids, yields *hydroxyacetylpæonol*, $C_{11}H_{12}O_4$, a compound crystallising in colourless needles melting at 68°, and decomposing into pæonol, acetic acid, and paramethoxysalicylic acid (m. p. 158°) when boiled with alkalis; its alcoholic solution gives a violet colour with ferric chloride. The same products are obtained when dehydrodiacetylpæonol is heated on the water-bath with aqueous or alcoholic potash for 30 minutes.

Dehydracetylpæonol, $C_{11}H_{10}O_3$, is produced by boiling the last-mentioned hydroxy-compound with dilute hydrochloric acid, or dehydrodiacetylpæonol with sodium carbonate; it forms colourless prisms, melts at 113°, and is sparingly soluble in cold water.

Dehydromethylacetylpæonol, $C_{12}H_{12}O_3$, is obtained by the interaction of potassium hydroxyacetylpæonol and methyl iodide; it crystallises from dilute alcohol in colourless needles, melts at 126°, and is sparingly soluble in water. *Isomethylpæonol*, $C_{10}H_{12}O_3$, is formed when the last compound is boiled with alkalis; it possesses the characters of a phenol, gives a reddish-violet colour with ferric chloride, crystallises in colourless, rhombic prisms, and melts at 58°. On boiling the above-mentioned diacetylpæonol (m. p. 130°) with alcoholic potash, it yields a compound melting at 159°, which is perhaps identical with Duisberg and v. Pechmann's β-methylumbelliferone methyl ether (Abstr., 1884, 66; compare following abstract). A. R. L.

Constitution of Dehydrodiacetylpæonol and of Dehydrodiacetylresacetophenone. By Y. Tahara (*Ber.*, **25**, 1292—1305). —From his own experiments, as well as those of Nagai (last abstract), the author concludes that the constitution of "dehydrodiacetylpæonol" is $OMe\langle\begin{matrix}CH_2\text{—}C(:CH\cdot COAc)\\ CH\cdot CH:C\cdot CO\cdot CH\end{matrix}$, and that of "dehydrodiacetylresacetophenone" $OH\cdot C\langle\begin{matrix}CH_2\text{—}C(:CH\cdot COAc)\\ CH\cdot CH:C\cdot CO\cdot CH\end{matrix}$.

"Isomethylpæonol," obtained by Nagai (*loc. cit.*), forms a *phenylhydrazone*, $C_{10}H_{12}O_2{:}N_2HPh$, which crystallises in long, colourless prisms and melts at 101°; it is found to be identical with hydroxymethoxyphenyl ethyl ketone, $OH\cdot C_6H_3(OMe)\cdot COEt$ [1 : 2 : 4], described by Goldzweig and Kaiser (*J. pr. Chem.* [2], **43**, 90). *Dehydrodiacetylpæonol phenylhydrazone*, $C_{13}H_{12}O_3{:}N_2HPh$, crystallises in short prisms, melts at 213°, and gives *dehydracetylpæonol phenylhydrazone*,

$$C_{11}H_{10}O_2{:}N_2HPh,$$

melting at 206°, when boiled with alcoholic potash; the latter is a phenolic compound, and yields a methyl derivative melting at 150°.

Bromodehydracetylpæonol, $C_{11}H_9BrO_3$, formed by brominating dehydracetylpæonol in ethereal solution, melts at 175—177°, and gives dehydracetylpæonol on treatment with alkali. Diacetylresorcinol (Nencki and Sieber, Abstr., 1881, 591) is obtained by mixing resaceto-

phenone and fused sodium acetate (equal parts) with acetic anhydride (2 parts) at the ordinary temperature; when, however, the mixture is boiled for some hours, acetyldehydrodiacetylresacetophenone, $C_{14}H_{12}O_5$, which crystallises in colourless prisms and melts at 127°, is formed; the latter, on treatment with dilute ammonia, yields dehydrodiacetylresacetophenone, $C_{12}H_{10}O_4$, which crystallises in silky needles and melts at 182°. When the last compound is boiled with sodium carbonate solution, dehydracetylresacetophenone, $C_{10}H_8O_3$, is obtained; it crystallises in colourless, rhombic prisms and melts at 250°; the same compound is produced when dehydrodiacetylpæonol is heated in a sealed tube with hydrochloric acid at 160° for five hours.

The author shows that the diacetylpæonol melting at 130° (last abstract) is α-acetyl-β-methylumbelliferone methyl ether, and consequently the compound which Nagai obtained by boiling it with alcoholic potash is β-methylumbelliferone methyl ether, as he supposed. A. R. L.

Hydrobenzoic Acid. By O. Aschan (*Ber.*, **25**, 886—888).—A criticism of some remarks by Markovnikoff (this vol., p. 714).

The author has redetermined the melting and boiling points of hydrobenzoic acid, and obtains the numbers 28° and 232—233° (corr.). Markovnikoff's numbers are 28·5—29·5° and 232—234°.

E. C. R.

Reactions of Amidobenzoic Acids. By O. de Coninck (*Compt. rend.*, **114**, 595—597 and 758—760).—When the amidobenzoic acids are heated out of contact with air with potassium, sodium, magnesium, or zinc, variable quantities of ammonia are evolved. Evolution of ammonia is also observed when these acids are heated with potassium, sodium, barium, strontium, and magnesium oxides or hydroxides, zinc oxide, &c.

Soda-lime behaves differently. If rapidly heated with the ortho-acid for a short time, carbonisation takes place, and if the residue is treated with water, a pale-violet solution is obtained. The colour is discharged by a dilute acid, but restored by a dilute alkali. Addition of dilute sodium hydroxide produces a bluish fluorescence. The meta-acid under the same conditions gives a red-brown solution; with less soda-lime, a violet solution is obtained, with a tint very different from that given by the ortho-acid. The para-acid gives no similar coloration.

When heated with copper oxide, the ortho- and para- acids give no coloration; the meta-acid yields a substance dissolving in dilute alcohol, with a pale rose colour. With barium peroxide, there is incandescence, and the meta-acid yields a garnet-red solution; the ortho- and para-acids give no soluble coloured substance. Manganese peroxide, if carefully heated with the meta-acid, yields a violet solution when the product is treated with dilute alcohol; the ortho- and para-acids yield no such coloration.

If a dilute solution of chromic acid is poured into tubes containing equal quantities of the three amidobenzoic acids, the reduction takes place immediately with the ortho-acid, more slowly with the meta-,

and still more slowly with the para-acid. Solid chromic acid, on gently heating, produces incandescence, sometimes with explosion. When heated with arsenic acid, all three amido-acids yield violet or violet-red products soluble in alcohol, but the para-acid must be heated less strongly than the other two.

Orthamidobenzoic acid dissolves in warm nitric acid, forming a garnet-red solution which rapidly becomes deep brown, but remains clear if water is added before the change of colour takes place. The meta- and para- acids give similar colorations, and the latter offers the most resistance to the action of the nitric acid. Fuming nitric acid rapidly attacks orthamidobenzoic acid in the cold, forming a deep red-brown solution which at first remains clear after dilution, but soon becomes turbid. The meta-acid is also rapidly attacked, forming a red solution which remains permanently clear after dilution. The para-acid offers greater resistance, but forms a deep red liquid; on dilution, it changes to deep yellow, and remains clear. Aqua regia dissolves the ortho-acid completely, the meta-acid less readily, the para-acid still less readily. In the first case, the colour is bright red, and there is partial precipitation on dilution, but complete dissolution on heating; in the second case, the colour is amber-yellow and afterwards red, and there is complete dissolution on adding an equal volume of water and boiling; in the third case, the colorations are the same as with the meta-acid, but dissolution after dilution is not complete.

Boiling dilute hydrochloric acid gives a pale-violet coloration with orthamidobenzoic acid, but no coloration with the meta- and para-derivatives. The meta-acid dissolves only partially in a large excess of hydrochloric acid, but the para-acid dissolves completely. Strong hydrochloric acid behaves similarly, but produces no coloration with orthamidobenzoic acid.

Boiling dilute sulphuric acid dissolves orthamidobenzoic acid, forming a pale rose-coloured solution; the meta- and para-acids give no coloration. The ortho-acid is rapidly carbonised by strong sulphuric acid, but the meta- and para-derivatives offer considerable resistance to its action. C. H. B.

Formation of Allocinnamic Acid from Phenylpropiolic Acid. By C. Liebermann and W. Scholz (*Ber.*, **25**, 950—951).—When the acid obtained by Michael and Browne by combining phenylpropiolic acid with hydrogen bromide (Abstr., 1886, 702) is boiled with zinc filings and alcohol, it yields allocinnamic acid, and perhaps also isocinnamic acid (compare Erlenmeyer, Abstr., 1891, 200). The acid reduces alkaline permanganate without the formation of benzaldehyde, and in view of this, as well as its formation from phenylpropiolic acid, the authors regard its constitution as $\begin{matrix} Br\cdot C\cdot Ph \\ \| \\ H\cdot C\cdot COOH \end{matrix}$. A. R. L.

Condensation of Cinnamic and Allocinnamic Acids. By C. Liebermann and A. Hartmann (*Ber.*, **25**, 957—961).—Cinnamic acid condenses with phenols more readily than allocinnamic acid,

thus:—At the ordinary temperature, after several months, cinnamic acid and phenols give the same phenylhydrocoumarin which is obtained at a higher temperature in a few days from allocinnamic acid (see Abstr., 1891, 1484). Hydroxyphenylhydrocoumarin, $C_{15}H_{12}O_3$, prepared from cinnamic acid and resorcinol, behaves as the corresponding product from allocinnamic acid (*loc. cit.*). An isomeric *compound*, which is insoluble in water and melts at 133°, is formed from resorcinol and allocinnamic acid; whilst a third *isomeride* is produced by dissolving quinol and cinnamic acid in glacial acetic acid (5 grams of each), adding a mixture of glacial acetic acid (2 c.c.) and concentrated sulphuric acid (7 c.c.), and heating the whole on the water-bath for three hours; it crystallises from benzene in needles, melts at 133°, is sparingly soluble in hot water, and dissolves in alkalis with a yellow colour.

Xylylphenylpropionic acid, $C_6H_3Me_2{\cdot}CHPh{\cdot}CH_2{\cdot}COOH$, is obtained when cinnamic acid (5 grams) is dissolved in metaxylene (100 grams), sulphuric acid (5 grams) slowly dropped in, and the mixture heated on the water-bath for four hours; after distilling off the excess of xylene and purifying, it forms an amorphous, resinous mass, readily soluble in hot benzene; allocinnamic acid gives the same compound. The *calcium* salt separates as a white, flocculent precipitate on adding calcium chloride to the ammoniacal solution.

Diphenylpropionic acid, $CHPh_2{\cdot}CH_2{\cdot}COOH$, is prepared by heating together allocinnamic acid, benzene, and sulphuric acid; after purification, it forms small, white needles, and melts at about 145°; the calcium salt is soluble in water, and crystallises in needles.

A. R. L.

Phenyltrimethylenecarboxylic Acids. By E. Buchner and H. Dessauer (*Ber.*, **25**, 1147—1157).—The authors have not yet succeeded in determining the constitution of the phenyltrimethylenedicarboxylic acid prepared from ethyl phenylpyrazolinedicarboxylate; they therefore propose to term it Γα1-*phenyltrimethylene*-2-3-*dicarboxylic acid*, since it yields an anhydride, and must be, therefore, either Γ cis 1-phenyl-trans-2-3-dicarboxylic acid or Γ cis 1-phenyl-cis-2-3-dicarboxylic acid. The acid is not acted on by sodium amalgam, bromine, or hydrobromic acid. The *dimethyl salt* crystallises from light petroleum in colourless needles, melts at 63°, and boils at 200—214° under a pressure of 20 mm. The *silver salt*, $C_{11}H_8O_4Ag_2$, is stable; the *hydrogen sodium salt*, $C_{11}H_9O_4Na$, crystallises from water in slender, lustrous needles. The *anhydride*, $C_{11}H_8O_3$, is formed by heating the acid in a vacuum; it melts at 134°, and was previously mistaken for the monocarboxylic acid; the original acid is regenerated by the action of soda.

Γα1-Phenyltrimethylene-2-2-3-tricarboxylic acid is obtained by the hydrolysis of the ethereal salt (see below); on the addition of light petroleum to its solution in ether, it crystallises out with $4H_2O$; the anhydrous acid melts at 188°, and is not acted on by potassium permanganate in alkaline solution. The *trimethyl salt* is prepared by heating methyl malonate (1 mol.) with sodium methoxide (2 mols.) and methyl dibromhydrocinnamate (1 mol.) in methyl alcoholic solution for eight

hours; the product is treated with water, extracted with ether, the ether removed, and the residue fractionated under reduced pressure; the compound melts at 47° and boils at 209—210° under a pressure of 20 mm.; like the acid, it is stable towards potassium permanganate in alkaline solution. The *potassium salt*, $C_{12}H_9O_6K$, crystallises from water. On heating the anhydrous carboxylic acid at 180—200° in an atmosphere of carbonic anhydride, phenylisocrotonic acid is formed; the yield is 50 per cent. of the acid employed; phenylisocrotonic acid is converted into phenyldibromobutyric acid (m. p. 136°) by the action of bromine, whilst with hydrogen bromide γ-phenylbutyrolactone and γ-phenylhydroxybutyric acid are produced. *Silver phenylisocrotonate* is unstable, and yields the acid on distillation. The calcium salt, contrary to the observations of Jayne, is sparingly soluble in water, and loses 3 mols. H_2O in a vacuum over sulphuric acid. The barium salt is also sparingly soluble, and crystallises from water in needles.

Although it is unusual for the trimethylene ring to be resolved on heating trimethylenecarboxylic acids, the formation of phenylisocrotonic acid from the acid $C_3H_2Ph(COOH)_3$ is analogous to the formation of trimethylenecarboxylic acid and butyrolactone from trimethylene-1-1-dicarboxylic acid. J. B. T.

A Correction. By E. Laves (*Ber.*, **25**, 1070—1071).—In the printing of the author's paper on trithioorthoformates certain words were omitted, so that the following correction is to be made in the abstract (this vol., p. 613, line 17 from top):—For "in presence of phenyl groups . . . . disulphones are formed"; read "the latter are oxidised directly to trisulphones, whereas the former yield disulphone sulphides in presence of phenyl groups, disulphones in presence of ethyl groups."

In the paper, "Formation of trisulphones from disulphones" (this vol., p. 614, line 2 from top), for "by the action of sodium," read "by the action of sodium and lead mercaptides and of sodium benzenesulphinate." F. S. K.

Benzenesulphonitramide. By O. Hinsberg (*Ber.*, **25**, 1092—1096).—This substance, $NO_2{\cdot}NH{\cdot}SO_2Ph$, is obtained by adding finely-powdered benzenesulphonamide (50 grams) to cooled, strong nitric acid of sp. gr. 1·48 (200 grams), then adding cooled, strong sulphuric acid (100—150 grams), and pouring the mixture into much cold water. The nitramide is extracted with ether, and recrystallised from alcohol. It forms large, transparent tables, easily soluble in water, alcohol, and ether, but precipitated in a crystalline form by the addition of mineral acids to an aqueous solution. It melts and decomposes at about 100°, nitrous oxide being evolved and benzenesulphonic acid formed. The same decomposition takes place when it is warmed with strong sulphuric acid or acetic anhydride, or is heated at 150° with hydrochloric or hydrobromic acid, or with water. Strong hydriodic acid converts it into phenyl bisulphide and ammonia; nitrous acid does not attack it; ammonium sulphide forms the ammonium salt, which is not further reduced, but stannous chloride

reduces the nitramide to benzenesulphonamide. It has an acid taste, and forms salts. The *potassium salt*, $NO_2{\cdot}NK{\cdot}SO_2Ph$, crystallises in white prisms with a slightly bitter taste. It is readily soluble in hot, very sparingly in cold, water, and is much more stable than the amide itself, not decomposing until heated to 275°. When the silver salt is treated with methyl iodide, benzenesulphomethylnitramide of known constitution, $NO_2{\cdot}NMe{\cdot}SO_2Ph$, is formed; consequently the nitramide has itself the constitution assigned above. C. F. B.

Dibenzyl Ketone and Dibenzylcarbinol. By V. Bogdanowska (*Ber.*, **25**, 1271—1277).—*Dibenzylcarbinol*, $CH(CH_2Ph)_2{\cdot}OH$, is prepared by dropping sodium in small pieces into an ethereal solution of dibenzyl ketone, cooled by water; the reaction extends over 7—8 days, and a large excess of sodium must be employed. It is a colourless, highly refractive liquid, having a sp. gr. 1·0619 at 16·5°; it boils at 327°, and gives the corresponding ketone on oxidation with potassium dichromate and dilute sulphuric acid. The *benzoyl* derivative crystallises in transparent, four-sided prisms, and melts at 50—51°. When the carbinol is reduced with hydriodic acid and phosphorus, it yields dibenzylmethane; whilst, if it is heated at 265° in a sealed tube with methyl iodide, the same hydrocarbon is obtained, but, in addition, a small quantity of another, $C_{30}H_{22}$, which melts at 268—269°.

Dihydroxydiphenyldibenzylmethane, $C(CH_2Ph)_2(C_6H_4{\cdot}OH)_2$, is obtained by fusing dibenzyl ketone with twice the calculated quantity of phenol, adding concentrated sulphuric acid, and, after 24 hours, driving the excess of phenol over with steam; the compound is obtained from the residual oil, which, after purification, solidifies and crystallises from benzene in four-sided tables.

When dibenzyl ketone is heated at 60—70° with 1 per cent. aqueous potash, a current of air being passed through meanwhile, the acid $C_{15}H_{14}O_3$, melting at 160—161°, is obtained. This acid has probably the constitution $CH_2Ph{\cdot}CPh(OH){\cdot}COOH$; it appears to give stilbene on distillation. A. R. L.

Metaphenyltoluene. By G. Perrier (*Compt. rend.*, **114**, 484—486).—An ethereal solution of metabromotoluene (1 mol.) and bromobenzene (1 mol.) is heated with sodium (excess) in a reflux apparatus at 40—50° for five hours. The product of distillation is purified from diphenyl by repeated fractionation and exposure to low temperature, and then consists of *metaphenyltoluene*, C_6H_4MePh, a liquid of aromatic odour, boiling at 270°, and not solidifying at −23°. Metaphenyltoluene is oxidised by dilute nitric acid (sp. gr. 1·14) to diphenylmetacarboxylic acid, $C_{12}H_9{\cdot}COOH$, which crystallises in nacreous plates, melts at 159°, and is identical with the acid prepared by Schmidt and Schultz from diphenylbenzene, and by Barth and Schröder from benzoic acid.

Metaditolyl, $C_6H_4Me{\cdot}C_6H_4Me$, which is obtained in small quantity as a secondary product in the above preparation of metaphenyltoluene, boils at 287—288°. It is oxidised by dilute nitric acid to metatolylbenzenemetacarboxylic acid, $C_6H_4Me{\cdot}C_6H_4{\cdot}COOH$, which crystallises

in silky needles, melts at 204°, and dissolves in alcohol, ether, and chloroform, and less freely in water. Its salts crystallise well.

Jn. W.

Dimetaditolyl. By R. Löwenherz (*Ber.*, **25**, 1032—1037; compare Täuber, Abstr., 1890, 782).—*Metanitrorthotolidine*, $C_{14}H_{15}N_3O_2$, is formed, together with a dinitro-compound, when potassium nitrate is gradually added to an ice-cold sulphuric acid solution of orthotolidine, and the salt thus produced is decomposed with alkali. It crystallises from alcohol in dark-red needles, melts at 156° with previous softening, and is insoluble in light petroleum, and only moderately easily soluble in cold alcohol and ether, but more readily in benzene and boiling glacial acetic acid. The *sulphate* crystallises in yellowish, microscopic plates, and is only very sparingly soluble in hot water, by which it is decomposed; the *hydrochloride* is a colourless, crystalline compound, and resembles the sulphate in its behaviour with hot water. By combining diazotised nitrotolidine with naphthionic acid there is formed a tetrazo-dye, corresponding with benzopurpurin 4 B, which imparts to cotton a bluish-red colour, and which has only a slightly less affinity for the cotton fibre than that of the tolidine dye, the sensibility of the two dyes as regards acids being the same. The *diacetyl* derivative, $C_{18}H_{19}N_3O_4$, crystallises from glacial acetic acid in slender, yellow needles, melts at 290°, and is soluble in hot alcohol, but only very sparingly in ether and benzene.

Dibenzylidenenitrotolidine, $C_{28}H_{23}N_3O_2$, prepared by heating an alcoholic solution of the base with benzaldehyde, crystallises from alcohol in plates, melts at 147°, and is readily soluble in benzene, but only sparingly in ether and alcohol, and insoluble in water.

Nitrodicresol, $C_{14}H_{13}NO_4$, is obtained by diazotising nitrotolidine; it crystallises from water in golden needles, melts at 187°, and is readily soluble in cold alcohol, ether, and glacial acetic acid, but more sparingly in benzene and cold water; its aqueous solution gives a reddish-orange coloration with alkalis.

Metamidorthotolidine was obtained in an impure condition by reducing the nitro-compound with tin and hydrochloric acid; it is very readily soluble in alcohol, but only very sparingly in ether and water, and resinifies on exposure to the air. The *hydrochloride* crystallises from water in prisms, and is very readily soluble in water. The *acetyl* derivative, $C_{20}H_{23}N_3O_3$, separates from alcohol in colourless crystals, does not melt below 290°, and dissolves freely in boiling alcohol, but is almost insoluble in ether and benzene.

Dimetaditolyl dicyanide, $C_{16}H_{12}N_2$, can be prepared from orthotolidine by Sandmeyer's method; it crystallises from alcohol in yellowish needles, melts at 190°, and is moderately easily soluble in ether, benzene, and glacial acetic acid, but only sparingly in light petroleum.

Ditolyldicarboxylic acid, $C_{16}H_{14}O_4$, prepared by boiling the preceding compound with moderately concentrated sulphuric acid, separates from hot, dilute alcohol as a colourless, flocculent precipitate, does not melt below 300°, and sublimes when strongly heated with partial decomposition; it is insoluble in water, and only sparingly soluble in boiling alcohol.

F. S. K.

Formation of an Orthamidoditolylamine from Parahydrazotoluene. By E. Täuber (*Ber.*, **25**, 1019—1025).—It has long been known that parahydrazotoluene under certain conditions undergoes an intramolecular change, with formation of a new substance termed paratolidine, it being assumed that the change in question was similar to that of hydrazobenzene to benzidine (*Ber.*, **3**, 554; Abstr., 1879, 239). As, however, the hydrogen atoms in the para-position to the hydrazo-group are already substituted by methyl, the amido-groups cannot occupy the para-position in the new compound as they do in benzidine, and the author, therefore, regarded it as probable that the so-called paratolidine contained the amido-groups in the peri-position, its constitution being represented by the formula $NH_2{\cdot}C_6H_3Me{\cdot}C_6H_3Me{\cdot}NH_2$ [$(NH_2)_2 : (Me)_2 = 2:2' : 5:5'$]. The substance possessing this constitution has, however, recently been prepared by the author and Loewenherz (Abstr., 1891, 1491), and possesses very different properties from those of the so-called paratolidine, and a renewed investigation of the substance was therefore required. The results obtained showed that it is not a derivative of diphenyl but an *orthamidoditolylamine*, $C_6H_4Me{\cdot}NH{\cdot}C_6H_3Me{\cdot}NH_2$ [$NH : Me = 1:4$ and $NH : NH_2 : Me = 1:2:5$] (compare Jacobsen and Fischer, this vol., p. 839, Witt and Schmidt, this vol., p. 862). It shows all the characteristic reactions of an orthodiamido-compound, giving an azimide with nitrous acid, an azonium base with benzil, and a benzenyl derivative with benzaldehyde. Schultz (Abstr., 1884, 903) obtained a ditolyl from the base by the action of nitrous acid, but the author has, under varying conditions, never observed the formation of this compound, and believes that Schultz obtained it owing to the employment of paratoluidine containing a small quantity of an isomeride.

Orthamidoditolylamine is best obtained by pouring alcohol (500 c.c.) on to parahydrazotoluene (50 grams), gradually adding a solution of stannous chloride (60 grams) in 25 per cent. hydrochloric acid (150 c.c.), cooling, and allowing the mixture to remain for 24 hours, then adding water and an excess of soda; the crude product is dissolved in hot alcohol, and the cooled solution precipitated with water. The base then forms white plates, having a fatty lustre, melts at 107°, and dissolves readily in alcohol, ether, and benzene, sparingly in light petroleum. With ferric chloride, the alcoholic solution becomes claret coloured, and the hydrochloride blood-red, whilst the colourless solution of the base in sulphuric acid becomes deep-blue on the addition of sodium nitrite, the colour gradually changing to greyish-green.

The *azonium* base, $C_{28}H_{24}N_2O$, obtained by heating orthamidoditolylamine with benzil, alcohol, and hydrochloric acid, separates from alcohol in greenish-yellow crystals melting at 173°, and readily soluble in water; when amorphous, it dissolves very easily in alcohol, ether, and benzene, but in the crystalline condition is only sparingly soluble in these liquids. The *azimide*, $\begin{matrix}N{-}N{\cdot}C_6H_4Me\\ \|\quad\ \ |\\ N{-}C_6H_3Me\end{matrix}$, forms white, granular crystals, and melts at 93°; the *benzenyl* derivative, $\begin{matrix}CPh{\cdot}N{\cdot}C_6H_4Me\\ \|\quad\ \ |\\ N{-}C_6H_3Me\end{matrix}$, obtained by heating the base with alcohol and benz-

aldehyde, crystallises from alcohol in colourless needles, and melts at 185°; the benzylidine compound is probably first formed and converted into the benzenyl base by slow oxidation. H. G. C.

Condensation of Aldehydes with Azo-compounds. By J. Barsilowsky (*Chem. Centr.*, 1892, i, 57—58; from *Bull. Acad. St. Pétersbourg* [2], **34**, 259—289).—In order to study the reaction which takes place between aldehydes and azo-compounds in the presence of dehydrating substances, the author heated benzaldehyde with azobenzene in the presence of zinc chloride, when dibenzilidenebenzidine was obtained, identical with that prepared from benzaldehyde and benzidine by Schiff. The former reaction is explained by the readiness with which azobenzene is converted into benzidine, and since the reaction takes place in the same manner in the presence of hydrochloric acid, the author concludes that the oxygen of the aldehyde group unites with the hydrogen of the amido-group. If benzaldehyde and azobenzene be heated in the absence of a dehydrating agent, no change occurs until the temperature rises to 205—210°, when the compound $O<\begin{matrix}CHPh\\|\\NPh\end{matrix}$ is obtained. It forms colourless, lustrous plates or needles, is soluble in benzene, sparingly soluble in water or mineral acids, melts at 164°, and boils at 368—370°. In a corresponding manner, the three nitrobenzaldehydes are condensed in the presence of zinc chloride, benzilidenebenzidines being formed; in the absence of a dehydrating agent, compounds corresponding with the above are obtained, in which the carbon atom and the oxygen atom of the aldehyde group and the nitrogen of the azo-group form a ring. From paranitrobenzaldehyde, in the presence of zinc chloride, there is formed *paradinitrobenzilidenebenzidine*,

$$C_{12}H_8(N{:}CH{\cdot}C_6H_4{\cdot}NO_2)_2,$$

pale-yellow plates, insoluble in water, alkalis, and light petroleum, sparingly soluble in ether and alcohol, soluble in benzene, melting point 242°; and also *paranitrobenzilidenebenzidine*, $CH(C_6H_4{\cdot}NH)_2{\cdot}C_6H_4{\cdot}NO_2$, crystallising from benzene in brown plates, melting at 221°. In the absence of zinc chloride, the compound $O<\begin{matrix}CH{\cdot}C_6H_4{\cdot}NO_2\\|\\NPh\end{matrix}$ is obtained as yellow, silky threads from benzene solution, or lustrous needles by sublimation; it melts at 210—211°. From metanitrobenzaldehyde, in the presence of zinc chloride, *dimetanitrobenzilidenebenzidine* is obtained; it forms pale yellow prisms, soluble in benzene, and melts at 237—238°. In the absence of zinc chloride, no definite result was obtained.

From orthonitrobenzaldehyde, in the presence of zinc chloride, *diorthonitrobenzilidenebenzidine* was obtained as light-yellow prisms, soluble in benzene, and melting at 221—222°. J. W. L.

Action of Paramidodimethylaniline on Ketones. By H. Vogtherr (*Ber.*, **25**, 635—640).—When paramidodimethylaniline is mixed with benzile in molecular proportion in alcoholic solution, and

a few drops of aqueous potash added, a substance of the composition $COPh{\cdot}CPh{:}N{\cdot}C_6H_4{\cdot}NMe_2$ separates out. It is deposited from alcohol in red crystals, melts at 138—139°, dissolves also in ether, and is decomposed even by traces of dilute acids into benzile and the base. A second molecule of the base could not be made to react with benzile.

Paramidodimethylaniline reacts in a similar manner with benzoylacetone. The substance formed, $C_{18}H_{20}N_2O$, crystallises from alcohol in lemon-yellow needles with a silky lustre, melts at 135—136°, dissolves also in ether, and is decomposed by dilute acids. No reaction takes place with a second molecule of the base.

When benzoïn and paramidodimethylaniline are mixed in molecular proportion in alcoholic solution, a few drops of an alkali added, and the mixture heated, the substance which separates on cooling is not a derivative of benzoïn, but a condensation product,

$$CHPh{:}N{\cdot}C_6H_4{\cdot}NMe_2,$$

of benzaldehyde with the base, and yields benzaldehyde when treated with an acid. No doubt the benzoïn had been first decomposed by the small quantity of alkali, and the base had reacted with the benzaldehyde thus formed, for it was shown that phenylhydrazine, a substance resembling amidodimethylaniline in its reactions, although it forms a condensation product with benzoïn, yet in the presence of potash yields a substance which is a condensation product of phenylhydrazine with benzaldehyde. A condensation product, $C_{22}H_{22}N_2O$, of benzoïn with amidodimethylaniline may, however, be obtained by melting together the two substances for 15 minutes in a porcelain vessel, dissolving the mass in alcohol, and boiling with animal charcoal. On cooling, orange plates separate out, which melt at 126—127°, dissolve readily in ether, and also in dilute acids without undergoing decomposition. Under other circumstances, some of the benzile derivative was formed.

The reaction of amidodimethylaniline with deoxybenzoïn is similar to that with benzoïn, and under some circumstances the benzile derivative is formed. To obtain the deoxybenzoïn condensation product, $C_{22}H_{22}N_2$, molecular proportions of the base and of deoxybenzoïn were heated for an hour at a temperature just below the boiling point of the mixture, and the mass was dissolved in alcohol and boiled with animal charcoal. On cooling, yellow needles separate, which melt at 138—139°, dissolve in ether, and are decomposed by dilute acids into deoxybenzoïn and the base.

C. F. B.

Hydroxyaurines and their Carboxylic Acids. By N. Caro (*Ber.*, **25**, 939—949).—An extension of the method of preparing certain aurine derivatives (D. R.-P., 49970; *Ber.*, **23**, Ref. 163). *Methylenedisalicylic acid*, $CH_2[C_6H_3(OH){\cdot}COOH]_2$, is obtained by the condensation of salicylic acid (2 mols.) with formaldehyde (1 mol.) in the presence of concentrated hydrochloric acid. *Aurinetricarboxylic acid*, $O<\begin{matrix}C_6H_3{\cdot}COOH\\ |\\ C[C_6H_3(OH){\cdot}COOH]_2\end{matrix}$, is formed when a mixture of methylenedisalicylic acid (2 parts) and salicylic acid (1 part) is

stirred into one of concentrated sulphuric acid (13 parts) and sodium nitrite (1 part); it is poured into water, the precipitated compound dissolved in alkali and reprecipitated by hydrochloric acid; after again dissolving in alkali, sodium hydrogen sulphite is added until the solution is colourless, and it is neutralised with hydrochloric acid, when the sulphurous acid compound separates as a yellow powder; the latter, on heating at 100°, yields aurinetricarboxylic acid as a red powder having a metallic lustre, which is then crystallised from 50 per cent. alcohol. When its ammoniacal solution is boiled with lime-water, the *salt* $(C_{22}H_9O_9)_2Ca_5$ is obtained; whilst on the addition of calcium chloride to the same solution, the salt $(C_{22}H_{11}O_9)_2Ca_3$ separates. The *aluminium*, *calcium*, *barium*, and *magnesium* salts of this and all the aurinecarboxylic acids to be described are insoluble in water.

Methylenedisalicylic acid gives with β-resorcylic acid the *compound* $O<\begin{matrix}C_6H_2(OH)\cdot COOH\\ |\\ C[C_6H_3(OH)\cdot COOH]_2\end{matrix}$; with gallic acid, the *compound*

$$O<\begin{matrix}C_6H(OH)_2\cdot COOH\\ |\\ C[C_6H_3(OH)\cdot COOH]_2\end{matrix};$$

and with phenol, aurinedicarboxylic acid, $O<\begin{matrix}C_6H_4\\ |\\ C[C_6H_3(OH)\cdot COOH]_2\end{matrix}$; which, in spite of its containing one less carboxyl group, colours mordants. All these compounds form calcium salts corresponding with the number of carboxyl and hydroxyl groups present.

Methylenediresorcylic acid, $CH_2[C_6H_2(OH)_2\cdot COOH]_2$, is obtained by condensing β-resorcylic acid with formaldehyde in the presence of dilute hydrochloric acid; it separates from alcohol as a white, microcrystalline powder, melts at 236° with decomposition, and is insoluble in water. The hydroxyaurinecarboxylic acids obtained by condensing the last mentioned compound with salicylic, β-resorcylic, and gallic acids are briefly described.

Methylenedigallic acid, $CH_2[C_6H(OH)_3\cdot COOH]_2$, is formed from gallic acid and formaldehyde, and has been already prepared by Baeyer (this Journal, 1873, 501); it likewise condenses with hydroxy-acids and phenols, but the reactions must be conducted with cooling, as the products easily decompose.

Methylenediresorcinol, $CH_2[C_6H_3(OH)_2]_2$, produced from resorcinol and formaldehyde, separates from alcohol in white, microscopic crystals, and decomposes without melting at 250°.

Methylenedipyrogallol, $CH_2[C_6H_2(OH)_3]_2$, (Baeyer, *loc. cit.*), is obtained from pyrogallol and formaldehyde, and melts at 241° with decomposition. By condensing methylenediphenol (dihydroxydiphenylmethane) with phenol, aurine is obtained; whilst by condensing it with salicylic acid, aurinecarboxylic acid is produced.

The tinctorial properties of the aurinecarboxylic acids increase with the number of carboxyl groups which they contain; those derived from methylenedisalicylic acid colour alumina mordants red, and iron mordants violet; those from methylenediresorcylic acid colour alumina mordants orange-brown and iron brown; whilst

the introduction of the gallic acid residue into either produces a brownish shade. The aurinecarboxylic acids derived from methylenedisalicylic acid gave a dark line in the spectrum between D and *b*; whereas those derived from methylenediresorcylic acid exhibit, in addition to this, an absorption between *b* and F. The compound obtained from resorcylic acid and methylenedisalicylic acid belongs to the last-mentioned class; whilst aurinecarboxylic acid exhibits the absorption of the salicylic acid derivatives, and in addition to this an absorption in F. A. R. L.

Action of Hypochlorous Acid on β-Naphthaquinone. By E. Bamberger and M. Kitschelt (*Ber.*, **25**, 888—898; compare this vol., p. 494).—It was previously stated (*loc. cit.*) that an acid (m.p. 203°) is obtained when β-naphthaquinone is treated under certain conditions with hypochlorous acid. The experiments to be described show that this acid is the *δ-lactone* of *orthocarboxyphenylglyceric acid*, $C_6H_4<\begin{matrix}CO\text{---}O\\CH(OH)\end{matrix}>CH\cdot COOH$. It is prepared by passing the chlorine from manganese dioxide (125 grams) and hydrochloric acid (1250 grams) into a solution of sodium carbonate (375 grams) in water (1250 grams), adding finely powdered β-naphthaquinone (12·5 grams) with agitation, and after five minutes acidifying with hydrochloric acid, evaporating the solution to half, and extracting it with ether. The pure compound crystallises in rhombic tables, melts at 204·5°, gives an intensive lemon-yellow colour with ferric chloride, reduces ammoniacal silver solution slowly at 100°, and when heated at 225—230° yields another acid, melting at the same temperature as that obtained by heating it with hydrochloric acid (see below), but it is not identical with it. When treated with alkali at the ordinary temperature, it behaves as a monobasic acid; whilst at 100°, salts of ortho-carboxyphenylglyceric acid, $COOH\cdot C_6H_4\cdot[CH(OH)]_2\cdot COOH$, are obtained, but these are reconverted into salts of the lactonic acid if their aqueous solutions are left for a time. When silver nitrate is added to a cold ammoniacal solution of the lactonic acid, the silver salt of the latter separates as a white precipitate soluble in boiling water; whilst at 100° the silver salt of orthocarboxyphenylglyceric acid is precipitated as a white, flocculent precipitate. The *acetyl* derivative, $C_6H_4<\begin{matrix}CO\text{---}O\\CO(OAc)\end{matrix}>CH\cdot COOH$, crystallises in white needles, and yields a soluble silver salt crystallising in lustrous needles. When orthocarboxyphenylglyceric lactone is heated with hydriodic acid and phosphorus at 160°, orthocarboxyhydrocinnamic acid (see Abstr., 1888, 712) is formed; whilst *othocarboxy-α-hydroxycinnamic lactone*, $C_6H_4<\begin{matrix}CO\cdot O\\CH:C\cdot COOH\end{matrix}$, is produced by heating it at the same temperature with concentrated hydrochloric acid. The latter crystallises in long needles, melts at 237°, is readily soluble in hot water, sparingly in cold, does not react with acetic chloride, and reduces ammoniacal silver solution when heated with it, forming a mirror. Like the last described lactonic acid, it neutralises two equivalents of alkali at 100°,

but one only at the ordinary temperature. It is readily reduced by sodium amalgam, and is oxidised by alkaline permanganate. The above described lactonic acids have been recently obtained in a similar manner by Zincke (this vol., p. 720), who has, however, interpreted his results differently (compare also this vol., p. 859).

A. R. L.

Tetrachlororthodiketohydronaphthalene, its Hydrates and Alcoholates. By T. Zincke and T. Arnst (*Annalen*, **267**, 319—341; compare Abstr., 1188, 489).—The hydrate of tetrachlororthodiketohydronaphthalene, $C_{10}H_4Cl_4O_2,H_2O$, begins to melt at 82—83°, and at 100° the turbid liquid froths a little and becomes quite clear. The *dihydrate*, $C_{10}H_4Cl_4O_2,2H_2O$, crystallises in long, colourless needles and melts at about 90°; the trihydrate begins to melt at about 89°, the turbid liquid frothing up and becoming quite clear at 100°. The ethylate, $C_{10}H_4Cl_4O_2,EtOH + \frac{1}{2}H_2O$, crystallises unchanged from boiling light petroleum in long needles, and melts at 103—105°, with effervescence. The *methylate*, $C_{10}H_4Cl_4O_2,MeOH + \frac{1}{2}H_2O$, crystallises from light petroleum in long, colourless needles, melts at 88—89°, and decomposes over sulphuric acid.

Ethyl tetrachloro-α-hydroxyhydrindenecarboxylate,

$$CCl_2<\begin{matrix}C_6H_4\\CCl_2\end{matrix}>C(OH)\cdot COOEt,$$

is formed when the ethylate just referred to is treated with 10 per cent. sodium carbonate at the ordinary temperature. It separates from hot alcohol in colourless, transparent, seemingly monoclinic crystals, melts at 163°, and is readily soluble in ether, but only sparingly in light petroleum. The *acetyl* derivative, $C_{14}H_{12}Cl_4O_4$, separates from hot alcohol in compact crystals, melting at 119—120°. When the ethyl salt is boiled with dilute sulphuric acid, it is converted into dichloroketohydroxyhydrindenecarboxylic acid (*loc. cit.*), a crystalline compound melting at 130° with effervescence; on heating the ethyl salt with concentrated nitric acid, it is converted into *ethyl dichloroketohydroxyhydrindenecarboxylate*, $C_{12}H_{10}Cl_2O_4$, a compound which forms small, lustrous crystals, and melts at 100°.

Methyl tetrachloro-α-hydroxyhydrindenecarboxylate, $C_{11}H_8Cl_4O_3$, separates from a mixture of ether and light petroleum in colourless crystals, melts at 130—131°, and is readily soluble in methyl or ethyl alcohol; on treatment with concentrated nitric acid, it yields methyl dichloroketohydroxyhydrindenecarboxylate (m.p. 124—125°).

Tetrachloro-α-hydroxyhydrindenecarboxylic amide, $C_{10}H_7Cl_4O_2N$, is formed when anhydrous ammonia is passed into an ice-cold benzene solution of tetrachlororthodiketohydronaphthalene; it crystallises from alcohol in colourless needles, melts at 189° with decomposition, and is readily soluble in alcohol and ether, but only sparingly in benzene. The *acetyl* derivative is very unstable, and melts at about 179°. When the amide is heated with dilute sulphuric acid, it is converted into dichloroketohydroxyhydrindenecarboxylic acid, but with hot nitric acid it yields dichlorodiketohydrindene. The amide is completely decomposed by water at 120° yielding dichloroketoindene and the *amide* of dichloroketohydroxyhydrindenecarboxylic

acid; the last named compound crystallises from alcohol in colourless needles, melts at 246° with decomposition, and is only sparingly soluble in cold alcohol, and almost insoluble in ether and water.

F. S. K.

Action of Bleaching Powder and Hypochlorous Acid on Quinones. By T. Zincke (*Ber.*, **25**, 1168—1180).—The author, in conjunction with O. Scharfenberg (this vol., p. 720), has described two compounds, $C_{10}H_6O_4$ and $C_{10}H_8O_5$, obtained by the action of bleaching powder on β-naphthaquinone. The former is a dihydroxynaphthaquinone; the latter the δ-lactone of orthophenylglycerolcarboxylic acid. The author has now obtained an intermediate compound of the formula $C_{10}H_8O_4$, and believes it to be dihydroxydiketotetrahydronaphthalene.

Dihydroxydiketotetrahydronaphthalene, $C_6H_4<\begin{matrix}CO\text{——}CO\\ CH(OH)\cdot CH\cdot OH\end{matrix}$, is obtained by adding a solution of bleaching powder (110—115 c.c.) containing 3·6 per cent. of hypochlorous acid to β-naphthaquinone (10 grams) suspended in water (200 c.c.). The quinone rapidly dissolves, and the solution is then filtered and extracted with ether. On concentrating the ethereal solution, the compound is obtained pure. It crystallises in white needles, which turn red on exposure to air, melts at 95—96°, is easily soluble in alcohol, acetic acid, and hot water, more sparingly in cold water and ether, and very sparingly in light petroleum, chloroform, and benzene. When heated in the presence of mineral acids, it is partly converted into dihydroxynaphthaquinone; with bleaching-powder solution, it yields the acid $C_{10}H_6O_5$. It has remarkable reducing properties, precipitates silver from a solution of silver nitrate, and reduces ferric chloride and potassium ferricyanide. When heated in a current of hydrogen at 100—103°, 1 mol. of water is evolved and a compound is obtained which is reconverted into the dihydroxydiketone when treated with water. It is not attacked by acetic chloride in the cold, and, when heated with it, is converted into a compound which melts at 131—132°, and yields hydroxynaphthaquinone on treatment with soda. It dissolves in dilute sodium hydroxide to a colourless solution which very rapidly turns reddish-brown, and then deposits the sodium salt of hydroxynaphthaquinone. When treated with aniline in cold alcoholic solution, it yields anilido-α-naphthaquinone (m. p. 190°). When treated with aniline in acetic solution, it yields anilidonaphthaquinoneanilide (m. p. 179—180°). With toluylenediamine it yields two eurhodoles.

The *eurhodole* $C_6H_4<\begin{matrix}CO\cdot C=N\\ CH:C\cdot NH\end{matrix}>C_7H_6$ is obtained by adding the calculated quantity of toluylenediamine hydrochloride to an aqueous solution of the diketone. It crystallises from benzene in slender, white needles, melts at 183—184°, and does not form salts either with acids or with alkalis.

The *eurhodole* $C_6H_4<\begin{matrix}C(OH):C—N\\ CH=\!=C—N\end{matrix}>C_7H_6$ is obtained by heating the preceding eurhodole with acetic acid or dilute hydrochloric acid.

It forms slender, yellow needles, melts at 169—170°, is easily soluble in alcohol and benzene, and forms salts both with acids and with alkalis.

The *oxime*, $C_6H_4<\begin{matrix}CO\cdot C:N\cdot OH\\ CH:C\cdot OH\end{matrix}$ or $C_6H_4<\begin{matrix}CO--C:N\cdot OH\\ C(OH):CH\end{matrix}$, is obtained by adding excess of an aqueous solution of hydroxylamine hydrochloride to a concentrated, alcoholic solution of the diketone. It crystallises in slender, lustrous, yellow needles, is easily soluble in alcohol and ether, sparingly so in benzene and light petroleum, melts about 152—155° with a violent explosion, and is decomposed by boiling water and by cold, aqueous soda. E. C. R.

Action of α- and β-Naphthylamine on Ethyl Bromosuccinate. By C. Hell and R. Poliakoff (*Ber.*, **25**, 965—972).—When ethyl bromosuccinate and α-naphthylamine are mixed together in the proportion of 1 mol. of the former to rather more than 2 mols. of the latter, and the mixture heated to 100°, a reaction quickly takes place with separation of a solid substance. The latter, after removal of the liquid portion and washing with ether, consists of α-naphthylamine hydrochloride, mixed with a greenish-grey powder, the quantity of which increases when a larger proportion of naphthylamine is employed, or when the heating is continued for a longer time. The oily product solidifies after a time, and on recrystallisation from alcohol forms stellate groups of needles melting at 150°, which are insoluble in water, sparingly soluble in ether and light petroleum, more readily in chloroform. It consists of *ethyl α-naphthylamidosuccinate*, $COOEt\cdot CH(NH\cdot C_{10}H_7)\cdot CH_2\cdot COOEt$, and dissolves in concentrated acids, but is reprecipitated by water. When heated with an excess of alcoholic potash, it is decomposed, but, with the theoretical quantity at 40—50°, it yields the corresponding potassium salt as a voluminous crystalline powder, which, on treatment with acids, yields free *α-naphthylamidosuccinic acid* or *α-naphthylaspartic acid*, $COOH\cdot CH(NH\cdot C_{10}H_7)CH_2\cdot COOH$. This forms a white, crystalline powder, which melts at 210° with decomposition, and dissolves readily in alcohol and chloroform, but only sparingly in water and benzene; *barium* and *calcium* salts form white, crystalline powders.

When the ethyl salt is treated with α-naphthylamine, or when a large excess of the latter is heated with ethyl bromosuccinate, considerable quantities of the *dinaphthylamide* of *α-naphthylamidosuccinic acid*, $C_{10}H_7\cdot NH\cdot CO\cdot CH(NH\cdot C_{10}H_7)CH_2\cdot CO\cdot NH\cdot C_{10}H_7$, are formed, together with the green substance previously mentioned, which consists of the compound $COOEt\cdot CH(NH\cdot C_{10}H\text{-})CH_2\cdot CO\cdot NH\cdot C_{10}H_7$.

The former is separated by treatment with cold alcohol, and crystallises in silvery needles or plates which melt at 276—277° with decomposition. The second compound may be obtained pure by recrystallisation from boiling absolute alcohol, but retains its green colour; it melts at 223° with decomposition.

β-Naphthylamine reacts in a similar manner with ethyl bromosuccinate; the *ethyl β-naphthylamidosuccinate* forms an oil which boils with slight decomposition at 108° under a pressure of 20 mm. When carefully hydrolysed, it yields the corresponding *β-naphthylamidosuc-*

cinic acid, which is much less stable than the α-acid, and becomes brown in the air, especially in presence of acids and alkalis; it melts with decomposition at 189°. By the further action of β-naphthylamine the *ethyl mononaphthylamide* and the *dinaphthylamide* are obtained; the former is a yellow, microcrystalline powder which melts at 215° with decomposition; the latter forms golden plates, and melts at 250° with decomposition. H. G. C.

Homonucleal Amidonaphthols and Related Derivatives. By E. Grandmougin and O. Michel (*Ber.*, **25**, 972—985).—In consequence of the recent communications of Heermann (Abstr., 1891, 1379) and Seidel (this vol., p. 721) on the above subject, the authors publish the results they have obtained in the same field, although these are not yet completed.

1 : 2-Nitronaphthol, $OH{\cdot}C_{10}H_6{\cdot}NO_2$ [OH : NO_2 = 1 : 2], is best prepared by oxidising finely divided 1 : 2-nitrosonaphthol with nitric acid according to the method of Stenhouse and Groves (this Journal, 1877, ii, 51); the product is distilled in a current of steam, 1 : 2-nitronaphthol passing over in a state of purity. Its *silver* salt, $C_{10}H_6NO_3{\cdot}Ag$, forms a voluminous, red precipitate, and its *acetyl* derivative $OAc{\cdot}C_{10}H_6{\cdot}NO_2$ large, pale-yellow needles, which yield salts of the nitronaphthol on treatment with alkalis.

1 : 2-*Amidonaphthol*, $OH{\cdot}C_{10}H_6{\cdot}NH_2$, is formed by the reduction of 1 : 2-nitronaphthol and of orthohydroxyazo-derivatives of α-naphthol, but is best prepared according to the method of Liebermann and Jacobsen (Abstr., 1882, 521) by reducing 1 : 2-nitrosonaphthol with stannous chloride and hydrochloric acid, removing the tin by hydrogen sulphide, evaporating, and filtering from oxidation products. The hydrochloride separates out on cooling, and is purified by dissolving in boiling water, and reprecipitating with concentrated hydrochloric acid, a little sulphurous acid being also added. The impure salt quickly undergoes decomposition, and does not react smoothly with reagents; on acetylation, it yields a mixture of different products. The ethers of 1 : 2-amidonaphthol may be obtained by the method of Heermann (*loc. cit.*), or by the reduction of the ethers of orthohydroxyazo-compounds of α-naphthol; they are well crystallised substances, are volatile with steam, and yield diazo-compounds which combine with alkaline phenol solutions, forming beautiful, red colouring matters.

1 : 4-Amidonaphthol was prepared by the method already described by Seidel (*loc. cit.*), the stannous chloride being obtained by dissolving the requisite quantity of tin in hydrochloric acid, which avoids the difficulties often experienced owing to the employment of oxidised or adulterated tin salts. The crude hydrochloride is purified in the same manner as the hydrochloride of the 1 : 2-compound. Unlike the latter, 1 : 4-amidonaphthol yields well crystallised derivatives, the reactions proceeding very smoothly; nitrous acid gives, however, no trace of a diazo-compound, but converts it at once into α-naphthaquinone with evolution of nitrogen, the yield of the quinone being very satisfactory; 1 : 4-diamidonaphthalene is acted on by nitrous acid in the same manner, no diazo-derivatives being formed. *Diacetyl-*

1 : 4-*amidonaphthol*, $OAc{\cdot}C_{10}H_6{\cdot}NHAc$, is the sole product of the action of acetic anhydride and sodium acetate on 1 : 4-amidonaphthol hydrochloride; it forms white, prismatic crystals, melts at 158°, sublimes even at 110°, and is insoluble in alkalis.

1 : 4-Nitronaphthol ethyl ether was prepared by the authors in the manner which has also been recently described by Heermann, whose description they confirm. On reduction, it yields the corresponding 1 : 4-*amidonaphthol ethyl ether* $OEt{\cdot}C_{10}H_6{\cdot}NH_2$, the hydrochloride of which forms well-developed crystals. The same compound may be also obtained by the reduction of paraphenylazo-α-naphthol ethyl ether, which is interesting as showing that in these ethers the ethyl group is combined with the oxygen (compare Goldschmidt and Brubacher, Abstr., 1891, 1209). The amido-compound readily yields diazo-derivatives, which combine with phenols to form reddish-violet colouring matters.

2 : 1-Amidonaphthol is most readily prepared by the reduction of Orange II (β-naphtholazobenzeneparasulphonic acid) with stannous chloride and hydrochloric acid. The hydrochloride separates in an almost pure condition on cooling in the form of lustrous, white crystals which rapidly become violet; they may be further purified by precipitation from aqueous solution with concentrated hydrochloric acid. On oxidation, this compound, as is well known, yields β-naphthaquinone, which is most readily prepared in this manner, the freshly prepared amidonaphthol hydrochloride (which need not be dried) being mixed with dilute sulphuric acid and poured into a solution of potassium dichromate; the β-naphthaquinone separates out in a pure condition, and is filtered off and dried at the ordinary temperature. 200 grams of Orange II yield 55 grams of β-naphthaquinone, or 60 per cent. of the theoretical quantity. The filtrate contains considerable quantities of phthalic acid.

Nitrous acid also converts 2 : 1-amidonaphthol into β-naphthaquinone without formation of an intermediate diazo-compound; with acetic anhydride and sodium acetate, it yields a mixture of acetyl derivatives, the *diacetyl* derivative being the chief product; smaller quantities of the acetylamido-β-naphthol $OH{\cdot}C_{10}H_6{\cdot}NHAc$, described by Böttcher (Abstr., 1883, 1113), are also obtained. H. G. C.

Products of the Reduction of Alkylated Azo-Colours of the Naphthalene Series. By O. N. Witt and C. Schmidt (*Ber.*, **25**, 1013—1019).—The methyl and ethyl ethers of anilineazo-α-naphthol may be readily prepared according to the method described by Zincke and Bindewald (Abstr., 1885, 391); in addition to the properties there mentioned, these ethers are distinguished by the fact that they dissolve in sulphuric acid or alcoholic hydrochloric acid with a reddish-violet coloration, which changes in a short time to deep-blue, owing to the elimination of the alkyl group and formation of the phenol.

When the ethyl ether is treated with stannous chloride and hydrochloric acid in presence of alcohol, it is not converted into aniline and ethoxy-α-naphthylamine, but yields a mixture of two bases, which can be separated by fractional crystallisation of the hydro-

chlorides. The base which yields the more easily soluble hydrochloride will be described in a later communication. The less soluble hydrochloride, on treatment with ammonia, yields the free base, which crystallises from alcohol in snow-white, nacreous plates, melts at 167°, and shows a greyish-green fluorescence in dilute alcoholic solution. It has the composition $C_{18}H_{18}N_2O$, and the authors at first believed that the hydrazo-compound had been formed, and had then undergone the intramolecular change corresponding to the formation of benzidine from hydrazobenzene, in which case it would be an ethoxydiamidophenylnaphthalene,

$$OEt\cdot C_{10}H_5(NH_2)\cdot C_6H_4\cdot NH_2 \ [OEt : C_6H_4\cdot NH_2 : NH_2 = 1 : 3 : 4].$$

The behaviour of the base towards oxidising agents, however, renders this view impossible, for nitric acid converts it into the bright-red compound, α-naphthaquinoneanilide, $C_{10}H_5O_2\cdot NHPh$ [O : O : NHPh = 1 : 4 : 3], and nitrous acid yields a mixture of the same compound with a colourless, crystalline substance, having the composition $C_{18}H_{15}N_3O$. The formation of the first-named derivative is most easily explained by supposing that, instead of the benzidine intramolecular change, the hydrazo-compound first formed is converted into an amidophenylnaphthylamine derivative, namely, *ethoxyphenyl-orthodiamidonaphthalene*, $OEt\cdot C_{10}H_5(NH_2)\cdot NHPh$ [OEt : NH_2 : NHPh = 1 : 4 : 3] (compare Jacobsen and Fischer, this vol., p. 839; Täuber, this vol., p. 853). This also explains the formation of the compound $C_{18}H_{15}N_3O$, which would be the azimide, $OEt\cdot C_{10}H_5<^{NPh}_{\ \ N}>N$; it crystallises in vitreous rhombohedra or needles, and melts at 160°. In order to further characterise it as an orthodiamido-derivative, it was boiled with formic acid, and thus converted into the *methenyl* derivative, $OEt\cdot C_{10}H_5<^{NPh}_{\ \ N}>CH$, which crystallises in needles melting at 184—186°. Further it unites with benzile in presence of acetic acid, forming *ethoxyphenylnaphthostilbazonium hydroxide*, the *chloride* of which, $OEt\cdot C_{10}H_5<^{NPhCl\cdot CPh}_{N\text{———}CPh}$, crystallises in glistening yellow needles, fairly soluble in water and readily in alcohol, forming pure yellow solutions; these show a remarkable, luminous green fluorescence. The *nitrate* is very sparingly soluble, and the free *hydroxide* forms pale-yellow crystals.

Paratoluidineazo-α-naphthol may be converted into the methyl and ethyl ethers by the action of alcoholic potash and methyl iodide or ethyl bromide. The *methyl* ether forms red prisms, melting at 100—101°, and the *ethyl* ether melts at 125°. The yield of these compounds is not nearly so good as with the ethers of aniline-azo-α-naphthol; but on reduction they only yield a single base, and not a mixture of two bases, as is the case with the derivatives of the latter compound. H. G. C.

Oxidation of Acenaphthene. By C. Graebe and E. Gfeller (*Ber.*, **25**, 652—657).—A description is given of the details by observing which an almost theoretical yield of naphthalic acid may

be obtained when acenaphthene is oxidised with potassium dichromate and acetic acid.

After this acid has been removed from the product of the reaction by digesting with 5 per cent. aqueous soda, *acenaphthenequinone*, $C_{10}H_6<\overset{CO}{CO}>$ [CO : CO = 1 : 1′], may be extracted with a hot solution of sodium hydrogen sulphite, and precipitated from this solution by the addition of acids. It crystallises and sublimes in fine, yellow needles, melts at 261°, and dissolves in benzene and acetic acid. When it is boiled with 30 per cent. aqueous potash, and a mineral acid added to the solution, a monobasic acid, $C_{12}H_8O_3$, is precipitated, which, unlike naphthalic acid, dissolves in carbonates in the cold, even after being heated to its melting point. It melts at 172°, crystallises from alcohol in needles, is converted by oxidation into naphthalic acid, and forms characteristic compounds with phenylhydrazine and hydroxylamine. It is therefore probably either

$$CHO\cdot C_{10}H_6\cdot COOH \quad \text{or} \quad C_{10}H_6<\overset{CH(OH)}{CO}>O.$$

Naphthalaldehydic acid. Oxynaphthalide.

It yields a *monacetyl derivative* when heated with acetic anhydride at 180°. That acenaphthenequinone reacts with potash in a different manner from phenanthraquinone, &c., is explained from stereochemical considerations.

A *diketone*, probably $C_{10}H_6<\overset{CO\ CO}{C=C}>C_{10}H_6$, is obtained by crystallising from chloroform the residue left after extraction with sodium hydrogen sulphite. It forms orange needles which melt at 294°, and after sublimation resemble alizarin. It dissolves but sparingly in benzene and acetic acid, takes up two atoms of bromine, yields a derivative $C_{24}H_{12}O.N_2HPh$, with phenylhydrazine, and is oxidised by dichromate and acetic acid to naphthalic acid. C. F. B.

Preparation of β-Alizarinamide. By C. Lauth (*Bull. Soc. Chim.* [3], **6**, 836).—Nitroalizarin (1 part) is dissolved in dimethylaniline (4 parts), to which either syrupy dimethylaniline chloride (1 part) or hydrochloric acid (0·75 part) is added, and the mixture is heated gradually to 150°, until the product dissolves with a pure blue colour in aqueous soda. The product, after treatment with hot dilute hydrochloric acid to remove excess of dimethylaniline, is dissolved in hot dilute sodium hydroxide solution, leaving a slight residue of a brown oxidation product of dimethylaniline, and the amidoalizarin is precipitated from the alkaline solution by hydrochloric acid. Nitroalizarin is reduced more slowly when similarly treated either with aniline or dimethylaniline in presence of sulphuric acid.

T. G. N.

Constitution of Turpentine and Camphor. By J. N. Collie (*Ber.*, **25**, 1108—1118).—In this paper an attempt is made to suggest formulæ for turpentine, camphor, and camphoric acid, which shall show the connection of these compounds with one another, and at the

same time explain as far as possible the known reactions and decompositions of these substances.

The following formula suggested for turpentine (pinene):—

is one which agrees well with the properties of that substance; such as the formation of cymene from pinylamine and pinyl dichloride, also the production of pinol, terpenylic acid, and terebic acid by oxidation. It contains a 6-carbon ring, but yet should behave also as an ethylenic hydrocarbon; at the same time it is capable of showing the conversion of pinene into camphor and camphoric acid.

Pinene.

Pinene hydrochloride.

Camphene.

This formula differs from that proposed by Wallach in that it contains *no ethylenic bond*. This is in agreement with the optical and other physical properties of camphene.

The conversion into camphor is explained as follows:—

Camphene.

Camphene hydrochloride.

Intermediate product.

Borneol.

Camphor.

This formula accounts for the formation of such substances as paracymene, metacymene, dimethylethylbenzene, carvacrol, orthocresol, &c., from camphor.

During the oxidation of camphor to camphoric acid a considerable change in the molecule is assumed to take place in order to harmonise with the idea that camphoric acid is a hexamethylene derivative.

Camphor

Camphoric acid.

By using exactly the same molecular rearrangement as that employed above, the author shows how camphoic acid (by oxidation of camphene), cineolic acid (by the oxidation of cineol), and campholic acid (from camphor), may all possibly be hexamethylene derivatives. J. N. C.

Menthol. By A. Berkenheim (*Ber.*, **25**, 686—698).—When menthol, $C_{10}H_{19}OH$, is added in successive small portions to a carefully cooled mixture of phosphoric chloride and light petroleum, there is formed from 100 grams of menthol (1) 70 grams of *menthyl chloride*, $C_{10}H_{19}Cl$, an optically inactive liquid boiling at 209·5—210·5° (uncorr.), and having the sp. gr. at 0°/0° = 0·9565 and at 15°/15° = 0·947, and (2) 15 grams of a menthene, $C_{10}H_{18}$, boiling at 167—169° (uncorr.). This menthene, when warmed with phosphoric chloride, yields a *chloride*, $C_{10}H_{17}Cl$, boiling at 204—208°. Menthyl chloride is not affected by zinc and hydrochloric acid, and is converted by zinc-dust and acetic acid into the above-mentioned menthene; but it is reduced when heated for 30 hours at 200° with hydriodic acid and phosphorus in a sealed tube. *Menthonaphthene*, $C_{10}H_{20}$, boiling at 169—170·5°, is thus obtained. It is an inactive liquid, possessing only a feeble odour when pure, and the sp. gr. at 0°/0° = 0·8067 and at 15°/15° = 0·796. It does not take up bromine, is not attacked by strong sulphuric or nitric acid at the ordinary temperature, gives when heated with fuming nitric acid a liquid nitro-derivative, and with bromine and aluminium bromide a viscid bromide. If the heating in the sealed tube is continued for only 15—20 hours, some *menthyl iodide*, $C_{10}H_{19}I$, is also obtained; this, when not quite pure, boils at 140—143° under 30 mm. pressure, and has a sp. gr. at 15°/15° = 1·357. When chlorine is allowed to react with the vapours of menthonaphthene, an inactive liquid is obtained, volatile with steam, boiling at 208—210°, and with a sp. gr. at 0°/0° = 0·9553. It would seem to be identical with the above-mentioned menthyl chloride. When menthyl chloride (70 grams) is heated with potassium acetate and acetic acid for 20 hours in a sealed tube at 150°, some (20 grams) is left unaltered, and some menthene, $C_{10}H_{18}$ (25 grams), is formed. This menthene boils at 170—171°, has sp. gr. at 0°/0° = 0·8287 and at 20°/20° = 0·816, and refractive index $[n]_D$ = 0·145359 at 20°, corresponding with a molecular refraction of 45·06 (theory for one double bond = 45·65, for two 47·34). It oxidises readily in the air. But whilst the menthene obtained from menthol is dextrorotatory with a maximum rotation of +20°, this menthene, obtained from inactive menthyl chloride, is lævorotatory (in a thickness of 200 mm. $[\alpha]_D$ = −56°), and the menthyl chloride which, as mentioned above, was not converted into menthene, is found to be no longer inactive, but is now lævorotatory (in a thickness of 200 mm. $[\alpha]_D$ = −62°). The inactive menthyl chloride must thus have consisted of a mixture of dextro- and lævo-rotatory varieties, and the former was converted into lævorotatory menthene, while the latter was unattacked. By further heating with potassium acetate and acetic acid, it may, however, be converted into a dextrorotatory menthene boiling at 167—169°; in a thickness of 50 mm. $[\alpha]_D$ = +28°.

Menthone, $C_{10}H_{18}O$, was prepared by the action of chromic acid on menthol in acetic acid solution, and warmed with phosphoric anhydride. A diterpene, $C_{20}H_{32}$, was obtained, together with a hydrocarbon $C_{10}H_{18}$ which was not isolated. The diterpene is a very viscid, fluorescent, inactive liquid boiling at 320—325°; it takes up bromine and hydrochloric acid, and yields a yellowish, amorphous nitroproduct when treated with fuming nitric acid. When menthone is added in successive small portions to a cooled mixture of phosphoric chloride and light petroleum, a *monochloride*, $C_{10}H_{17}Cl$, and a *dichloride*, $C_{10}H_{18}Cl_2$, are obtained. The monochloride boils at 205—208°, has the sp. gr. at 0°/0° = 0·9833 and at 15°/15° = 0·970, and is lævorotatory; in a thickness of 50 mm. $[\alpha]_D = +30°$, of 75 mm. $[\alpha]_D = +45°$. The dichloride boils at 150—155° under 60 mm. pressure, and has the sp. gr. at 0°/0° = 1·0824. The monochloride is doubtless formed from the dichloride by the loss of a molecule of hydrochloric acid, but it was not found possible to remove the second molecule from the monochloride. When bromine is added to a cooled acetic acid solution of menthene, *menthene dibromide*, $C_{10}H_{18}Br_2$, is formed. It is a rather viscid oil, boiling at 167—172° under 50 mm. pressure, and with the sp. gr. at 0°/0° = 1·4453. When it is heated with alcoholic potash for 15 hours on the water-bath, a hydrocarbon $C_{10}H_{16}$ is obtained. This boils at 172—174° (uncorr.), has an odour like that of limonene, and the sp. gr. at 0°/0° = 0·8540 and at 20°/20° = 0·8408; it unites with bromine and hydrochloric acid.

Terpine hydrate, $C_{10}H_{20}O_2 + H_2O$, was heated for 20 hours with strong hydriodic acid on the water-bath. The products were an *iodide*, $C_{10}H_{19}I$, a *diterpene*, $C_{20}H_{32}$, and possibly a hydrocarbon, $C_{10}H_{18}$, boiling at 167—170°. The diterpene boils at 320—325°, has the sp. gr. at 0°/0° = 0·9521 and at 20°/20° = 0·9428, and resembles very closely in its properties and reactions the diterpene obtained from menthone. The iodide is an oil with an odour like that of the naphthene iodides; it boils at 138—142° under 30 mm. presssure, and has the sp. gr. at 15°/15° = 1·370. When it is treated with silver acetate, ether added, and the whole allowed to remain for two days, an acetate is obtained, and a hydrocarbon, $C_{10}H_{18}$, boiling at 168—170°. This latter has at 21° sp. gr. = 0·813 and refractive index $[n]_D = 1·45339$, corresponding to a molecular refraction of 45·89 (theory for one double bond 45·64). The acetate was hydrolysed by warming it with the theoretical amount of alcoholic potash on the water-bath. The alcohol, $C_{10}H_{20}O$, thus obtained boils at 210—214°, and has an odour like that of menthol, but it cannot be got to solidify. It is inactive, and has the sp. gr. at 0°/0° = 0·9151 and at 15°/15° = 0·9063.

Menthol has thus been shown to be connected with the naphthenes; the particular naphthene obtained from it must have a ring of 6 carbon atoms, since menthol can be converted into cymene. It is also connected with the terpenes, for terpine hydrate yields an alcohol, $C_{10}H_{20}O$, much resembling menthol; and, further, from menthol has been obtained a hydrocarbon, $C_{10}H_{16}$, which possesses the properties of a terpene. C. F. B.

Oxygen Compounds of Ethereal Oils. By F. W. Semmler and F. Tiemann (*Ber.*, **25**, 1180—1188).—The authors have come to the conclusion that the characteristic odour of many ethereal oils is not entirely dependent on the terpene or camphor-like constituents which they contain; but that alcohols, ethereal salts, aldehydes, and ketones of the aliphatic series essentially influence the odour. They have accordingly commenced a research on these aliphatic compounds.

Oil of bergamot is composed of the following constituents:—Limonene, 40 per cent.; dipentene, 10 per cent.; linaloöl, 25 per cent.; linaloöl acetate, 20 per cent.; and bergaptene, 5 per cent. A preparation, which smells exactly like oil of bergamot, cannot be obtained by mixing the above compounds, as the odour of the oil is influenced by the very slight quantity of other compounds which it contains. Oil of bergamot yields a small quantity of a crystalline compound when treated with sodium hydrogen sulphite. It cannot be distilled at the ordinary pressure, but under 15 mm. boils without decomposition until the bergaptene begins to distils over. At 60—65°, almost pure limonene comes over; at 77—82°, dipentene; at 87—91°, linaloöl (Abstr., 1891, 539); and at 99—105°, linaloöl acetate.

Linaloöl acetate, $C_{10}H_{17}\cdot OAc$, has a sp. gr. 0·8951 at 20°/20°, is lævorotatory, and has the characteristic odour of oil of bergamot. It is easily hydrolysed with alcoholic potash, and the linaloöl may be extracted from the mixture with ether. Linaloöl so obtained boils at 88—90° under 15 mm., and has a sp. gr. 0·8724 at 20°/20°.

"Oil of petitgrain" has a sp. gr. 0·8891 at 20°/20°, and consists of aurantiol acetate (about 70 per cent.), limonene, a high boiling sesquiterpene, and oxygenated compounds, which have a considerable influence on the odour. *Aurantiol acetate*, $C_{10}H_{17}\cdot OAc$, boils at 102—106° under 15 mm. pressure, and has a characteristic, pleasant odour, and sp. gr. 0·8988 at 20°/20°. *Aurantiol*, $C_{10}H_{18}O$, is obtained by heating the acetate with alcoholic potash, boils at 93—95° under 15 mm., has a sp. gr. 0·8691 at 20°/20°, directly adds on 4 atoms of bromine, and is lævorotatory; $n_d = 1·4682$.

Oil of lavender is lævorotatory, cannot be distilled at the ordinary pressure, and consists of lavendol, lavendol acetate, a small quantity of limonene, a sesquiterpene, and oxygenated compounds which greatly influence the odour. *Lavendol*, $C_{10}H_{18}O$, is the chief constituent of the oil, boils at 85—91° under 15 mm. pressure, has a sp. gr. 0·8672 at 20°/20°, is lævorotatory, and has a characteristic odour; $n_d = 1·4651$. *Lavendol acetate* forms about 10 per cent. of the oil, boils at 97—105° under 15 mm., has a sp. gr. 0·8972 at 20°/20°, and is lævorotatory. E. C. R.

Camphene and Camphoric Acid. By W. O. Wallach (*Ber.*, **25**, 916—927).—The author's experiments, and those of Wagner, have shown, in opposition to those of Brühl, that camphene is an unsaturated compound. Brühl, however (this vol., p. 625), has acknowledged the inaccuracy of his conclusions, but has raised several objections to the author's method of preparing camphene by heating bornyl chloride with aniline; the author points out, however,

that the conditions published by him were not obeyed. The melting point of camphene given by Brühl (53—54°) is too high, that previously given by the author (49°) being established.

Brühl (this vol., p. 203) puts forward tetramethylene formulæ for camphor and camphoric acid; the author states that he can find nothing in Brühl's experiments which serves for the discussion of the constitution of the compounds in question. Brühl considers that camphoric acid is an unsaturated compound, but such a view is untenable in the light of Bamberger's experiments, and the work of v. Baeyer on unsaturated acids generally. Whilst the arguments employed by Brühl can be used in support of other formulæ, there are several objections to the tetramethylene formulæ, which are not mentioned by him. Wreden has shown (this Journal, 1877, ii, 446) that two hydrocarbons, C_8H_{16} and C_8H_{14}, which he believed to be hexahydro- and tetrahydro-metaxylene, are formed by reducing camphoric acid, whereas, if it possessed a tetramethylene formula, it ought to furnish an unsaturated hydrocarbon, C_8H_{14}. The author has repeated Wreden's experiments, and isolated a saturated hydrocarbon giving numbers on analysis agreeing with the formula C_8H_{16}; it also agreed with Wreden's description of his compound, and, like the latter, yielded trinitrometaxylene (m. p. 180°) on nitration. The presence of a hydrocarbon containing less hydrogen could not, however, be decided. The author points out in conclusion that Brühl's first communications on the terpenes contained only physical experiments, and without depreciating the value of these, he considers that too much stress has been laid on them. A. R. L.

Derivatives of Santonin. By P. Gucci and G. Grassi-Cristaldi (*Gazzetta*, **22**, i, 1—55).—*Santoninamine*,

$$\begin{array}{l} NH_2\cdot CH\cdot CMe{:}C\cdot CH_2\cdot CH_2\cdot CH\text{—}CHMe. \\ \quad\quad\quad\

readily in water. It is very unstable, changing, even during crystallisation, to a yellow, insoluble compound. The *hydrochloride* obtained from the freshly prepared base crystallises from alcohol in monoclinic prisms, $a : b : c = 0{\cdot}6206 : 1 : 0{\cdot}2418$; $\beta = 82° 52' 30''$, melts at 199°, and dissolves readily in water. On heating the aqueous solution to 100°, it decomposes, hyposantonin being formed. It is lævogyrate, $[\alpha]_D = -136{\cdot}83$. The *platinochloride*,

$$(C_{15}H_{21}NO_2)_2,H_2PtCl_6,$$

forms tabular or acicular, orange-red crystals, or occurs in the amorphous condition.

On heating santoninamine or one of its salts with nitrous acid, hyposantonin is formed, with evolution of nitrogen. The reaction may be represented by the equation $C_{15}H_{21}NO_2 + HNO_2 = N_2 + 2H_2O + C_{15}H_{18}O_2$, but a compound $C_{15}H_{20}O_3$, containing 1 mol. H_2O more than hyposantonin, is probably formed as an intermediate product. In aqueous solutions, santoninamine remains unaltered in the cold, but, on warming, it is entirely split up into hyposantonin and ammonia. Aqueous solutions of its salts are likewise stable in the cold, but begin to decompose at 60°

Hyposantonin, $\begin{matrix} CH\cdot CMe{:}C\cdot CH_2\cdot CH_2\cdot CH\text{—}CHMe \\ \| \quad\quad\quad\quad\quad\quad\quad\quad | \quad | \\ CH\cdot CMe{:}C\text{————}CH\cdot O\cdot CO \end{matrix}$, has already been described (Abstr., 1890, 904); it melts at 152—153°, and crystallises in rhombic tables, $a : b : c = 0{\cdot}718 : 1 : 1{\cdot}36$. It is dextrorotatory, $[\alpha]_D = +32{\cdot}37$ to $+32{\cdot}71$. In alkaline solutions, hyposantonin changes slowly in the cold, and rapidly on heating into hyposantonic acid, of which it appears to be the lactone.

Hyposantonic acid, $\begin{matrix} CH\cdot CMe{:}C\cdot CH_2\cdot CH_2\cdot CH\cdot CHMe\cdot COOH \\ \| \quad\quad\quad\quad\quad\quad\quad\quad | \\ CH\cdot CMe{:}C\text{————}CH\cdot OH \end{matrix}$, is best prepared by pouring a boiling alcoholic solution of hyposantonin into boiling baryta-water, and decomposing the cold, dilute solution of the barium salt with a slight excess of extremely dilute hydrochloric acid. When pure, the acid crystallises in large, transparent, monoclinic tables, $a : b : c = 1{\cdot}421 : 1 : 0{\cdot}954$; $\beta = 81° 47'$. It is freely soluble in strong alcohol, moderately so in ether, but only very sparingly in cold benzene or chloroform. The crystals phosphoresce with an intense green light when crushed. On treatment with acetic anhydride, the acid loses 1 mol. H_2O, and is quantitatively converted into hyposantonin. On heating the acid alone to 100°, it likewise loses 1 mol. H_2O, but the product is isohyposantonin. It is lævogyrate, $[\alpha]_D = -4{\cdot}62$.

Isohyposantonin, previously described (Abstr., 1890, 902—904), melts at 167·5—168·5, and crystallises in rhombic pyramids, $a : b : c = 0{\cdot}9127 : 1 : 1{\cdot}8148$. It is lævorotatory, $[\alpha]_D = -73{\cdot}73$.

Isohyposantonic acid, $C_{15}H_{20}O_3$, is prepared by pouring a boiling alcoholic solution of isohyposantonin into baryta-water and decomposing the barium salt with dilute hydrochloric acid. It is very unstable, and cannot be crystallised from any solvent on account of its ready conversion into isohyposantonin. Unlike the latter, it dissolves in cold, concentrated alcohol, and the solution is only slowly

decomposed. It is dextrorotatory, $[\alpha]_D = +71{\cdot}56$. The *silver* salt, $C_{15}H_{19}O_3Ag$, was also prepared. On treatment with methyl iodide, the silver salts of both hypo- and isohypo-santonic acid yield isohyposantonin.

Dihydrosantinic (dihydrodimethylnaphthylpropionic) acid,

$$\begin{matrix} CH\cdot CMe{:}C\cdot CH_2\cdot CH_2 \\ \| \quad\quad | \quad\quad | \\ CH\cdot CMe{:}C\cdot CH{:}C\cdot CHMe\cdot COOH \end{matrix}$$

and *dihydroisosantinic* acid are best prepared together by passing a current of hydrogen chloride through a solution of hyposantonin or isohyposantonin in 90 per cent. alcohol, distilling at a reduced pressure, neutralising the product with sodium carbonate, extracting with ether, and distilling. The acids are obtained pure from their barium salts, and separated by fractional crystallisation from 90 per cent. alcohol. These acids are isomeric with each other, and with the lactones from which they are prepared, all having the percentage composition corresponding with the formula $C_{15}H_{18}O_2$. Dihydrosantinic acid forms a white, crystalline powder, melts at 120—121°, and dissolves readily in cold alcohol, ether, chloroform, and benzene, but is insoluble in water. It is dextrorotatory, $[\alpha]_D = +62{\cdot}07$ to $60{\cdot}69$. Dihydroisosantinic acid is also obtained as a finely crystalline powder, melts at 96—97°, dissolves in alcohol, &c., more freely than the preceding acid, but is insoluble in water. It is inactive to light.

On treating dihydrosantinic acid with bromine in molecular proportion in carbon tetrachloride, a mixture of two isomerical monobromo-derivatives is formed; one of these crystallises in minute, colourless, hexagonal pyramids, and decomposes at 150—160°; the other crystallises in monoclinic prisms, and decomposes at 145—146°; both have the composition $C_{15}H_{17}BrO_2$. When dihydroisosantinic acid is treated with bromine in the manner described, the product consists of silky, acicular crystals which have not yet been thoroughly examined.

Santinic (dimethylnaphthylpropionic) acid, $C_{15}H_{16}O_2$, is prepared by boiling a glacial acetic acid solution of dihydrosantinic acid with a slight excess of iodine for about eight hours in a reflux apparatus. The product, after partial purification, is converted into the barium salt and decomposed with hydrochloric acid, when the pure acid is obtained. It crystallises from dilute alcohol in silky, lustrous needles, melts at 132—132·5°, dissolves readily in most organic solvents, but is insoluble in water. It is very soluble in alkalis and alkali carbonates, but is partially reprecipitated from its solutions by carbonic anhydride. On heating it above its melting point in an atmosphere of carbonic anhydride, it sublimes unaltered. The *silver* salt has the composition $C_{15}H_{15}AgO_2$; salts of the following metals —barium, calcium, strontium, magnesium, zinc, cadmium, lead, mercury, and manganese—can be obtained by precipitating their solutions with a solution of ammonium santinate. Hyposantonin or isohyposantonin may be substituted for dihydrosantinic acid in the preparation of santinic acid; when, however, isohyposantonin is used, the product is very impure. Santinic acid is dextrorotatory, $[\alpha]_D = +61{\cdot}88$ to $64{\cdot}37$. It probably has the constitution

$$\begin{array}{l} CH\cdot CMe{:}C\cdot CH{:}CH \\ CH\cdot CMe{:}C\cdot CH{:}C\cdot CHMe\cdot COOH \end{array}$$

Isosantinic acid, $C_{15}H_{16}O_2$, is obtained in a manner similar to santinic acid by the action of iodine on dihydroisosantinic acid. It melts at 132·5—133°. Its properties are the same as those of santinic acid, with the exception that it is inactive to light.

Dimethylethylnaphthalene, $C_{14}H_{16}$.—A mixture of this hydrocarbon with dimethylethyldihydronaphthalene, $C_{14}H_{18}$, is obtained on mixing dihydrosantinic or dihydroisosantinic acid (4 grams) with crystallised baryta (3 parts), drying, powdering, dehydrating at 250° in a vacuum, and distilling the residue at 260° in a vacuum. A small quantity of free hydrogen, equivalent to about one-third of the two hydrogen atoms attached to the naphthalene nucleus, passes over with the hydrocarbons. On treating the mixture with iodine, it is completely converted into dimethylethylnaphthalene, a clear, heavy, colourless, fluorescent oil which distils at 298—302°. On treating santinic and isosantinic acids in the manner described, the product consists entirely of dimethylethylnaphthalene, no hydrogen being evolved. No definite compounds could be obtained by the oxidation of either of the above hydrocarbons.

Paradimethylphthalic acid, $\begin{array}{l} CH{:}CMe\cdot C\cdot COOH \\ CH{:}CMe{:}C\cdot COOH \end{array}$—The anhydride of this acid is obtained by oxidising either of the dihydrosantinic or hyposantonic acids in alkaline solution with potassium permanganate, removing the excess of permanganate and the oxides of manganese, acidifying with sulphuric acid, and distilling. The anhydride is carried over by the steam, and a yellow, oily acid residue remains, from which a further quantity of the anhydride may be obtained by prolonged oxidation with nitric acid. It crystallises from ether in white, shining, rhombic plates, $a : b : c = 0{\cdot}425 : 1 : 0{\cdot}525$, melts at 143·5°, dissolves very sparingly in water, sparingly in absolute alcohol and ether, but very freely in light petroleum, benzene, or chloroform. In aqueous solutions, it is partly converted into the corresponding acid. It is readily soluble in hot alkaline hydrates and carbonates, and is not reprecipitated on acidification. On heating it above its melting point, it volatilises, forming a very light sublimate. On heating it with resorcinol and concentrated sulphuric acid, and making alkaline with soda or potash, a dichroic solution is obtained which is green by reflected, and brown or reddish-brown by transmitted, light. The acid is obtained by evaporating a solution of the anhydride in 90 per cent. alcohol in a vacuum in presence of paraffin. It crystallises from ether in monoclinic prisms, $a : b : c = 1{\cdot}312 : 1 : 0{\cdot}655$; $\beta = 87°\ 11'\ 46''$, melts at 96°, dissolves very freely in ether, alcohol, benzene, and chloroform, moderately in cold water, and very sparingly in light petroleum. On heating it above its melting point, it loses water and solidifies, the anhydride being formed. The *silver* salt, $C_6H_8Ag_2O_4$, forms shining crystals; the *ammonium* salt precipitates solutions of barium, magnesium, manganese, zinc, and lead.

On distilling a mixture of the anhydride with dry baryta, paradimethylbenzene passes over at about 400°.

The authors conclude by discussing the evidence for the constitutional formulæ given in the paper. S. B. A. A.

Constituents of Coto Bark. By G. Ciamician and P. Silber (*Ber.*, **25**, 1119—1138; compare Abstr., 1891, 578).—The formulæ previously suggested by the authors for hydrocotoïn and protocotoïn prove to be correct, as the trichlorinated derivative, $C_6Cl_3(OMe)_3$, on treatment with sodium in alcoholic solution, yields trimethoxybenzene [1 : 3 : 5]. The molecular weights of "dibenzoylhydrocoton" and "oxyleucotïn" are only half those indicated by the formulæ of Jobst and Hesse, since these compounds are identical with methylhydrocotoïn and methylprotocotoïn respectively. By the action of bromine in excess on methylhydrocotoïn, tribromotrimethoxybenzene [$(OMe)_3 = 1 : 3 : 5$] and benzoic acid are formed. Jobst and Hesse's "hydrocotoïn" prepared by the action of potash on "dibenzylhydrocoton" proves to be symmetrical trimethoxybenzene; the error in the vapour density determination is probably due to its being carried out at too low a temperature. Methylprotocotoïn, on treatment with bromine in excess, yields symmetrical tribromotrimethoxybenzene and piperonylic acid; the latter is converted quantitatively into 3 : 4-dihydroxybenzoic acid by fusion with potash.

The compound previously termed paracumarhydrin, obtained by the oxidation of protocotoïn, is acetopiperone, $C_6H_3Ac<^{O}_{O}>CH_2$ [O : O : Ac = 1 : 3 : 4], since, on oxidation with potassium permanganate in alkaline solution, it yields piperonylic acid and piperonylketonic acid.

On heating protocotoïn (5 grams) with potash (10 grams) and methyl alcohol (10 c.c.) in a sealed tube for 6—8 hours at 150°, a compound is obtained which crystallises from alcohol, melts at 154—154·5°, and has the formula $C_{13}H_7O_3(OMe)_3$; it is insoluble in water, dissolves in alkalis, and is reprecipitated by carbonic anhydride; a reddish-brown coloration is produced with ferric chloride, and a dark-green with nitric acid. By the action of acetic anhydride and anhydrous sodium acetate, the *diacetyl derivative*,

$$C_{13}H_5O(OMe)_3(OAc)_2,$$

is formed; it crystallises from alcohol in colourless needles, melting at 126—127°. The original compound, on treatment with methyl iodide and potash, yields a pentamethoxy-derivative,

$C_6H_2(OMe)_3{\cdot}CO{\cdot}C_6H_3(OMe)_2$ [$(OMe)_3 = 1:3:5$; $CO = 1$; $(OMe)_2 = 3:4$],

this compound crystallises from alcohol in small, colourless plates, melts at 157°, and is insoluble in alkalis. The *bromo-derivative*, $C_{13}H_4BrO(OMe)_5$, is deposited from alcohol in prisms melting at 144°; by the action of bromine in excess symmetrical tribromotrimethoxybenzene and bromoveratric acid are formed, thus proving its composition.

Two compounds are obtained by the action of potash (20 grams) and methyl alcohol (20 c.c.) on methylprotocotoïn (10 grams) for six hours at 130—140°; the one is identical with the compound described above (m. p. 154·5°); the second, which is separated by

fractional crystallisation from alcohol, melts at 180°, is soluble in alkalis with a yellow colour, and gives a greenish-yellow coloration with nitric acid; its formula is $C_{13}H_6O_2(OMe)_4$; on treatment with methyl iodide and potash, the pentamethoxy-compound (m. p. 157°); see above) is formed; the acetyl derivative crystallises from alcohol and melts at 170°.

On treating protocotoïn with potash and ethyl alcohol under pressure at 155°, an *ethoxy-derivative*,

$$OH\cdot C_6H_2(OMe)_2\cdot CO\cdot C_6H_3(OEt)\cdot OH,$$

is formed, and crystallises from alcohol in yellow prisms, melting at 150—151°; it resembles the trimethoxy-compound in general properties. The *diacetyl derivative*, $C_{13}H_5O(OMe)_2(OAc)_2\cdot OEt$, crystallises in hexagonal plates which melt at 118°. On treatment with methyl iodide and potash, a tetramethoxyethoxy-compound,

$$C_6H_2(OMe)_3\cdot CO\cdot C_6H_3(OMe)\cdot OEt,$$

is formed, melting at 162°. J. B. T.

Aristolochin. By J. Pohl (*Chem. Centr.*, 1892, i, 42—43; from *Arch. expt. Path. Pharm.*, **29**, 282—301).—*Aristolochin*, $C_{32}H_{22}N_2O_{13}$, a poisonous constituent of the seeds and roots of the Aristolochiaceæ, has been separated and examined by the author. The ground-up seeds and roots were first extracted with light petroleum, which separates an oil and a physiologically inactive substance. The residue was then exhausted with alcohol (96 per cent.), the alcohol distilled off, and the residue dissolved in water. Sulphuric acid precipitated a yellow substance, which was dried, and exhausted first with light petroleum, and then with ether or alcohol. The latter separates the aristolochin, which crystallises as the solvent evaporates. With concentrated sulphuric acid, it gives a dark-green coloration; fused with potash, the coloration is purple-red; it is precipitated by the alkalis and lead acetate; it does not reduce cupric oxide. Treated with glacial acetic acid and zinc-dust, a product is obtained which is not bitter, and the alcoholic solution of which has a green fluorescence. Aristolochin forms a crystalline salt with barium.

Physiologically it acts similarly to aloïn, but much more energetically. J. W. L.

The Chlorophyllic Substances of the Pericarp of the Grape. By A. Étard (*Compt. rend.*, **114**, 231—233).—The dry material obtained by the desiccation of 100 kilos. of grape skins is treated with carbon bisulphide. From 0·3 to 1 kilo. of extract is obtained; it consists essentially of chlorophyll and some of its accompanying substances, and is free from sugars, gums, and salts. The mass is green, and has the consistency of tallow. By distillation in a vacuum it yields 85 per cent. of acids, consisting of palmitic acid and a small proportion of unsaturated liquid acids. By hydrolysis with alcoholic potash, free from soda, dilution with water, and filtration, a white substance soluble in ether is obtained. The name *œnocarpol* is proposed for this compound. It forms long needles melting at 304°;

its solution in ether has a rotation $\alpha = +60{\cdot}8°$. By heating with acetic anhydride in sealed tubes at 130°, the acetyl derivative melting at 215° is obtained. The formula of œnocarpol is $C_{26}H_{39}(OH)_3,H_2O$. On heating, water is first lost, then, at 405° (Baudin's thermometer) a hydrocarbon $C_{26}H_{36}$ distils over. This substance has a tenacious odour, and appears, like the polyterpenes, to be balsamic in character. It slowly combines with water to give fine crystals, fusing at 175°, of the composition $(C_{26}H_{36})_2,H_2O$. With potash, œnocarpol gives brilliant, infusible, slightly soluble needles, of a compound having the composition $C_{26}H_{39}(OH)_3,KOH,H_2O$, a formula which may be written $C_{26}H_{41}(OH)_4{\cdot}OK$. From the potassium salt, metallic derivatives have been obtained, having the formulæ $2(C_{26}H_{42}O_3,H_2O),3AgOH$ and $2(C_{26}H_{42}O_3,PbO),Pb(OH)_2$, which again yield œnocarpol hydrate on treatment with hydrogen sulphide. By oxidation with chromic acid, œnocarpol yields an amorphous acid, $C_{26}H_{42}O_5$, which saturates alkaline carbonates, and yields a balsam on distillation.

On treating the carbon bisulphide extract with lead acetate and passing a current of hydrogen sulphide, œnocarpyl palmitate may be extracted by means of neutral solvents; it fuses at 272°, and is saponifiable. W. T.

Organic Phosphorus Compounds. By P. Heermann (*J.pr. Chem.* [2], **45**, 296—300).—The author records the failure of his attempts to produce compounds of the type of pyrroline in which phosphorus shall take the place of nitrogen. The action of hydrogen phosphide on mucic acid and of the same gas, or of phosphonium iodide, on acetonylacetone and on dixylylethylene diketone were tried, but with negative results. Messinger and Engels have studied the action of hydrogen phosphide on aldehydes (Abstr., 1888, 441; 1889, 35).

A. G. B.

Nomenclature of Compounds containing Nitrogenous Nuclei. By O. Widman (*J. pr. Chem.* [2], **45**, 200—212).—The author criticises Hantzsch's system of nomenclature (this vol., p. 312), and points out its weaknesses as compared with his own system. He also replies to some criticisms of Knorr (Abstr., 1889, 1218). A. G. B.

γ-Bromoquinoline. By A. Claus (*J. pr. Chem.* [2], **45**, 222—236).—Claus maintains that Decker's case for the 3′-position of the bromine in this bromoquinoline (this vol., p. 630) is not made out. He is not satisfied that Baeyer and Bloem's carbostyril (m. p. 266°, Abstr., 1883, 196) is 4′-bromocarbostyril, and is of opinion that the evidence which he quotes is rather in favour of its being 3′-bromocarbostyril, in which case Decker's compound (m. p. 253°, *loc. cit.*) would be 4′-bromocarbostyril. Analogy between the reactions of the substitution derivatives of pyridine and those of quinoline must not be pressed as an argument in favour of the orientation of the latter being in the pyridine ring, because the influence exerted on such reactions by the existence of the benzene ring in quinoline is known to be considerable.

The oxidation of the bromoquinoline in question yields a bromopyridinedicarboxylic acid, which readily loses carbonic anhydride when heated, forming a bromopyridinecarboxylic acid (Abstr., 1887, 159), which is shown to be a bromonicotinic acid, inasmuch as it yields nicotinic acid (m. p. 228°) by treatment with sodium amalgam; there is thus little doubt that the dicarboxylic acid is a quinolinic acid derivative, and that the bromine is in the 4′-position in both acids. The question has been even more definitely settled by the direct bromination of nicotinic acid in a chloroform solution; such a reaction would be expected by *a priori* reasoning to yield *3′-bromonicotinic acid*. The acid, thus prepared, crystallises in prisms, melts at 275°, and is fairly soluble in cold water, whilst the acid prepared from the bromoquinoline, as referred to above, crystallises in laminæ, melts at 183°, and is very sparingly soluble in cold water (Abstr., 1887, 159). The difference between these two acids is sufficiently marked to enable us to definitely ascribe the constitution 3′-bromo- and 4′-bromo-nicotinic acid respectively to them (this vol., p. 630).

The "so-called γ-bromoquinoline and its derivatives" thus regain the position from which it was attempted to thrust them.

3′ : 4′-Dibromonicotinic acid crystallises in colourless prisms, melts at 243°, and is sparingly soluble in cold water. A. G. B.

Halogen Alkyl Compounds of Hydroxyquinolines and their Decomposition by Alkalis and by Silver Oxide. By A. Claus, H. Howitz, C. Massan, and G. Raps (*J. pr. Chem.* [2], **45**, 237—260; compare Abstr., 1891, 1252).—*2-Hydroxyquinoline methiodide*, $C_9NH_6{\cdot}OH,MeI$, is obtained by heating a mixture of 2-hydroxyquinoline and methyl iodide for several hours in a sealed tube at 130°; after treatment with animal charcoal, the product crystallises from aqueous alcohol in aggregates of lustrous needles and prisms; it melts at 251°. The *methochloride* can be prepared by decomposing the methiodide in aqueous solution by silver chloride; it crystallises in flat, yellow needles, and melts at 238°. The *methohydroxide*, $C_9NH_6{\cdot}OH,MeOH$, is obtained by treating either of these methohalides with silver oxide or potassium hydroxide; it crystallises in very hygroscopic needles, and dissolves very easily in water and alcohol, but not in ether and allied solvents; the aqueous solution is yellowish-red by transmitted light, and shows a green fluorescence by reflected light; it is strongly alkaline. It is to be noted that there is no difference between the action of silver oxide and that of potassium hydroxide on these 2-hydroxyquinoline derivatives (compare Abstr., 1891, 1252).

Two sulphonic acids are obtained when isoquinoline is sulphonated (compare Hoogewerf and Van Dorp, Abstr., 1887, 505); they are temporarily distinguished as I and II. When the sulphonation is effected with 40 per cent. anhydrosulphuric acid at 180—200°, the acid I is the chief product; at 300°, however, the acid II is almost exclusively produced. With 60 per cent. anhydrosulphuric acid at 110—112°, the acid I is again the larger product. The acids are separated by the fractional crystallisation of their barium salts, of which the salt I is the less soluble, and crystallises first in long,

lustrous, colourless needles. The salt II forms aggregates of small needles. Both salts contain water of crystallisation, which is not completely expelled below 200°. The corresponding hydroxyisoquinolines are obtained by fusing these salts with sodium or potassium carbonate, dissolving the melt in water, and acidifying with acetic acid; the hydroxyisoquinoline separates as a grey or brown powder, and is purified by boiling its alcoholic solution with animal charcoal.

Hydroxyisoquinoline I is a nearly colourless powder which dissolves easily in alcohol, sparingly in water and ether, and not at all in light petroleum and benzene; it sublimes in the form of colourless needles, and melts with decomposition at 230°; it does not volatilise with steam. The *hydrochloride* and *sulphate* form sulphur-yellow needles; the *platinochloride* crystallises, with 7 mols. H_2O, in long, brilliant, orange-red needles and prisms; the *methiodide* forms long, straw-yellow, anhydrous needles, and melts at 239° with decomposition; the *methochloride*, prepared from the methiodide by the action of silver chloride, forms yellow crystals, blackens at 220°, melts at 256—258°, and dissolves in water; the *methosulphate*, from the methiodide and silver sulphate, crystallises in greenish-yellow, flat needles and laminæ, which melt in their water of crystallisation at 100°, and decompose at 270—275°. By treatment with silver oxide, potassium hydroxide, or barium hydroxide, any of the above metho-derivatives yields the *methohydroxide;* this crystallises from water in long, reddish-yellow plates, and from alcohol in flat prisms; it melts with decomposition, and dissolves easily in water and alcohol, but not in ether; its solutions are strongly alkaline, and absorb carbonic anhydride, but no carbonate could be isolated.

Hydroxyisoquinoline II is similarly isolated. From alcohol it separates as a white, crystalline powder, and it is obtained in the same form by sublimation; it melts at 184°, and is not volatile with steam. In its other properties, it resembles the base I. The *hydrochloride*, *sulphate*, and *platinochloride* were prepared. The *methiodide* crystallises in long, brilliant, yellow needles (with 1 mol. H_2O), and melts in its water of crystallisation at about 100°, subsequently solidifying and melting finally with decomposition at 224°. The *methochloride* forms sulphur-yellow crystals, melts at 216—218°, and is freely soluble in water. The *methosulphate* melts first in its water of crystallisation at 100°, and finally with decomposition at 230°. The *methohydroxide* crystallises with water in which the crystals melt at 85—90°; when dry, it softens at 130°, but does not melt until about 180°, when it forms a thick, black liquid. There is thus no difference between the action of potassium hydroxide and that of silver oxide on these hydroxyisoquinoline derivatives, quaternary ammonium bases being produced in each case.

4-*Hydroxy-3-chloroquinoline* is obtained from the corresponding amidochloroquinoline by diazotising and treating the diazo-derivative with dilute cuprous chloride solution. It crystallises in pale-yellow needles, melts at 183—184°, sublimes, and is freely soluble in water, alcohol, ether, and chloroform. The *methiodide* crystallises in short, yellow needles, and melts with decomposition at 199—201°. The

methochloride crystallises in very soluble, yellow needles, which melt in their water of crystallisation at 100—110°, and when anhydrous at 235—240°.

The action of potassium hydroxide and of silver oxide on 4-hydroxy-3-chloroquinoline methiodide differ. When a strong solution of the methiodide is shaken with ether and a dilute solution of potassium hydroxide, the ether dissolves the liberated base and leaves it, on evaporation, as a thick, yellow oil, which rapidly oxidises in the air after the fashion characteristic of the alkylenequinolinium bases (compare Abstr., 1891, 1252; and 1890, 1323). When a strong solution of potassium hydroxide is used, the potassium compound of the base crystallises from the liquid, and is not dissolved by the ether, but the addition of water dissociates it, and the ether dissolves the base. When the ethereal solution is shaken with dilute hydrochloric acid, it is decolorised, and crystals of the methochloride described above are obtained from the hydrochloric acid solution. The authors regard this base as a *methylenehydroxyquinolinium* [$CH_2 : Cl : OH = 1' : 3 : 4$], and point out that the presence of a hydroxyl group in the 4-position does not influence the behaviour of the quinoline alkyl derivatives with potassium hydroxide, as do hydroxyl groups in 3- and 2-positions (compare Abstr., 1891, 1252, and above). They regard this fact as being especially important with respect to the 2-position, for considering quinoline a derivative of a benzene ring, the 4- and 2-positions are both meta-positions with respect to the nitrogen, and might be expected to have equal values. Some remarks as to the alkyl derivatives of some cinchona alkaloïds being of the nature of quinolinium bases are here made, but will be given more fully in a paper which will shortly appear in the *Annalen*.

The action of silver oxide on 4-hydroxy-3-chloroquinoline methiodide produces the quaternary ammonium base, the corresponding *methohydroxide;* this crystallises in large, brilliant, red, transparent prisms (with H_2O), blackens at 170°, and melts with decomposition at 240°; it is insoluble in ether, and is converted into the methochloride described above when treated with hydrochloric acid.

A recantation here follows: 1-hydroxyquinoline methiodide yields the same quaternary ammonium base whether acted on by excess of alkali or by silver oxide, the contrary statement made in *J. pr. Chem.* [2], **43**, 510 (Abstr., 1891, 1252) being an error. The "intermediate iodide" of Lippmann and Fleissner, obtained by treating 1-hydroxyquinoline methiodide (2 mols.) with potassium hydroxide (1 mol.) (Abstr., 1890, 1323), crystallises in brilliant, thin, orange-yellow needles, and not in red crystals as heretofore stated. When silver oxide is used, no "intermediate iodide" can be obtained.

1-*Hydroxyquinoline methohydroxide* forms red, prismatic crystals (with 1 mol. H_2O); it softens at 110°, melts at 115°, and dissolves in water, alcohol, and chloroform; in its other properties, it resembles the methohydroxides described above.

No "intermediate product" is obtained when 1-hydroxyquinoline methosulphate is treated with barium hydroxide or potassium hydroxide; but barium hydroxide yields the "intermediate iodide" when it acts on the methiodide. A. G. B.

Action of Alkalis on Alkyl Iodides of the Quinoline and Acridine Series. By H. Decker (*J. pr. Chem.* [2], **45**, 161—200). —With regard to the nomenclature used in this paper, it should be noted that Claus (this vol., p. 875) does not admit the orientation 3′-bromoquinoline ascribed by Decker (this vol., p. 630) to his 4′-bromoquinoline. "α-Quinolones" (2′-quinolones) is the name given by the author to derivatives of the lactam formula for carbostyril.

The work described below shows that La Coste's formula, $(C_9H_6BrNMe)_2O$ (Abstr., 1882, 980), for the compound obtained by the action of silver oxide on 3′-bromoquinoline is not even empirically correct, so that his view as to its constitution being that of an ammonium oxide is also invalid.

Bromomethylquinolone, $C_6H_4<\begin{matrix}N—CO\\ CH:CBr\end{matrix}$ [Br : Me : O = 3′ : 1′ : 2′], is prepared by adding an alkali to a saturated solution of 3′-bromoquinoline methiodide in water; a precipitate is formed which rapidly absorbs oxygen from the air and is converted into the new compound, of which La Coste's "ammonium oxide" (*loc. cit.*) was an impure specimen; by adding potassium ferricyanide to the alkali and gradually pouring in the solution of 3′-bromoquinoline methiodide, the compound may be obtained directly. It melts at 149° (not 147°). It is a very feeble base, forming unstable, crystalline salts; no platinochloride could be obtained. Its constitution is settled by the fact that it can be easily obtained by heating dry sodium 3′-bromocarbostyril (this vol., p. 630) with the calculated quantity of methyl iodide in benzene for three hours at 140°.

Bromethylquinolone [Br : Et : O = 3′ : 1′ : 2′] is similarly obtained; it crystallises in large, well-formed tables, melts at 116°, and is more soluble in alcohol and benzene than the methyl derivative.

The author considers that the mechanism of the change involved in the reaction between 3′-bromoquinoline methiodide, alkalis, and oxygen consists in (1) the formation of a phenol containing the group $N<^{Me}_{OH}$, (2) the oxidation of this group to $N\leqslant^{Me}_{O}$ simultaneously with the oxidation of the 2′-hydrogen atom, and (3) the immediate elimination of the oxygen from the group $N\leqslant^{Me}_{O}$, with the production of the quinolone. In support of (3) he quotes the instability of compounds containing the group $R_3{:}N{:}$, such as the tertiary amine dibromides, $R_3{:}N{:}Br_2$, which readily yield tertiary amines, $R_3{:}N$, when treated with alkalis. He further compares the reaction with the formation of pseudochlorocarbostyril from quinoline and hypochlorous acid (Abstr., 1886, 370), in which he considers the group $N<^{Cl}_{OH}$ to be first formed and subsequently oxidised, together with the 2′-hydrogen atom, by more hypochlorous acid. As further support, he points out that 1-substituted quinolines yield no carbostyril with hypochlorous acid (Abstr., 1888, 502; 1891, 1249). The action of methyl iodide on sodium 3′-bromocarbostyril consists in the formation of the methiodide containing the group $N<^{Me}_{I}$, and

the subsequent combination of the iodine atom of this group with the sodium atom in the 2′-sodoxyl group, resulting in the elimination of sodium iodide.

2-*Bromomethylquinolone*, obtained by treating 2-bromoquinoline methiodide (Abstr., 1889, 280) with an alkali and potassium ferricyanide, crystallises from alcohol in lustrous needles, and melts at 173°; the *platinochloride* was prepared.

3-*Bromomethylquinolone* melts at 145°, and 4-*bromo*-1′-*methyl*-2′-*quinolone* at 146—147°; they resemble the other isomerides in properties.

4-*Nitromethylquinolone* is obtained by the action of alkaline potassium ferricyanide on 4-nitroquinoline methiodide; it crystallises from alcohol in lustrous, yellow needles, melts at 167°, sublimes unchanged, dissolves in benzene and ether, and yields a *platinochloride*. As it is not identical with the nitromethylcarbostyril (m. p. 181°; Abstr., 1885, 1235) prepared from the so-called γ-nitrocarbostyril (Abstr., 1885, 1139), the orientation of the nitro-group in the latter must be either 2- or 3-.

4-*Nitroethylquinolone* forms yellow aggregates of crystals, melts at 135°, and is more soluble in alcohol, benzene, and water than the methyl derivative.

4-*Nitrodimethylquinolone* [$NO_2 : Me_2 : O = 4 : 3 : 1' : 2'$], prepared by the action of alkaline potassium ferricyanide on 3 : 4-methylnitroquinoline (nitroparatoluquinoline; Abstr., 1891, 325, crystallises from alcohol and melts at 192°; it dissolves in hydrochloric acid and gives a *platinochloride*.

Nitrobromoquinolinemethylium hydroxide [$NO_2 : Br : MeOH = 4 : 3' : 1'$] has been already obtained in an impure condition, and described as ananitro-γ-bromomethylquinoline (Abstr., 1889, 728); it crystallises from ether at −20° in long, yellow needles; it is permanent in the dark, but rapidly decomposed in light; it dissolves in excess of alkali with a red colour and apparently without decomposition, for ether or benzene decolorises the solution by extracting the base. By oxidation, it yields 4-*nitro*-3′-*bromomethylquinolone;* this crystallises in yellow, flat needles, sublimes unchanged, and melts at 232°. Reference has been already made (Abstr., 1889, 728) to the crystalline compounds which 4-nitro-3′-bromoquinolinemethylium hydroxide makes with the alcohols when crystallised from them. These compounds do not contain the alcohol as "alcohol of crystallisation," but are definite "alcoholates," containing an alkyl or other alcohol radicle in the place of the hydroxyl hydrogen, their formation being accompanied by elimination of water; they can be recrystallised from ether, benzene, chloroform, and the corresponding alcohol unchanged. They are insoluble in water, but are gradually converted by it into the hydroxide and corresponding alcohol; in some cases, another alcohol will perform the same function as water and cause the replacement of the existing radicle by the new alcohol radicle. The 4-nitro-3′-bromoquinolinemethylium ethoxide has been already described (*loc. cit.*); its crystallography is here detailed. The *methoxide* forms brown crystals, blackens gradually in light, melts at 81° to a thick, yellow oil which gradually solidifies again, and decomposes with

blackening at 120°; the *normal propoxide*, the *isopropoxide*, the *allyloxide* (m. p. 85°), the *isobutoxide* (m. p. 70°), the *normal butoxide* (m. p. 55°), the *trimethylcarbinyloxide* (m. p. 127° with decomposition), the *amyloxide* (m. p. 65°), and the *benzyloxide* (m. p. 120°) were obtained; the crystallographic measurements of most of them are given.

4-Nitro-3-bromoquinolinemethylium hydroxide, obtained by precipitating a saturated solution of 4-nitro-3-bromoquinoline methiodide with ammonia, did not crystallise, nor could its ethoxide be obtained otherwise than as a thick, yellow oil. It is easily oxidised to *4-nitro-3-bromomethylquinolone*, which crystallises in needles, melts at 203°, and dissolves in most solvents.

Nitro-4-bromomethylquinolone, obtained from nitro-4-bromoquinoline, crystallises in needles, and melts at 220°.

Acridinemethylium hydroxide, $C_{10}H_9NMeOH$, is a white precipitate, produced by adding sodium hydroxide to a solution of acridine methiodide; it is exceedingly unstable, immediately oxidising to *methylacridone*, $C_6H_4<\overset{CO}{\underset{NMe}{>}}C_6H_4$. This compound crystallises from alcohol in large, yellow needles, and melts at 190°; it dissolves in alcohol with a blue fluorescence, and in acids, from which it is precipitated unchanged by water; it is sparingly soluble in hot water and sublimes unchanged; a *platinochloride* was isolated.

Bernthsen (Abstr., 1883, 1133) described the compound obtained by crystallising from alcohol the product of the reaction between phenylacridine methiodide and sodium hydroxide, and named it phenylacridinemethylium hydroxide; this substance is really *phenylacridinemethylium ethoxide* (m. p. 108°), $C_6H_4<\overset{CPh}{\underset{NMe(OEt)}{>}}C_6H_4$. The *hydroxide* is obtained by crystallising the above-mentioned product from hot benzene; it forms large, brilliant tables which melt at 140°, dissolves in most solvents except water, and yields an unstable *carbonate*; attempts to obtain an oxidation product analogous to the 2′-quinolones were ineffectual. The *benzyloxide* melts at 133°.

A. G. B.

Oxidation of Benzoyltetrahydroquinaldine, and Nitro-derivatives of the same. By G. Walter (*Ber.*, **25**, 1261—1270). —Benzoyltetrahydroquinaldine is prepared by hydrogenising quinaldine with tin and hydrochloric acid, and treating the resulting tetrahydro-derivative by the Baumann-Schotten method; it crystallises in large, four-sided prisms or delicate needles, melts at 118°, is soluble in most organic solvents, and is hydrolysed by protracted boiling with hydrochloric acid. When it is boiled with alkaline potassium permanganate solution, and the filtrate evaporated and acidified with hydrochloric acid, carbonic anhydride is evolved and a gelatinous mass separates, from which boiling water extracts benzoic acid, whilst oxalic acid is present in the supernatant liquid. The above-mentioned mass is boiled with water and magnesia, filtered while hot, and the filtrate acidified, when *benzoylorthamidophenylacrylic acid*,

$$COOH{\cdot}C_2H_2{\cdot}C_6H_4{\cdot}NHBz,$$

separates, and is crystallised from alcohol; it forms thick needles,

melts at 191—193°, is sparingly soluble in hot water, and slowly reduces Fehling's solution in the cold. When the acid is heated with concentrated hydrochloric acid at 160—180°, or carefully fused with potash, indole and benzoic acid are produced. When administered to a dog, no increase of indoxyl was recognised in the urine, but the animal was lamed in the hinder extremities.

The excess of magnesia from which magnesium benzoylorthamidophenylacrylate is filtered contains the salt of benzoylanthranilic acid; the free acid remains when the mixture is treated with hydrochloric acid, and melts at 177°, as stated by Doebner and v. Miller (*Ber.*, **19**, 1196).

When benzoyltetrahydroquinaldine is allowed to remain in contact with fuming nitric acid for several days, a *mononitro*-derivative, which crystallises from alcohol in yellow needles and melts at 149°, is obtained; whilst, if heated at 50—60° with fuming nitric acid, a *dinitro*-derivative, which crystallises from alcohol in small, yellow needles and melts at 169—170°, is produced.

Metanitrobenzoyltetrahydroquinaldine, $C_{10}NH_{12}\cdot CO\cdot C_6H_4\cdot NO_2$, is prepared by shaking tetrahydroquinaldine with metanitrobenzoic chloride and aqueous sodium hydroxide; it crystallises in pale-yellow leaflets, and melts at 114°. When treated with concentrated nitric acid at 20—50°, a dinitro-derivative melting at 163—164° is obtained, whilst heating it at 90—100° with concentrated nitric acid yields a trinitro-derivative, which crystallises in long, delicate, sulphur-yellow needles, and melts at 184—185°. A. R. L.

Preparation of Isoquinoline from Naphthalene. By E. Bamberger and M. Kitschelt (*Ber.*, **25**, 1138—1147; compare this vol., p. 857).—*Lead isocumarocarboxylate*, $CH\ll^{C_6H_4\cdot COO}_{C(OH)\cdot COO}>Pb$, is insoluble and amorphous.

Isocarbostyrilcarboxylic acid, $C_6H_4<^{CO\cdot NH}_{CH:C\cdot COOH}$, is prepared by dissolving isocumarinecarboxylic acid in ammonia and acidifying the solution; it crystallises in slender, colourless, silky, lustrous needles which melt at 320° with previous decomposition; the acid is soluble in alcohol, acetone, and concentrated mineral acids, and is reprecipitated on the addition of water; with ferric chloride, an intense yellowish-red coloration is produced. The *silver* and *mercuric* salts are gelatinous; the *lead*, *copper*, *barium*, *zinc*, *cadmium*, *calcium*, and *ammonium salts* are crystalline; the acid is not acted on when heated with alkalis or acetic chloride, but is deposited from the latter in small, pale yellow needles, quite different in appearance from the ordinary crystals, and these are unaffected by repeated crystallisation from alcohol. On heating the acid below its melting point, or by heating the silver salt at 150—160°, *isocarbostyril*, $C_6H_4<^{CO\cdot NH}_{CH:CH}$, is formed, and may be purified by washing with dilute soda; it crystallises from benzene and readily sublimes, forming lustrous needles which melt at 208—209°; the compound is soluble in concentrated

mineral acids, and the solutions do not fluoresce; it gives precipitates with solutions of phosphotungstic acid, phosphomolybdic acid, potassium bismuthiodide, and mercuric nitrate. Isoquinoline is obtained by heating isocarbostyril with zinc dust in excess.

The authors point out that β-naphthol yields 75 per cent. of β-naphthaquinone, and that the latter gives, according to Zincke's method, 70—75 per cent. of dihydrohydroxyisocumarinecarboxylic acid, whilst the preparation of isocumarinecarboxylic acid, isocarbostyrilcarboxylic acid, isocarbostyril, and isoquinoline proceed almost quantitatively. J. B. T.

Julole. By W. Kaiser and A. Reissert (*Ber.*, **25**, 1190—1192, and 1193—1201).—To determine if the reaction which takes place between ethyl acetoacetate and tetrahydroquinoline (Abstr., 1891, 736) is a general one, the authors have examined the behaviour of tetrahydroquinoline and tetrahydroquinaldine towards ethyl ethylacetoacetate and ethyl benzoylacetate, and find that only in the case of tetrahydroquinoline and ethyl ethylacetoacetate is the condensation product formed in sufficient quantity to be isolated.

α_1-Keto-β_1-ethyl-γ_1-methyljuloline is obtained by gently boiling a mixture of molecular proportions of ethyl ethylacetoacetate and tetrahydroquinoline for one hour in a reflux apparatus. The cold product is poured into twice the volume of ice-cold concentrated sulphuric acid, then poured into water and excess of alkali added; the unaltered hydroquinoline is separated by steam distillation. The compound is obtained as a finely-divided, yellowish-brown precipitate. It crystallises from petroleum in beautiful, white needles, melts at 80°, and is easily soluble in alcohol, ether, acetic acid, chloroform, benzene, and mineral acids. It is also soluble in hot water, but does not crystallise from this solvent. When treated with phosphorus pentachloride, it yields an indigo-blue dye containing chlorine; this easily decomposes with evolution of hydrogen chloride and forms a dye insoluble in water (this vol., p. 498). The *picrate* crystallises in yellow needles and melts at 89°.

Bromo-α_1-keto-β_1-ethyl-γ_1-methyljuloline, $C_{15}H_{16}NO\cdot Br$, is obtained by adding an aqueous solution of bromine (1 mol.) to the preceding compound dissolved in hydrochloric acid, and heating until the colour of the bromine has disappeared. It crystallises from dilute alcohol in needles, melts at 140°, is easily soluble in alcohol, ether, benzene, chloroform, and acetic acid, but is insoluble in petroleum and water.

Nitroketoethylmethyljuloline, $C_{15}H_{16}NO\cdot NO_2$, is obtained by warming ketoethylmethyljuloline with concentrated nitric acid until a tarry precipitate begins to form, and then pouring into water. It crystallises from dilute alcohol in yellow leaflets, melts at 168°, and is easily soluble in hot alcohol and acetic acid, sparingly so in ether benzene, and chloroform, and insoluble in petroleum and water.

Whilst only about 12 per cent. of the theoretical yield of ketomethyljuloline is obtained by the condensation of ethyl acetoacetate and tetrahydroquinoline, the condensation of ethyl malonate and tetrahydroquinoline takes place much more readily, and a 50 per cent. yield is obtained.

α_1-*Keto*-γ_1-*hydroxyjuloline* is obtained by gently boiling molecular proportions of tetrahydroquinoline and ethyl malonate for about 7 hours in a reflux apparatus. The alcohol which is formed is then distilled off together with the unaltered malonate; in about half an hour, a second reaction sets in and alcohol again comes over. On cooling, a yellow, crystalline mass is obtained, which is washed with ether and alcohol. After boiling with animal charcoal, it crystallises from acetic acid in lustrous, white needles, melts about 300° with decomposition, and is soluble in hot acetic acid and concentrated mineral acids, sparingly so in hot alcohol, almost insoluble in ether and benzene, and insoluble in water, chloroform, petroleum, and dilute acids. The *hydrochloride* crystallises in long, white needles. The *barium* salt, $(C_{12}H_{10}NO_2)_2Ba$, is obtained as a finely-divided precipitate by adding barium chloride to a solution of the sodium salt, and, like the other salts of this compound, cannot be crystallised from water. Ketohydroxyjuloline, when heated with phenylhydrazine (1 mol.) in 50 per cent. acetic acid for 3—4 hours, yields a compound of the formula $C_{12}H_{11}NO_3$, which melts at 260°, does not reduce Fehling's solution, and is easily soluble in alcohol and hot acetic acid. When treated with 2 mols. of phenylhydrazine, it remains unchanged. The mother liquors of the compound melting at 260° were extracted with ether, and yielded a substance which crystallises in lustrous needles, melts at 125°, reduces Fehling's solution, and evolves phenylhydrazine when boiled with sodium hydroxide.

α_1-*Keto*-γ_1-*chlorojuloline*, $C_{12}H_{10}NOCl$, is obtained by heating ketohydroxyjuloline with phosphorus pentachloride and phosphorus oxychloride for half an hour at 120°. It crystallises in reddish needles, melts at 135°, is easily soluble in alcohol, ether, acetone, acetic acid, benzene, and concentrated acids, and insoluble in petroleum and alkalis.

α_1-*Keto*-γ_1-*benzoxyjuloline*, $C_{19}H_{15}NO_3$, is obtained by shaking the sodium salt of ketohydroxyjuloline with benzoic chloride, treating the mixture with alkali, and crystallising the insoluble portion from acetic acid. It crystallises in long, white needles, melts at 151°, and is insoluble in hot alcohol, acetone, acetic acid, and benzene, sparingly so in ether and petroleum, and insoluble in water, alkalis, and dilute acids.

α_1-*Keto*-β_1-*nitroso*-γ_1-*hydroxyjuloline* is obtained by adding the calculated quantity of potassium nitrite to a solution of the ketone in acetic acid; on diluting with water, about two-thirds of the ketone is precipitated unaltered; on adding alkali to the filtrate, a beautiful, green precipitate is obtained, which is soluble in dilute acids. If the filtrate be acidified and extracted with ether, the nitroso-compound is obtained. It crystallises in red needles, melts at 158° with decomposition, is soluble in hot water, alcohol, ether, benzene, and dilute acids, and yields a green solution with alkali hydroxides and carbonates. E. C. R.

Formation of Pyrazole Derivatives from the Dichlorhydrins and Tribromhydrin. By U. Alvisi (*Gazzetta*, **22**, i, 158—168).—A solution of phenylhydrazine (12·5 grams) and β-dichlorhydrin (5 grams) in benzene (20 grams), when boiled for 12 hours, deposits a

mixture (1·3 grams) of ammonium chloride and phenylhydrazine hydrochloride. This deposit is filtered off, and the solvent evaporated; on heating the residue at 137—140°, ammonia and water vapour are evolved, leaving a resinous mass which is extracted with ether. The residue consists of ammonium chloride, and the hydrochloride of a base which has not yet been studied. The ethereal solution is shaken with dilute hydrochloric acid, which extracts aniline, and the ether distilled off. The residue, on distillation, is found to be 1-phenylpyrazole.

When a benzene (20 grams) solution of α-dichlorhydrin (12 grams) and phenylhydrazine (30·5 grams) is boiled for 12 hours in a reflux apparatus, much ammonia is given off, and 1-phenylpyrazole is formed.

Similarly, on heating tribromhydrin (28 grams) and phenylhydrazine (42 grams), dissolved in benzene (25 grams), reaction readily occurs, and 1-phenylpyrazole is obtained. W. J. P.

New Series of Platinum Compounds derived from the Pyrazoles. By L. Balbiano (*Real. Accad. Linc.*, **7**, ii, 26—34).—The author has previously shown (Abstr., 1890, 1009) that pyrazole platinochloride loses its water of crystallisation at 100°, and on further heating at 200—210°, 4 mols. HCl are eliminated, and a substance of the composition $(C_3N_2H_3)_2PtCl_2$ is obtained. Analogous compounds prepared from substituted pyrazoles are now described.

On heating 1-phenylpyrazole platinochloride, it first loses its water of crystallisation, and then at 150—160° hydrogen chloride is evolved, leaving a substance of the composition $(C_3H_2N_2Ph)_2PtCl_2$. It is a light-yellow powder, sparingly soluble in boiling alcohol and water, insoluble in cold water and acids. It is not altered by heating in a closed tube with fuming hydrochloric acid at 100° for 3—4 hours.

1-Orthotolylpyrazole platinochloride, when heated at 160—170°, yields a compound of the composition $(C_3H_2N_2{\cdot}C_7H_7)_2PtCl_2$. It is a pale-yellow powder insoluble in water, sparingly soluble in boiling alcohol. It is purified by precipitating its boiling alcoholic solution with water. An isomeride of this substance having similar properties is obtained by heating 1-paratolylpyrazole platinochloride at 180°.

1 : 4 : 5-*Phenylmethylethylpyrazole platinochloride*,

$$(C_3HMeEtN_2Ph)_2,H_2PtCl_6 + 2H_2O,$$

is prepared by dissolving the pyrazole obtained from propionylpropaldehyde in hydrochloric acid, and treating with a concentrated acid solution of platinic chloride. It crystallises in beautiful, yellowish-red laminæ, and on heating at 160° yields a substance of the composition $(C_3MeEtN_2Ph)_2PtCl_2$, as a pale-yellow powder, insoluble in water and almost so in alcohol.

1 : 3 : 5-Phenyldimethylpyrazole platinochloride has been described by Knorr as crystallising with 4 mols. H_2O, the last of which it loses at 130—140°. The author finds that it contains only 2 mols. H_2O, which are eliminated at 100—110°. On heating at 210—230°, it yields a

substance of the composition $(C_3Me_2N_2Ph)_2PtCl_2$ as a yellow powder, insoluble in water. It is sparingly soluble in boiling alcohol, and is precipitated by water from this solution as a flocculent, yellow precipitate.

On boiling 1-phenylpyrazole (2 mol. proportions) with an aqueous solution of sodium platinochloride (1 mol. proportion), sodium chloride and hydrogen chloride are produced, and, on cooling the solution, the substance of the composition $(C_3H_2N_2Ph)_2PtCl_2$, described above, separates out. Under similar conditions 1 : 4 : 5-phenylmethylethylpyrazole and 1 : 4-phenylbromopyrazole yield only resinous products and reduced platinum. 1 : 3 : 5-Phenyldimethylpyrazole, when boiled with an aqueous solution of sodium platinochloride for 7—8 hours, deposits a resinous substance which, on extraction with boiling absolute alcohol and subsequent precipitation with water, yields the compound of the composition $(C_3Me_2N_2Ph)_2PtCl_2$ described above.

The author considers it probable that in these compounds the platinum is directly united with a pentad nitrogen atom in the pyrazole nucleus. W. J. P.

Tetrahydroketoquinoxalines. By M. Georgescu (*Ber.*, **25**, 952—957).—*Phenyltetrahydroketoquinoxaline*, $C_6H_4<\begin{matrix}NH\cdot CHPh\\ NH\cdot CO\end{matrix}$, is obtained by boiling an aqueous solution of 1 : 2-phenylenediamine and mandelic acid (equal mols.; compare Autenrieth and Hinsberg, this vol., p. 709); it crystallises from dilute alcohol in almost colourless leaflets, melts at 201—202°, and is not attacked by boiling alkali. *Phenyltetrahydroketotoluquinoxaline*, $C_6H_3Me<\begin{matrix}NH\cdot CHPh\\ NH\cdot CO\end{matrix}$, formed from 1 : 2-diamidotoluene and mandelic acid, melts at 201—202°. A *compound* which may have the constitution $C_6H_4<\begin{matrix}NH\cdot CH\cdot CH_2Ph\\ NH\cdot CO\end{matrix}$, is produced from 1 : 2-phenylenediamine hydrochloride and phenyl-β-lactic acid; it melts at 216°. The *homologue*

$$C_6H_3Me<\begin{matrix}NH\cdot CH\cdot CH_2Ph\\ NH\cdot CO\end{matrix}$$

is obtained from 1 : 2-diamidotoluene hydrochloride and mandelic acid; it melts at 240° with decomposition.

Cinnamyltetrahydroketoquinoxaline, $C_6H_4<\begin{matrix}NH\cdot CH\cdot CH:CHPh\\ NH\cdot CO\end{matrix}$, is obtained by heating 1 : 2-phenylenediamine hydrochloride with phenyl-α-hydroxycrotonic acid in molecular proportion in a sealed tube at 130—140° for 14 hours; it crystallises from alcohol in slightly yellowish needles, melts at 223—224°, and is soluble in hot water, but insoluble in alkalis; the homologous *compound* from 1 : 2-diamidotoluene forms almost colourless crystals, and melts at 185—186°; whilst *cinnamyltetrahydroketonaphthaquinoxaline*, from orthonaphthylenediamine hydrochloride, melts at 174°.

When an alcoholic solution of orthonaphthylenediamine hydro-

chloride and mandelic acid (equal mols., containing a little ammonia is heated in a reflux apparatus on the water-bath for some hours, a *compound*, $C_{10}H_6<\begin{matrix}NH\cdot CHPh\\ |\\ NH\cdot C\end{matrix}:N\cdot C_{10}H_6\cdot N:\begin{matrix}C\\ |\\ C\end{matrix}\!\!-\!\!-\!\!\begin{matrix}CHPh\cdot NH\\ |\\ NH\end{matrix}>C_{10}H_6$, crystallising from aniline in small, brick-red crystals, is obtained; it does not melt at 360°, is insoluble in water, and almost so in alcohol; it forms a pulverulent, dark violet *hydrochloride*. A similar compound, $C_{10}H_6<\begin{matrix}NH\cdot CH\cdot CH_2Ph\\ |\\ NH\cdot C\end{matrix}=N-C_{10}H_6-N=\begin{matrix}C\cdot CH_2Ph\cdot CH\cdot NH\\ |\\ C-NH\end{matrix}>C_{10}H_6$, is formed from orthonaphthylenediamine hydrochloride and phenyl-β-lactic acid.

Methyltetrahydroketotoluquinoxaline, $C_6H_3Me<\begin{matrix}NH\cdot CHMe\\ |\\ NH\cdot CO\end{matrix}$, is produced by heating 1 : 2-diamidotoluene hydrochloride and lactic acid in a sealed tube at 130°; it crystallises from boiling water in yellowish leaflets, and melts at 176—177°. *Methyltetrahydroketoquinoxaline*, $C_6H_4<\begin{matrix}NH\cdot CHMe\\ |\\ NH\cdot CO\end{matrix}$, obtained from 1 : 2-phenylenediamine hydrochloride and lactic acid, melts at 177°. A. R. L.

Oxazine Dyes. By R. Möhlau (*Ber.*, **25**, 1055—1066). The oxazine dyes may be divided into two groups, which stand in the same relation to one another as the indamines to the indophenols. For the members of the group corresponding with the indamines (gallocyanine, prune, Meldola's blue, muscarine, and Nile blue), the author proposes the collective name *quinoxazine*, as they may be regarded as derivatives of one of the two chromogens which he terms *phenoquinoxazine* (or *quinoxazine*), $\overset{4}{N}H:C_6H_3<\begin{matrix}\overset{1}{N}\\ O\\ \overset{2}{\ }\end{matrix}>C_6H_4$, and *naphthaphenoquinoxazine*, $\overset{4}{N}H:C_6H_3<\begin{matrix}\overset{1}{N}\cdot C\cdot C_6H_4\\ \|\\ O\cdot CH\cdot CH\\ \overset{2}{\ }\end{matrix}>CH$, respectively.

The members of the group corresponding with the indophenols (resorufine, resorufamine, orcirufine, and orcirufamine) may be regarded as derived from the chromogen *phenoquinoxazone* (or *quinoxazone*), $\overset{4}{O}:C_6H_3<\begin{matrix}\overset{1}{N}\\ O\\ \overset{2}{\ }\end{matrix}>C_6H_4$, and may collectively be called *quinoxazones*.

Nitrosodimethylmetamidophenol, $C_8H_{10}N_2O_2$ [NOH : O : NMe_2 or NO : OH : NMe_2 = 1 : 2 : 4], prepared by treating dimethylmetamidophenol with hydrochloric acid and sodium nitrite in ice-cold aqueous solution, and then decomposing the product with sodium carbonate (compare D. R.-P. 45268), separates from alcohol in brownish-yellow, moss-like crystals, melts at 169°, and is only sparingly soluble in cold water and ether, but moderately easily in alcohol, and readily in hot water; it gives with alumina, ferric oxide, and chromium sesquioxide coloured lakes, which can be fixed on

vegetable fibres. The *hydrochloride*, $C_6H_{10}N_2O_2,HCl$, crystallises in yellow prisms, and decomposes at 184°; it dissolves in water with partial dissociation, yielding a yellowish-red solution. The corresponding diethyl derivative, $C_{10}H_{14}N_2O_2$, crystallises from alcohol in lustrous, red prisms, melts at 84°, and dissolves freely in hot water, alcohol, and ether; it forms coloured lakes with the oxides of iron, chromium, and aluminium. The *hydrochloride*, $C_{10}H_{14}N_2O_2,HCl$, forms yellow, prismatic crystals, and decomposes at 170°.

Dimethyldiamidoquinoxazone, $^{5}NH_2\cdot C_6H_2{}^{4}O\langle{}^{1}_{2}N\rangle C_6H_3\cdot NMe_2$, is obtained when nitrosodimethylamidophenol is reduced with stannous chloride and hydrochloric acid, the ice-cold solution of the meta-hydroxyparamidodimethylaniline hydrochloride produced in this way treated with a slight excess of soda, and then air passed through the mixture for several hours; in the last process dimethylamine and ammonia are also formed. The quinoxazone separates from alcohol in yellow, lustrous, rhombic crystals, melts at 223°, and sublimes below its melting point; it is only sparingly soluble in boiling water, yielding a blue solution, but it dissolves moderately easily in alcohol, the reddish-violet solution showing a slight brownish-red fluorescence; it gives with ether, in which it is only sparingly soluble, a rose-red solution which shows a yellowish-red fluorescence, but it is insoluble in alkalis. Its molecular weight was determined in phenol solution, and found to correspond with the molecular formula $C_{14}H_{13}N_3O_2$. In an acetic acid bath it imparts to silk a bluish-violet colour and a brownish-red fluorescence. It has basic properties, and dissolves in excess of dilute mineral acids with an orange-red, in acetic acid with a greenish-blue, and in concentrated sulphuric acid with a bluish-violet coloration, which changes to orange-red on the addition of water. Solutions of the base and of its salts show very characteristic absorption spectra. When the base is treated with reducing agents, it gives a leuco-compound, which is soluble in acids and alkalis, and readily undergoes oxidation.

Dimethylamidoquinoxazone, $C_6H_3{}^{4}O\langle{}^{1}_{2}N\rangle C_6H_3\cdot NMe_2$, can be obtained by diazotising the preceding compound with amyl nitrite in ice-cold alcoholic sulphuric acid solution, and also by heating a mixture of nitrosoresorcinol, dimethylmetamidophenol, and concentrated sulphuric acid on the water-bath until a reaction commences. It separates from benzene in deep-brown, lustrous crystals, and sublimes below 250°, but without melting; it is soluble in alcohol, boiling water, ether, and benzene, the coloured solutions showing a brownish-red or a yellow fluorescence. It dissolves in concentrated sulphuric acid and in hydrochloric acid, yielding blue solutions, which turn red on the addition of water; the mon-acid sulphate crystallises from alcohol in prisms.

Diethyldiamidoquinoxazone, $C_{18}H_{17}N_3O_2$, prepared from nitroso-diethylmetamidophenol as described in the case of the corresponding

dimethyl derivative, separates from alcohol in lustrous, yellow, prismatic crystals, sublimes at 200°, and melts at 211°; it dissolves in boiling water with a violet-blue, in ether with a rose-red, and in alcohol with a reddish-violet coloration; the alcoholic solution shows a brownish-red and the ethereal solution a yellowish-red fluorescence. It gives with acetic acid blue, with concentrated sulphuric acid violet, and with excess of dilute mineral acids brownish-red solutions; its tinctorial action on silk in an acetic acid bath is similar to that of the dimethyl derivative. F. S. K.

The so-called Dinitrosoazobenzene. By F. Kehrmann and J. Messinger (*Ber.*, **25**, 898—901).—The authors find that the compound described as dinitrosoazobenzene by Willgerodt and Ferko (Abstr., 1888, 829) is in reality nitrophenylazimidobenzene (meso-phenylphentriazole; see next abstract), $\overset{4}{NO_2}\cdot C_6H_3\ll\overset{1}{N}\underset{N}{\overset{|}{\underset{2}{|}}}>NPh$; it is prepared by boiling together in a reflux apparatus bromodinitrobenzene [Br : $(NO_2)_2$ = 1 : 2 : 4] (20 grams), phenylhydrazine (2 mols.), sodium acetate (1 mol.), and alcohol (200 c.c.). The corresponding amido-derivative is obtained when the nitro-compound is boiled in a reflux apparatus with the necessary quantity of stannous chloride, an excess of hydrochloric acid, and alcohol for an hour; it crystallises from alcohol in lustrous, yellow, concentric groups of flat needles, melts at 183°, and is almost insoluble in water. The aqueous solution exhibits a green, the alcoholic a bluish-green, and the ethereal a blue fluorescence; whilst the solutions in benzene and chloroform fluoresce violet. When the base is dissolved in concentrated sulphuric acid, and the cooled solution treated with the calculated quantity of sodium nitrite solution, Gattermann and Wichmann's compound melting at 109° (Abstr., 1888, 829) is formed.

A. R. L.

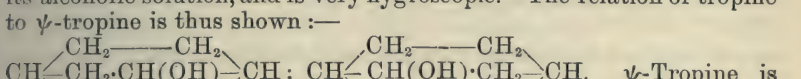
Nomenclature of Rings consisting of 2 Carbon and 3 Nitrogen Atoms. By F. Kehrmann and J. Messinger (*Ber.*, **25**, 901—903).—The authors adopt Widmann's nomenclature. The compounds $NH<\begin{matrix}N{:}CH\\|\\N{:}CH\end{matrix}$ and $N\ll\begin{matrix}NH{\cdot}CH\\||\\N{-}CH\end{matrix}$ are named orthotriazole and isorthotriazole respectively; whilst the substitution derivatives of these are distinguished by prefixing *N* or C, according as the substitution takes place in the NH or CH groups; in the former case, they may also be designated meso-derivatives. The complex

$$C_6H_4\ll\overset{|}{\underset{N}{\overset{|}{N}}}>NH$$

is named phentriazole. The same principle is used in the case of metatriazole, $NH<\begin{matrix}CH{:}N\\|\\CH{\cdot}N\end{matrix}$, and isometatriazole, $N\ll\begin{matrix}CH{\cdot}NH\\|\\CH{:}N\end{matrix}$. The dihydro- and tetrahydro-triazoles may be called triazolines and triazolidines respectively. A. R. L.

A Substance which contains a Ring of 18 Members, and gives an Abnormal Freezing-point Depression. By E. Lellman and B. Arnold (*Ber.*, **25**, 662—664).—The substance, melting at 231°, obtained by reducing orthodinitrodibenzylamine with stannous chloride in alkaline solution or with zinc-dust and soda in alcoholic solution, to which the constitution $HN<\begin{matrix}CH_2\cdot C_6H_4\cdot N\\ \|\\ CH_2\cdot C_6H_4\cdot N\end{matrix}$ was assigned (this vol., p. 316), gives no constant molecular depression of the freezing point, whatever solvent be used; the numbers obtained corresponded with molecular weights varying from 186 to 672. By determining the lowering of the boiling point, however, of a solution in phenol, a constant molecular weight of 437 was obtained. The formula of the substance must thus be doubled, giving a molecular weight of 446. A further argument for this is the fact that the substance $C_6H_4Me\cdot N<\begin{matrix}CH_2\cdot C_6H_4\cdot N\\ \|\\ CH_2\cdot C_6H_3\cdot N\end{matrix}$, obtained by reducing orthodinitrobenzylparatoluidine, melts at 211°. Hence, if the constitution at first assumed for the substance in question is correct; a replacement of hydrogen by tolyl has been attended by a lowering of the melting point from 231° to 211°, an unlikely occurrence. The formula must then be doubled and written $HN<\begin{matrix}CH_2\cdot C_6H_4\cdot N:N\cdot C_6H_4\cdot CH_2\\ CH_2\cdot C_6H_4\cdot N:N\cdot C_6H_4\cdot CH_2\end{matrix}>NH$. It contains a ring of 12 carbon and 6 nitrogen atoms, and may be termed *di-orthoazodibenzylamine*. Perhaps there is a connection between the size of this ring and the abnormal molecular depression.

C. F. B.



Adenine. By M. Krüger (*Zeit. physiol. Chem.*, **16**, 329—339: compare this vol., p. 219).—On decomposition, adenine, hypoxanthine, xanthine, and uric acid yield glycocine, carbonic anhydride, and formic acid; the relation between the amounts of the two last-named products depending on the amount of oxygen they contain. Adenine and hypoxanthine, moreover, both contain a radicle adenyl. On account of the close relationship between these substances, it appeared advisable to investigate the question whether adenine and hypoxanthine resemble uric acid and xanthine in containing an alloxan nucleus.

On treating adenine with bromine, a dark-red substance is formed which is bromadenine-tetrabromide-hydrobromide (Bruhns and Kossel, this vol., p. 220); under certain circumstances, however, this compound holds excess of bromine, which is evolved on the application of heat. Bromadenine is prepared from the compound so purified by dissolving it in warm sodium hydroxide and then passing a stream of carbonic anhydride through the solution. Bromadenine is by this means precipitated. Dry chlorine has no action on dry bromadenine; if, however, water is added, bromine is evolved. The oxidation products obtained from bromadenine by means of hydrochloric acid and potassium chlorate are alloxan, urea, oxalic acid, and another acid of undetermined constitution. In other words, this method of research shows the existence of an alloxan nucleus in

adenine; the oxalic acid is doubtless derived from the alloxan, and the urea probably from a urea nucleus which adenine also contains.

W. D. H.

ψ-Tropine and some ψ-Tropeïnes. By C. Liebermann and L. Limpach (*Ber.*, **25**, 927—939; compare Abstr., 1891, 1265).—By the spontaneous evaporation of its solution in benzene, ψ-tropine is obtained in large crystals belonging to the rhombic system, $a : b : c = 0{\cdot}8910 : 1 : 0{\cdot}7631$; observed forms $\infty\breve{P}\infty$, ∞P, P, and $\breve{P}\infty$. The *sulphate* separates in a crystalline form on the addition of ether to its alcoholic solution, and is very hygroscopic. The relation of tropine to ψ-tropine is thus shown :—

ψ-Tropine is converted into tropidine by the method described by Ladenburg for the conversion of tropine into the latter (Abstr., 1883, 670); tropidine platinochloride was obtained in crystals having the form observed by Bodewig (*Zeit. Kryst. Min.*, **5**, 566).

Mandelic ψ-tropeïne (*ψ-homatropine*), $C_8H_{14}NO{\cdot}CO{\cdot}CHPh{\cdot}OH$, is best prepared by a method similar to that devised by Ladenburg for the synthesis of atropine, thus :—A solution containing equivalent weights of ψ-tropine and mandelic acid is continually evaporated for four successive days, dilute hydrochloric acid (1 : 40) being added at intervals; it is a viscid oil, and both the *sulphate* and *hydrochloride* are very hygroscopic; the *platinochloride* is a yellowish precipitate which readily resinifies, and the *aurochloride* is a yellow precipitate. An acid solution of the base gives with potassium mercuric iodide a white, resinous precipitate, and with picric acid a yellow precipitate. The base yields mandelic acid and ψ-tropine when heated at 60° with barium hydroxide solution, and it is decomposed in the cold by an excess of mineral acids; a solution of the acetate is devoid of mydriatic properties.

Tropyl-ψ-tropeïne (*ψ-atropine*), $C_8H_{14}NO{\cdot}C_9H_9O_2$, is prepared, similarly to the last-described base, from ψ-tropine and tropic acid; it is a white, viscid oil, having a specific rotatory power in alcoholic solution $[\alpha]_D = -4{\cdot}9$; when it is dissolved in benzene, and petroleum added to the solution until it is turbid, white, nodular crystals separate after some weeks; these melt at 86—88°. The *hydrochloride* forms white, hygroscopic needles, and melts at 183° with decomposition; the *aurochloride* forms yellow needles, and melts at 198°. A moderately dilute solution of the base gives a bright-yellow, flocculent precipitate with platinic chloride, and it exhibits no mydriatic properties. It therefore differs from hyoscine, which, according to Ladenburg (Abstr., 1881, 56), is ψ-atropine; like the latter, however, it is hydrolysed by barium hydroxide solution with the formation of tropic acid and ψ-tropine. Although the difference between these two compounds is not yet ascertained, it is suggested that their relation may be similar to that of hyoscyamine to atropine. In the above synthesis of tropyl-ψ-tropeïne, about 50 per cent. of the tropic acid employed was converted into tropide; the authors have re-established the empirical formula given by Ladenburg for this com-

pound, but find that its molecular formula is twice this. When a solution of tropide and ψ-tropine in benzene is heated in a sealed tube at 120°, *ψ-tropine atropate*, $C_8H_{15}NO,C_9H_8O_2$, a compound soluble in water and melting at 129°, is produced; this was also prepared by way of control from tropine and atropic acid. The authors confirm Ladenburg's observation, that when tropide is heated at 60° with barium hydroxide solution, about four-fifths is converted into tropic acid; and they find that the remainder is transformed into atropic acid. The constitution of tropide is probably represented by the formula $CHPh<\begin{matrix}CH_2\cdot O\cdot CH_2\\CO-O-CO\end{matrix}>CHPh$. Tropyl-ψ-tropeïne (see above) can be obtained by heating ψ-tropine with tropide at 200°.

A. R. L.

Conversion of Cupreïne into Quinine. By E. Grimaux and A. Arnaud (*Annalen*, **267**, 379—380).—A reply to Hesse (*Annalen*, **266**, 240; this vol., p. 221); the authors maintain the correctness of the experiments which were criticised by Hesse, and claim to have been the first to accomplish the conversion of cupreïne into quinine, and also to prepare quinine dimethiodide (see further, *Compt. rend.*, **114**, 548). F. S. K.

Cinchonine. By M. Freund and W. Rosenstein (*Ber.*, **25**, 880—882).—The authors are continuing the work of Claus and Müller on the halogen alkyl compounds of cinchonine and the products obtained by treating them with potash.

Dimethylcinchonine, $C_{19}H_{20}Me_2N_2O$, is obtained by extracting with ether the product of the action of strong potassium hydroxide on an aqueous solution of methylcinchonine methiodide. It is a yellow oil, insoluble in water, and yields well-characterised salts. The *hydrochloride* crystallises in white plates, and melts at 124—125°. The *hydrobromide* is somewhat less soluble than the hydrochloride, and melts at 111°. The *hydriodide* melts at 74°. The *methiodide*, $C_{19}H_{20}Me_2N_2O,MeI$, is a well-crystallised compound, and melts at 175—177°. E. C. R.

Alkaloïds of Lupinus albus. By A. Soldaini (*Gazzetta*, **22**, i, 177—180).—The concentrated aqueous extract obtained from *Lupinus albus* is mixed with caustic lime and extracted with petroleum in a reflux apparatus. The solution yields two isomeric alkaloïds, the one being a solid substance crystallising in monosymmetric prisms, $a : b : c = 1{\cdot}7983 : 1 : 1{\cdot}6710$; $\beta = 83° 14'$, melting at 99°, and the other a viscous liquid. The solid alkaloïd is found by analysis and cryoscopic determinations to have the composition $C_{15}H_{24}N_2O$. Its *hydrochloride*, $C_{15}H_{24}N_2O,HCl + 2H_2O$, melts at (?) 124—135°. The *hydriodide*, $C_{15}H_{24}N_2O,HI$, melts at 185°. The *methiodide*, $C_{15}H_{24}N_2O,MeI$, melts at 233°, and the *bromide*, $C_{15}H_{24}N_2O,Br_3$, at 124—125°. The *platinochloride*, $(C_{15}H_{24}N_2O)_2,H_2PtCl_6$, the *aurochloride*, $C_{15}H_{24}N_2O,HAuCl_4$, and the *thiocyanate*, $C_{15}H_{24}N_2O,HSCN + H_2O$, which melts at 124°, have also been prepared. The liquid alkaloïd seems to be identical with the lupanine extracted from *Lupinus*

angustiflora by Hagen (Abstr., 1886, 163) and Siebert (Abstr., 1892, 223). W. J. P.

Ephedrine from Ephedra monostachia. By P. Spehr (*J. Pharm.*, **25**, 403—404; from *Pharm. Zeit. Russ.*, **31**, 1).—To obtain the alkaloïd, the coarsely-pulverised plant and root is extracted with alcohol of 80° Tr.; the alcohol is removed, sodium carbonate is added, and the liquid shaken with ether; the crude alkaloïd remaining on expelling the ether is then transformed into hydrochloride and purified by repeated crystallisation. The alkaloïd thus obtained, *ephedrine*, is not the only one which has received this name. Nagaï, of Tokio, extracted an alkaloïd from *Ephedra vulgaris* var. *helvetica*, to which he gave this name; and the commercial firm of Merck, of Darmstadt, has extracted from the same genus an alkaloïd named *pseudoephedrine*. To avoid confusion, the distinctive characters of these forms are given in the following table :—

	Nagaï's Ephedrine.	Pseudo-ephedrine.	Spehr's Ephedrine.
Formula	$C_{10}H_{15}NO$	$C_{10}H_{15}NO$	$C_{13}H_{19}NO$
Melting point of the base	210°	115°	112°
Melting point „ hydrochloride	216°	174°	207°
Solubility in water	scarcely soluble	1 : 454	very soluble
Solubility in alcohol	easily „	very soluble	„ „
Solubility in absolute ether	„ „	1 : 15	1 : 98
Solubility in benzene	„ „	1 : 26	1 : 1180
Solubility in chloroform	„ „	1 : 8	1 : 11
Taste	bitter	bitter	burning
Physiological action	very poisonous and mydriatic	very poisonous and mydriatic	very feeble
Crystalline form of the base	rhombic	rhombic	monoclinic
Crystalline form „ hydrochloride	„	„	hexagonal

J. T.

Glaucine. By J. A. Battandier (*J. Pharm.*, **25**, 350—351).—It is impossible to obtain pure crystallised salts by Probst's method. Brilliant, needle-shaped crystals of hydrobromide can be obtained by the following process :—The concentrated sap of the leaves of *Glaucium luteum* is extracted with ammonia and light petroleum. The petroleum is treated with water, acidified with acetic acid, and glaucine acetate is precipitated by ammonia as a white, curdy mass. Glaucine thus thrown down gradually darkens in colour even when protected from light. On dissolving it in 95 per cent. alcohol, and saturating the solution with aqueous hydrobrombic acid, glaucine hydrobromide immediately crystallises out, leaving the brown alteration products still dissolved in the alcohol. These crystals washed with a little strong alcohol, and recrystallised from boiling alcohol, yield beautiful, prismatic needles. The hydrobromide is much more soluble in water than in alcohol. Glaucine, or its salts, treated with concentrated sulphuric acid, gives a beautiful, sky-blue colour, which

only on heating, or after some days in the cold, becomes violet. The brown alteration products of glaucine give up to light petroleum a white alkaloïd resembling glaucine, but which affords an immediate violet colour with sulphuric acid. Recently prepared glaucine yields a colourless hydrobromide, but the mother liquors soon give crystals of a rosy tint, which are only decolorised with difficulty by animal black. A beautiful reaction for glaucine is the following:—4 drops of acid mercuric nitrate is added to 10 c.c. of sulphuric acid and stirred up; a porcelain saucer is smeared with this mixture, and minute crystals of glaucine, or one of its salts, are dropped on to the smears. On inclining the saucers, intense green striæ are formed which gradually become red. J. T.

Aristolochia argentina. By O. Hesse (*Pharm. J. Trans.* [3], **51**, 551).—The root of *Aristolochia argentina* is treated with ether and then with alcohol; on evaporation, the alcoholic extract yields a resinous mass partly soluble in solution of sodium hydroxide, and giving up to ether a base, for which the author proposes the name *aristine*. This base dissolves in hot glacial acetic acid, and, on cooling, crystallises out in gold-coloured laminæ and needles. It is sparingly soluble in hot alcohol, but more soluble in ether, chloroform, and benzene. It decomposes when heated to 260°. Concentrated sulphuric acid turns the acetic anhydride solution first blue, then greenish-blue. Its alcoholic solution is neutral, but forms red compounds with ammonia and with soda. The author mentions another base from the same source, which base he would call *aristolochine*, although the name has already been applied by Chevallier to a substance obtained from *Aristolochia serpentaria*. *Aristolochine* is precipitated from its acid solutions by caustic alkalis, and is soluble in alcohol, ether, chloroform, and benzene, which, on evaporation, leave it as a colourless, resinous mass. R. R.

"Pillijan": Lycopodium saururus. By P. N. Arata and F. Canzoneri (*Gazzetta*, **22**, i, 146—157).—This plant occurs in South America, and contains an alkaloïd named pillijanine, which has previously only been obtained in an impure state. The authors extract it in the following manner:—A quantity of the fresh plant (25 kilos.) is bruised and boiled with a large quantity of water acidified with tartaric acid. The liquid is filtered and partially evaporated on the water-bath, calcium hydroxide added, and the whole evaporated to dryness. The residue is then extracted with boiling alcohol for three days in a reflux apparatus, light petroleum and amyl alcohol being subsequently used to complete the extraction. The liquids used for extraction are mixed and distilled; the residue is dissolved in dilute acetic acid, filtered, and the solution treated with lead acetate, and again filtered. The lead is separated from the filtrate by hydrogen sulphide, and on evaporating the solution, a syrup is obtained, which is dissolved in water and extracted with ether. The aqueous solution is saturated with sodium carbonate and extracted with chloroform. On evaporating the chloroform solution the alkaloïd (15—20 grams) is obtained as a reddish mass, possessing

a powerful odour resembling that of coniine. It is further purified by precipitating the aqueous solution of its sulphate with caustic alkali, and extracting with light petroleum. The alkaloïd crystallises from the petroleum solution in needles melting at 64—65°, and has the composition $C_{15}H_{24}N_2O$. Solutions of its salts give yellowish precipitates with auric chloride, potassium dichromate, iodine solution, and bromine-water. Ferric chloride, potassium ferricyanide, and tannin solutions give reddish, green, and whitish precipitates respectively. The *sulphate*, $(C_{15}H_{24}N_2O)_2,H_2SO_4 + 2\frac{1}{2}H_2O$, forms large, deliquescent crystals. The *hydrochloride* crystallises with difficulty in small tablets, and is very deliquescent. The *platinochloride* crystallises in yellow laminæ, is very soluble in water and alcohol, and decomposes at 200° without melting. The *aurochloride* forms splendid, yellow crystals, very rapidly altered by light. On distilling pillijanine in a current of hydrogen, a volatile base having the properties of nicotine is obtained; the alkaloïd is hence very possibly amyloxynicotine, $C_{10}H_{13}N_2{\cdot}OC_5H_{11}$. It acts as a powerful poison. A dose of 0·1—0·2 gram of the hydrochloride administered to a dog causes convulsions, violent vomiting, contraction of the pupil of the eye, and finally death. W. J. P.

Peptone Salts from Glutin. By C. Paal (*Ber.*, **25**, 1202—1236). —Mineral acids act on glutin in a similar manner to pepsin and trypsin, yielding peptones, which combine with the acid present to form salts; these dissolve not only in water, but also, unlike the free peptones, in absolute ethyl and methyl alcohol. For their preparation, 100 parts of purest commercial gelatin are warmed on the water-bath with 160 parts of water and 40 parts of concentrated hydrochloric acid until a portion of the product is completely soluble in a large quantity of absolute alcohol, and the whole is then poured into 4—5 vols. of absolute alcohol. After filtering off the inorganic salts, the solution is precipitated with ether, the residue redissolved in alcohol, and the solution evaporated under diminished pressure. The glutin peptone hydrochloride thus obtained forms a brittle, white, vesicular mass, and is readily soluble in water, methyl alcohol, ethyl alcohol, and acetic acid, somewhat less easily in propyl alcohol, sparingly in amyl alcohol, and insoluble in ether, carbon bisulphide, and benzene. It is very hygroscopic, remains unchanged at 130°, and gives the characteristic peptone reaction with biuret; it is lævorotatory in aqueous solution, $[\alpha]_D$ being about −60°. The quantity of hydrochloric acid found in the different preparations varied from 10·5—12·5 per cent., whilst the ash is only about 0·5 per cent. If stronger hydrochloric acid than that mentioned above is employed, or if the heating be continued for a longer time, salts containing a larger percentage of acid can be obtained.

The quantity of carbon and hydrogen varies considerably in the different preparations, the former being in some cases higher than that of glutin (for which the author finds C = 50·1, H = 6·68), and in others less; this is due to the fact that in most cases more or less etherification has taken place during the treatment with alcohol; the compounds formed may, however, be hydrolysed by long-continued

boiling with water. The salts were found to be almost free from sulphur.

The fact that by varying the strength of the hydrochloric acid, and the time allowed for the reaction, compounds containing a varying amount of acid are obtained, tends to show that these salts are a mixture of compounds representing different degrees of peptonisation; this has been confirmed by subjecting the alcoholic solutions to fractional precipitation with ether, and subsequent fractional crystallisation of some of the precipitates from alcohol. The salts thus obtained contain a varying percentage of acid, their solubility in alcohol decreasing with the decrease in the proportion of acid. A much more satisfactory separation is obtained by subjecting an aqueous solution of the salts to dialysis, for although they have not been obtained crystalline (probably owing to their hygroscopic nature), they, nevertheless, pass through the dialyser, and must be regarded as crystalloïds. In this manner, a salt containing 10·56 per cent. of acid was separated into two portions, that passing through the dialyser containing 14·19 per cent. of acid, and the residue only 5·79, the latter being insoluble in absolute alcohol. The percentage of carbon and hydrogen, calculated on free peptone, remains fairly constant, except in so far as the salts passing through the dialyser are concerned; the decrease in this case is due to the fact that in evaporating the large volume of solution obtained, a quantity of alcohol is split off. It was found that only those salts containing 10 per cent. of acid and upward are soluble in absolute alcohol, and those fractions which are only just dissolved are much less soluble in propyl alcohol, and insoluble in amyl alcohol; the salts containing less than 10 per cent. are all readily soluble in methyl alcohol, and these also dissolve in alcoholic solution of the salts containing more acid.

The same separation may be brought about by treating the alcoholic solution of the salt with mercuric chloride: two mercurochlorides are thus obtained, one of which separates out at once, and the second on the addition of ether; these correspond to the insoluble and soluble hydrochlorides, and may, like the mercurochlorides of the free peptones, be employed for therapeutical purposes.

If glutin be warmed with a weaker acid than that first mentioned, a salt may be obtained which dissolves in methyl alcohol, but is insoluble in ethyl alcohol, and contains 6·85 per cent. of hydrochloric acid. It closely resembles the salts already described, and may, like them, be separated into fractions containing different percentages of acid, that containing the highest percentage being somewhat soluble in ethyl alcohol. By the action of pepsin on glutin in presence of very dilute hydrochloric acid, a peptone salt is also obtained which closely resembles the salt last described, but is not completely soluble in cold methyl alcohol; it is separated by dialysis into two fractions, one of which contains 2·97 per cent. HCl, and is almost insoluble in methyl alcohol, whilst the other contains 11·13 per cent. HCl.

In all cases it appears that the salts formed either by the action of

acid or of pepsin and acid are separable into two portions containing a maximum and minimum percentage of acid, and it therefore appears probable that the molecule of glutin contains two atom-complexes, which in the first stage of the reaction yield two separate molecules. These differ greatly in the resistance they offer towards further change, the one which forms salts containing a larger quantity of acid, being more readily converted into its ultimate products of decomposition, namely, the amido-acids.

The acid in the glutinpeptone salts is very firmly combined, and great difficulty was experienced in converting the salts into the free peptones. This was first accomplished by adding a large excess of alkali and removing the inorganic substances by dialysis, but great loss of substance also takes place. It was then found that the change may be brought about quantitatively by adding a slight excess of pure silver sulphate, filtering from silver chloride, removing the excess of silver with hydrogen sulphide, and the sulphuric acid with the necessary amount of baryta-water. The glutinpeptones thus obtained are soluble in all proportions in water, but insoluble in alcohol and ether; their aqueous solutions have an acid reaction towards litmus, but do not turn Congo paper blue. On analysis, it was found that the percentage of carbon was rather less, and that of hydrogen rather more, than in the case of glutin; this is in complete agreement with the supposition that they are products of hydrolysis.

Attempts were also made to determine the molecular weights of these substances by the cryoscopic method in aqueous solution and by the boiling-point method in aqueous and methyl and ethyl alcoholic solution. The results show that the molecule of peptone salt becomes smaller as the percentage of acid increases; further, that the salts are dissociated in aqueous and methyl alcoholic solutions, but not in ethyl alcoholic solution, for the molecular weight deduced from the boiling point of the solutions in the last solvent is double that deduced in the same manner from the boiling point of the solutions of the same salt in the other two solvents. In water and methyl alcohol, the molecule of the salt is therefore dissociated into 2 mols., whence it follows that these salts consist of 1 mol. of peptone and 1 mol. of hydrochloric acid. The molecular weight of the free peptones was found to be about 300 in three cases, and about 215 in a fourth case, and that of glutin itself about 900.

The author concludes that the glutin molecule is resolved with assimilation of water into peptone molecules of gradually decreasing molecular weight, till a point is reached at which the peptonisation ceases, and the simpler peptones are resolved into amido-acids, lysin, lysatin, &c. As, however, the molecule of the proteïds consists of two atom-complexes which present a varying resistance to further hydrolysis, the simpler products of decomposition are always mixed with unaltered peptones. H. G. C.

Solubility of Fibrin. By C. Fermi (*Zeit. Biol.*, **28**, 229—236). —The dissolution of fibrin and its change into peptone are the two criteria by means of which the presence of a proteolytic ferment is ascertained. But in those cases in which the ferments are weak the

change into peptone is difficult to make out, and the solution of the fibrin remains the only test. It is thus important to know how far fibrin is soluble in acids, saline solutions, and so forth when no proteolysis occurs, and the difficulties are increased by the fact that fibrin prepared from arterial blood is more difficult of solution than that from venous blood (Denis, *Physiol. der Sang*, Paris, 1838, 1856, 1859; Scherer, *Ann. Chem. Pharm.*, **40**, 18; Zimmerman, *Roser and Wunderlich's Archiv physiol. Heilk.*, **5**, 349; **6**, 53); moreover, the fibrin differs in different animals (Scherer, Zimmerman, Deutschmann, *Pflüger's Archiv*, **10**, 501).

The following are the results of the present investigation :—

1. Pig's fibrin dissolves in 5 per 1000 hydrochloric acid in a few hours, ox fibrin requires several days. Pig's fibrin does not dissolve much more quickly if pepsin is added.

2. The same is true for other acids (malic, formic, oxalic, butyric, acetic, citric, lactic, nitric, sulphuric). Pig's fibrin always dissolves most easily, ox fibrin least easily; the fibrins of the sheep and horse are intermediate.

3. Hydrochloric acid is the most powerful; nitric, sulphuric, acetic, and butyric acids the least.

4. Warmth accelerates the solution.

5. Boiled fibrin is very difficult of solution.

6. The dissolved fibrin is a proteïd which is precipitated by neutralisation.

7. Fibrin does not appear to contain within itself a fibrin-dissolving ferment.

It thus is seen that the mere solution of the fibrin is no trustworthy test for a proteolytic enzyme. If, however, there is no other available, due attention must be paid to the source of the fibrin, the strength of the acid used, and the time taken for solution; a large number of control tests must be employed. W. D. H.

Hæmocyanin. By A. B. Griffiths (*Compt. rend.*, **114**, 496).—Blood of *Homarus*, *Sepia*, or *Cancer* is precipitated by magnesium sulphate, and the precipitate dissolved in water, reprecipitated by alcohol, purified, and dried at 60°, and finally in a vacuum. The analyses of specimens thus prepared from different sources agree well, and lead to the empirical formula $C_{867}H_{1363}N_{223}CuS_4O_{258}$. Hæmocyanin is more stable than hæmoglobin. Jn. W.

Blue Colouring Matter in the Blood of Crustaceæ. By F. Heim (*Compt. rend.*, **114**, 771—774).—Hæmocyanin, the blue colouring matter formed by the action of air on the almost colourless blood of the Crustaceæ, is usually described as a proteïd analogous in properties and function to the hæmoglobin of the Vertebrata. It is also said to contain copper as an essential constituent, and to be the only proteïd in the blood of Crustaceæ.

The author confirms the statement that it exists in two states, reduced and colourless, oxidised and coloured. The combination with oxygen is destroyed by exposure in a vacuum, passage of an inert gas, action of reducing agents, &c.

Contrary to the usual statement, the author finds that the blood of the Crustaceæ contains serum identical in its properties with that of the Vertebrata, and paraglobulin derived from the serum. Dialysis consequently yields a mixture of hæmocyanin with a large quantity of serum, and not pure hæmocyanin.

Copper is not an essential constituent of hæmocyanin; although present in the lobster, it does not occur in the crab, hermit crab, crayfish, sea crayfish, and about half the Crustaceæ.

Direct estimation shows that the quantity of available oxygen present in hæmocyanin is not greater than that present in water.

Attempts to isolate pure hæmocyanin were not successful, and it is doubtful whether it is really a proteïd. It differs essentially from hæmoglobin in the absence of a metal as a necessary constituent of its molecule and in its feeble absorption coefficient for oxygen; it does not crystallise, does not combine with carbonic oxide, and does not resist putrefaction. The so-called hæmocyanin observed by Fredericq in the putrefied blood is blackish, and not blue, and has none of the properties of hæmocyanin. It is analogous to melanin, and is formed also in the putrefaction of hepatic tissue. C. H. B.

Physiological Chemistry.

Unorganised Ferments. By G. Tammann (*Zeit. physiol. Chem.*, **16**, 271—328).—Whereas mineral acids further all hydrolyses, the enzymes only act on particular materials, some producing hydrolysis of starch, others of proteïds, and so forth. The hydrolysis produced by acids is complete; that produced by enzymes (with certain exceptions—invertin, rennet) is usually incomplete, especially if the quantity of material to be acted on is large. This is due to the fact that during its activity the ferment is converted into an inactive modification, and the transformation usually occurs before the ferment reaction is completed. This change is brought about by the products of the ferment action; removal or dilution of these products, or elevation of temperature, allows the ferment action to continue, as by these means the inactive is reconverted into the active modification. Too high a temperature, however, changes the ferment in such a way that it is not possible to obtain from it again the active modification. W. D. H.

Unorganised Ferments. By J. Jacobson (*Zeit. physiol. Chem.*, **16**, 340—369).—Soluble ferments, in addition to their specific action, have in common the power of liberating oxygen from hydrogen peroxide. The ferments specially investigated in the present research were emulsin, diastase, and pancreatin. The influence of elevated temperature in destroying the activities of the ferments differentiates their two actions; at a certain temperature (differing

in different ferments, and according to whether they are in a dry or dissolved condition), the power to decompose hydrogen peroxide is lost; the specific action of the ferment is usually weakened at this temperature, but it is not destroyed until a higher temperature is applied.

Alkali up to 0·12 per cent. augments the oxygen-liberating activity of the ferments; a percentage of 0·25 destroys it. Hydrochloric acid of a strength of 0·008 per cent. lessens, and of 0·035 destroys, this activity.

The influence of a very large number of inorganic and organic compounds in this direction was also tried; and the results are given in detail. There appears, however, to be no general conclusion to be drawn from these experiments: some hinder, some accelerate, and others have little or no influence; it is not possible to class these according to their chemical constitution. W. D. H.

Glycolysis in Blood. By M. Arthus (*Compt. rend.*, **114**, 605—608).—Glycolysis in blood is a phenomenon of chemical fermentation and is not due to the development of microorganisms; it takes place in blood collected aseptically in sterilised vessels. The presence of actually living elements in the blood is not necessary, for the destruction of the sugar takes place in serum or oxalated plasma free from globules, in blood diluted with several volumes of water, and in blood which, after being kept for 24 hours at 15°, is mixed with 1 per cent. of sodium fluoride. The glycolytic ferment does not preexist in living blood, but is formed outside the blood vessels at the expense of the elements of the envelopes of the white corpuscles. Its formation seems to be a consequence of the extravascular life of these corpuscles. Fresh blood shows very little glycolytic power, but this power gradually develops when the blood is kept. Addition of sodium fluoride to freshly drawn blood prevents the development of the glycolytic ferment, but does not prevent its destructive action on sugar if time has been given for the development of the ferment before the addition of the fluoride. Sodium oxalate has a similar effect. The action of the ferment is very feeble at 0°, but becomes more energetic as the temperature rises, and is strongly marked at 40° to 50°; at 55°, the ferment is destroyed. It will be seen that the glycolytic ferment behaves in many ways similarly to the fibrin ferment: glycolysis will continue for several days at 10° in defibrinated aseptic blood, and for several weeks in aseptic oxalated blood. Direct experiment shows that the apparent absence of glycolysis when the blood is first drawn is not due to a compensating development of sugar from glycogen or other substances; it is due to the fact that the glycolytic ferment does not preexist in the blood, but is formed after the latter is removed from the blood vessels. C. H. B.

Fermentation of Blood. By Berthelot and G. André (*Compt. rend.*, **114**, 514—520).—The experiments were made with defibrinated bullock's blood of sp. gr. 1·045 at 15°, and fermentation was allowed to continue for 130 days, at first at a temperature of 35°, and towards the end at 45°. The products under these conditions are carbonic

anhydride, ammonia, traces of hydrogen sulphide, volatile fatty acids, and non-volatile nitrogenous compounds. The liquid retains the reddish-brown tint of altered blood. The following table shows the composition of 1000 c.c. of the original defibrinated blood, exclusive of inorganic salts and water, together with the composition of the products :—

	C.	H.	N.	O.	Total.
					grams.
Original blood	87·0	11·8	26·0	37·6	162·4
Carbonic anhydride	7·3	—	—	20·0	27·3
Ammonia	—	3·6	16·7	—	20·3
Volatile fatty acids	26·5	4·4	—	21·1	52·0
Non-volatile nitrogen compounds.	53·0	8·0	9·7	32·4	103·1

Of the total quantity of carbonic anhydride formed, 22·5 grams is evolved in the gaseous state, whilst 4·8 grams remains in combination in the liquid. It is especially noteworthy that the gas evolved is quite free from hydrogen and nitrogen. In the case of the ammonia, 3·6 grams remains in the liquid in the form of compounds decomposable by magnesium oxide, whilst the rest is either evolved during fermentation, or can be expelled by a current of hydrogen.

The carbonic anhydride and ammonia are formed in practically equivalent proportions, as in the fermentation of urea, but in the case of blood they are derived from proteïds which are analogous to ureïdes in their mode of decomposition. Two-thirds of the total quantity of nitrogen is converted into ammonia, and hence it would seem that two-thirds of the proteïds decompose after the manner of ureïdes.

The volatile fatty acids include all members of the acetic series from formic to caproic acid, and even beyond, but their mean composition lies between that of propionic and butyric acids, the extremes of the series being present in comparatively small quantity. These products are similar to those resulting from butyric fermentation, with the essential difference that no hydrogen is evolved during the change.

The non-volatile nitrogen compounds are :—(1.) An insoluble, brown compound of a humoid character; it has the empirical composition $C_{18}H_{24}N_2O_3$, and is a condensed anhydride. (2.) Nitrogenous acids forming crystallisable barium salts, the first crop having the composition $C_{55}H_{105}Ba_2N_9O_{22}$, and the second $C_{31}H_{56}BaN_6O_{16}$. (3.) A non-crystallisable compound soluble in alcohol; it has the composition $C_{18}H_{33}N_3O_{10}$ or $C_6H_{11}NO_3$. (4.) Compounds insoluble in alcohol but forming salts partially crystallisable from water; they are formed in small quantity, but seem to be amido-acids related to the fatty series, the salts having the mean empirical formula $C_{12}H_{24}N_2O_3 + nRO$. The composition of the nitrogen compounds formed from 1000 c.c. of blood is summarised in the following table :—

	C.	H.	N.	O.
Brown, insoluble substance	4·62	0·50	0·56	1·06
Nitrogenous acids	18·88	3·02	3·66	11·12
Compounds soluble in alcohol	25·76	4·08	5·00	19·02
Compounds insoluble in alcohol	2·86	0·46	0·52	1·24
	51·92	8·03	9·74	32·44

No volatile nitrogenous bases are formed, nor any alcohol or acetone; but traces of a pungent compound, probably a thioaldehyde, and of a volatile substance with a camphoraceous odour were observed.

It will be noticed that whilst the total weight of the carbon compounds in 1000 c.c. of blood was 162·4 grams, the total weight of the products was 202·7 grams. The increase of 40·3 grams is due solely to oxygen and hydrogen, which, moreover, have been assimilated in the proportions in which they exist in water. Further, two molecules of water have been assimilated for each molecule of ammonia formed; this ratio is characteristic of the nitriles. On the other hand, the formation of ammonia and carbonic anhydride in equivalent proportions, a relation characteristic of the ureïdes, would indicate the assimilation of one molecule of water for each atom of nitrogen. The ureïdes, however, require the assimilation of a molecule of water before decomposing by further hydrolysis in the manner of urea. One-third of the total nitrogen remains in solution in the form of stable nitrogen compounds.

It is noteworthy that one-twelfth of the carbon is evolved in the form of carbonic anhydride, and one-third of the remainder is converted into fatty acids, and two-thirds into amido-compounds.

The comparative simplicity of these relations is of considerable interest. C. H. B.

Formation of Glycogen from different Sugars. By C. Voit, J. G. Otto, A. C. Abbott, G. Lusk, and F. Voit (*Zeit. Biol.*, **28**, 245—292).—From the examination of previous and the present researches on glycogen formation in the liver, it is believed that glycogen may originate in two ways: first, it is a temporary store of carbohydrate food, and, secondly, it may be the result of proteïd metabolism. The present research was performed on animals (rabbits, hens) in which the hepatic glycogen had been reduced to a minimum by starvation, and relates chiefly to the former of the two sources of glycogen just alluded to. The estimation of the glycogen was performed either by Brücke's or Külz's method. Large doses of different sugars were given. Dextrose, lævulose, cane sugar, and maltose increased the hepatic glycogen; lactose and galactose did not, or only very slightly.

The change which these sugars undergo in the alimentary canal was then investigated; cane sugar and maltose are inverted. Lævulose, lactose, and galactose are absorbed as such, and after

large doses pass as such into the urine. The liver appears unable to form glycogen from sugars which, like lactose and galactose, do not pass into the condition of either dextrose or lævulose. In fact, these appear to be the only forms of sugar which, when present in the blood, lead to the storage of glycogen in the liver. When subcutaneously injected, the hepatic glycogen rises in amount. No other form of sugar behaves in this way. Regarding lævulose, the liver cells must either form glycogen from it direct, or after previously changing it into dextrose. The latter possibility would not be improbable, as E. Fischer has shown; moreover, the action of the cells of the mammary gland in converting dextrose into lactose is somewhat analogous.

W. D. H.

The Behaviour of Milk Sugar in a Diabetic. By F. Voit (*Zeit. Biol.*, **28**, 353—360).—A diabetic patient was taking strict diet, and the amount of sugar in the urine reduced to a low ebb. On one occasion 100 grams, on another 150 grams, of milk sugar was administered; the sugar in the urine at once went up. A pure culture of *Saccharomyces apiculatus* was added to the urine, and fermentation allowed to go on. After a few days' fermentation, the urine contained no sugar. This fungus causes the alcoholic fermentation of glucose, but not of lactose. Thus there was no lactose in the urine. The dose given was not large enough to cause the appearance of this sugar in the urine. The explanation given of what had occurred is the following:—Before the sugar was given, the small amount of diabetic sugar in the urine must have originated from proteïd metabolism. Lactose appears in the urine more readily than any other form of sugar, not because it is burnt in the organism with greater difficulty, but as it is a form of sugar from which it is not possible for the liver to make glycogen, its "assimilation limit" is low, and so passes unused into the urine. In fact, in diabetics it appears to be more readily burnt in the body than dextrose, and takes the place of some of the dextrose originating from proteïd metabolism. Hence, when lactose is given, a large quantity of dextrose remains unburnt, and passes as such into the urine. W. D. H.

Transformation, in the Animal Economy, of Sulphanilic Acid into Sulphanilocarbamic Acid. By J. Ville (*Compt. rend.*, **114**, 228—231).—Sulphanilic acid was administered to dogs with their ordinary food; from the urine, part was recovered as an alkaline sulphanilate, and part as alkaline sulphanilocarbamate. This corresponds with the formation of taurocarbamic acid from taurine under similar circumstances (Salkowski, *Ber.*, **6**, 744).

For the extraction of the sulphanilocarbamic acid (Abstr., 1891, 1066), the urine is evaporated to a syrup, and treated with four or five times its volume of absolute alcohol. After standing for 24 hours, the precipitate is collected, washed with alcohol, and dried over sulphuric acid in a vacuum. It is then dissolved in a small quantity of water, and an excess of dilute sulphuric acid and alcohol is added. The precipitate is filtered off, and the filtrate evaporated over sulphuric acid to a syrup; this is diluted with water, neutralised with barium carbonate, filtered, and the barium precipitated by the calcu-

lated amount of sulphuric acid. Hydrochloric acid is removed by silver carbonate, and the liquid treated with hydrogen sulphide, filtered, and evaporated. The acid is dissolved out from the residue with absolute alcohol, the alcohol evaporated, and the residue decolorised by treatment with animal charcoal in aqueous solution, and finally evaporated over sulphuric acid in a vacuum.

Sulphanilocarbamic acid thus obtained crystallises in feathery plates, very soluble in water and absolute alcohol, completely insoluble in ether, chloroform, and benzene. The aqueous solution is decomposed by sodium hypobromite, with abundant evolution of nitrogen. When heated in a closed vessel at 135—140° with an excess of baryta-water, it decomposes with evolution of ammonia and formation of barium carbonate and sulphanilate.

Sulphanilic acid is obtained in brilliant, rhombic plates from the filtrate from the first alcoholic precipitation. W. T.

Decomposition of Fibrin, Gelatin, Peptone, and Asparagine in the Human Body. By L. Graffenberger (*Zeit. Biol.*, **28**, 318—344).—This investigation was undertaken in connection with Voit's theory of floating proteïd, to ascertain when the greatest rise of urea excretion occurred after the ingestion of nitrogenous material. The urine was collected at intervals of two hours; the diet was fixed, and on different occasions fibrin, gelatin, peptone, and asparagine were taken in addition. After taking fibrin, the increased output of nitrogen accounted for 49·2 per cent. of the fibrin taken. The greatest rise in urea occurred in the second period (that is, the third and fourth hours) after the meal. It fell somewhat in the third period, and after that fell rapidly. With gelatin, the same occurred, except that the fall after the fourth hour was more rapid. With peptone, the increase was as marked in the third as in the second period. With asparagine, there was a second rise, more marked than the first, in the fourth and fifth periods. W. D. H.

Influence of Water and Sodium Chloride on Nitrogenous Excretion. By D. Dubelir (*Zeit. Biol.*, **28**, 237—244).—Three experiments on a dog are recorded. The animal being in a state of nitrogenous equilibrium, it was found that water increased the volume of the urine, but did not alter the output of nitrogen. Sodium chloride also increased the volume of the urine, and lowered the excretion of nitrogen by 9 per cent. W. D. H.

Physiological Action of Gallic and Tannic Acids. By C. T. Mörner (*Zeit. physiol. Chem.*, **16**, 255—267).—Baumann and Wolkow (Abstr., 1891, 1129) have shown that homogentisic acid which occurs in the urine in cases of alcaptonuria, reduces an ammoniacal solution of silver nitrate, and this reaction serves for the estimation of the acid. The present investigation shows that it may also be applied to the estimation of gallic acid in the urine. By its means, a percentage of 0·001 of gallic acid, artificially mixed with the urine, can be recognised. The amount of ammonia used was 1 c.c. of the concentrated solution (or 3 c.c. of the 10 per cent. solution) to

10 c.c. of urine. The end reaction was ascertained by testing with hydrochloric acid the filtrate off from the reduced silver. From comparative experiments with normal urine, it is found necessary to deduct 1·3 c.c. of the silver solution used for 50 c.c. of urine.

When gallic acid is given by the mouth (to human beings and dogs) in small quantities, none appears in the urine; but, given in larger quantities, a certain amount passes as such into that secretion; thus, when 6, 4, 2, and 1 gram respectively are administered, 30, 20, 5, and 2 per cent. respectively appear in the urine. When tannin is given, none reappears as such in the urine; it seems to be entirely destroyed in the body; when large doses are given, however, a small quantity of gallic acid is found in the urine; when 8 to 10 grams are administered, only 1 per cent. is found as gallic acid in the urine.

Pyrogallol is not found. This coincides with some previous work of Stockman's (*Brit. Med. J.*, 1887, 1077). W. D. H.

Choline, Neurine, and Allied Compounds. By E. Schmidt (*Annalen*, **267**, 249—254).—On comparing the chemical constitutions of choline, muscarine, betaïne, and neurine, it is at once evident that apparently small differences in chemical composition and in structure have a very considerable effect on the physiological action of the compounds in question. In the case of neurine, $OH\cdot NMe_3\cdot CH{:}CH_2$, for example, it would seem that its poisonous action is closely connected with the presence of the vinyl group; consequently, it might be supposed that a compound of like nature, but containing an acetenyl in the place of the vinyl group, would be an equally powerful, or even a more powerful, poison. This view was put to the test of experiment, and found to be correct. *Acetenyltrimethylammonium hydroxide*, $OH\cdot NMe_3\cdot C{:}CH$ (compare Bode, this vol., p. 806), is a more virulent poison than neurine; on injecting only 1 milligram of this substance into the vein of a cat, respiration and the action of the heart immediately cease. *Allyltrimethylammonium hydroxide*, $OH\cdot NMe_3\cdot CH_2\cdot CH{:}CH_2$ (*loc. cit.*), on the other hand, is a relatively non-poisonous substance.

In order to ascertain the influence of the position, and of the number, of hydroxyl groups on the physiological action of compounds such as choline and muscarine, attempts were made to prepare isocholine, $OH\cdot NMe_3\cdot CHMe\cdot OH$, but without success; isomuscarine, $OH\cdot NMe_3\cdot CH(OH)\cdot CH_2\cdot OH$, was, however, obtained without much difficulty (*loc. cit.*), and was found to have a strongly poisonous action, but quite a different one, in many respects, from that of muscarine.

Chemistry of Vegetable Physiology and Agriculture.

New Method of Yeast Purification. By J. Effront (*Bull. Soc. Chim.* [3], **6**, 705—709; compare Abstr., 1891, 1532).—A complete temporary arrest of cell formation is caused by the addition of an alkali

fluoride (300 milligrams per 100 c.c. of wort), and yeasts so treated may be preserved for six months. On transference of the yeast to ordinary wort, the reproductive activity and the rate of alcohol formation increase; the results vary with the species of yeast employed, *S. cerevisiæ* affording the best results. Larger amounts of fluorides destroy the lactic and butyric bacilli, with but temporary effect on the yeast cells. Making use of the fact that the reproductive power of *S. cerevisiæ* is much more enhanced by fluorides than that of *S. Pastorianus*, the author finds that the treatment of three successive generations of mixed yeast cells, as above described, is sufficient to eliminate the latter variety. A comparative fermentation of a wort which with ordinary yeast lasted three days, but in the case of the same yeast, treated as above, was protracted during three weeks, resulted in favour of the prepared yeast, as judged by the density, limpidness, and taste of the beer. T. G. N.

Conditions influencing the Action of Fluorides on Fermentation. By J. Effront (*Bull. Soc. Chim.* [3], **6**, 786—793; compare preceding abstract).—The author details several experiments tending to prove that, in order to influence most favourably the suppression of the lactic and butyric fermentations, the wort to which the fluorides are added should be slightly acid, and that healthy development with increased reproductive activity of the yeast is assisted by the presence of alkaline phosphates, the maximum effect being attained at a temperature of 50—60°. T. G. N.

Nitrification in Organic Media of Acid Reaction. By E. Chuard (*Compt. rend.*, **114**, 181—184).—Turf-earth contains no nitrogen as nitric acid when freshly taken from its natural position. By exposure to the air, nitrification takes place to such an extent that a sample, containing no nitric acid to begin with, in the course of a twelvemonth was found to contain 0·298 per cent. N_2O_5.

The addition of chalk or potassium carbonate was found to exert a retarding effect on the nitrifying process; calcium sulphate exerted a similar action.

The nitrification, therefore, differs essentially from that taking place in arable soils, where a neutral or alkaline medium and comparative freedom from organic matter favour the process.

Whether the difference is due to the action of a different organism, or whether the process of nitrification is different from that obtaining in arable soils, has not yet been determined.

Encouraging results have been obtained by using turf-earth as a manure for vines, where it is essential to employ dressings rich in organic matter.

A cultivation of the organism in inorganic liquids has yielded a product in 10—15 days which gives the diphenylamine reaction; but no active nitrification, similar to that of the organism from arable soil, has been obtained. W. T.

Comparative Nitrification of Humus and Undecomposed Organic Matter. By P. Pichard (*Compt. rend.*, **114**, 490—493;

compare this vol., p. 656).—Humus is not readily attacked by nitrifying agents. The actual amount of nitrification is increased by the addition of calcium carbonate and sulphate, which hinder the volatilisation of the ammonia. The sulphate, however, can only be used for dry, porous soils, as in most soils the sulphide to which it is liable to be reduced is not reoxidised, and exercises, therefore, a retarding influence on the nitrification. In soils manured with undecomposed organic matter, such as seed-cake, the nitrification is much more rapid, and is still further facilitated by the addition of calcium sulphate. The proportion of nitrogen nitrified in vegetable soils containing 3—5 grams of organic nitrogen per kilogram is increased by diluting the soil with granitic sand, probably by facilitating aëration. In spite of the slow nitrification of humus, the amount of nitrates formed in sandy soils, poor in calcium salts, would be enough for the needs of the vegetation, were it not for the washing action of the rain. To increase the amount of nitrification, humus soils must, therefore, be mixed with calcium carbonate, a small amount of sulphate, and clay, or manured with compost mixed with calcium sulphate and loam. Jn. W.

Soluble Colouring Matters produced by Bacteria in Distilled Medicinal Waters. By L. Viron (*Compt. rend.*, **114**, 179—181).—Three pigments have been isolated from dark-green orange-flower water. One of these dissolves in water with a light-violet coloration, rapidly becoming brown in the air. It is without action on carbazole dissolved in concentrated sulphuric acid; by nitric and hydrochloric acids, its colour is changed to red. The second pigment dissolves in concentrated alcohol with a yellow colour; it is not influenced by nitric and hydrochloric acids, but, with carbazole in sulphuric acid, it gives a violet-blue coloration and then an indigo-blue precipitate. The third pigment is insoluble in methyl and ethyl alcohols, but dissolves in water with a fine, green coloration. It gives no reaction with the acids or carbazole. These colouring matters have been produced by the action of micro-organisms, which have been isolated by the author. The organism producing the first pigment is considered to be a variety of *Micrococcus cyaneus*. The organism yielding the yellow pigment has been named *Bacillus aurantii*. A third organism consists of small, spindle-shaped bodies, which tint gelatin green by reflected light but yellow by transmitted light; the pigment communicates an intense green coloration to water. An organism met with in much-altered waters produces a yellowish-green fluorescent coloration; it resembles *Bacillus fluorescens liquefaciens*.

W. T.

Vegetable Cell Membranes. By E. Schulze (*Zeit. physiol. Chem.*, **16**, 387—438).—The vegetable cell wall has a complicated composition. Some of the constituents, when heated with dilute mineral acids, easily yield galactose, mannose, arabinose, and xylose; others are not converted into glucoses unless concentrated mineral acids are employed, and the heating continued for some hours. The first group are named hemi-celluloses; the second, celluloses. One of the latter (dextroso-cellulose) yields dextrose, and is of wide distribution. In

some cases, celluloses yield mannose and xylose. The constituents of the cell wall are polymeric anhydrides of glucoses. It is impossible to say whether all these substances are merely mixed together or in a state of combination. Due regard must be paid to the probability that the reagents employed considerably alter the various materials present in the natural condition. W. D. H.

Occurrence of Mannitol and Sorbitol in the Fruit of the Cherry Laurel. By C. Vincent and Delachanal (*Compt. rend.*, **114**, 486—487).—Fully ripe cherry laurel fruit, gathered in September, was pounded into a paste, mixed with water, and allowed to ferment for some days. The mass thus obtained yielded a dark-red liquid, which, after clarification with lead acetate and removal of excess of lead, was concentrated in a vacuum to a syrup from which mannitol soon crystallised in characteristic long, silky needles.

The remaining syrup was treated with alcohol to precipitate the dissolved mannitol, the alcohol distilled off, and the residue treated with sulphuric acid and benzaldehyde. The resulting sorbitol benzoic acetal was then hydrolysed with dilute sulphuric acid, the acid removed by baryta, the sorbitol extracted with ether, and the ethereal solution evaporated in a vacuum to a syrup and allowed to crystallise. The sorbitol thus obtained was identical with that prepared from mountain ash berries. Jn. W.

Occurrence of Guanidine in Plants. By E. Schulze (*Ber.*, **25**, 658—661).—Vetch-seedlings, which had grown for three weeks in the dark, were dried, powdered, and digested with 92 per cent. alcohol. The filtered extract was distilled, the residue treated with water, and some tannin, and then lead acetate added. The precipitate was filtered off, and to the filtrate a solution of phosphotungstic acid added, and the precipitate collected, washed with dilute sulphuric acid, dried between filter paper, and decomposed with cold lime-water. The filtered solution was freed from lime by means of carbonic anhydride, again filtered, neutralised with nitric acid, and concentrated on the water-bath; crystals separated out which were shown to be identical in their properties with guanidine nitrate. 1 gram was obtained from 3 kilos. of dried seedlings. Lossen has shown that guanidine is formed in small quantity by the oxidation of proteïds, and it may perhaps have thus been formed in the seedling plant; it does not occur in vetch seeds which have not germinated.

C. F. B.

Vegetation of the Vine. By L. Roos and E. Thomas (*Compt. rend.*, **114**, 593).—During the first 10 or 12 weeks of vegetation, a saccharose exists in the leaves, sap, and even the grape, contrary to the opinion of Petit. This saccharose disappears during the fourth month of vegetation; the organs specified then contain a mixture of sugars, in which glucose predominates. The increase in the absolute amount of sugar does not correspond to diminution in acidity, and hence it is not always true that the acidity of fruits diminishes in proportion to the approach of ripeness. The diminution in the absolute acidity is observed at the moment when the amount of

levulose perceptibly increases in the fruit. At this point, the rotatory power changes in sign, and the lævorotatory power increases until the fruit is ripe, when it is practically identical with that of invert sugar. C. H. B.

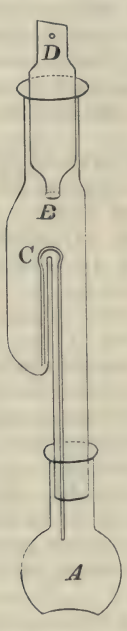
Ammonia in Rain-water and in the Atmosphere. By A. Muntz (*Compt. rend.*, **114**, 184—186).—The author upholds the deductions drawn from determinations of the amount of ammonia in rain-water in tropical regions given in a previous paper (this vol., p. 381). He points out that the objections to these conclusions brought forward by Albert-Lévy (this vol., p. 381) are founded on observations taken in the neighbourhood of Paris, and quotes the results of Angus Smith, of Boussingault, and of the Rothamsted observations in support of the average value (0·50 milligram) of the ammonia per litre of rain-water adopted by the author for temperate climates. W. T.

Experiments on the Growth of Wheat in a Sterile Siliceous Sand. By A Pagnoul (*Ann. Agron.*, **17**, 538—544).—For the results of the 1890 experiments, see Abstr., 1891, 104. In 1891, similar experiments were instituted, cylinders of impermeable ware 13·6 inches high and of 120·64 sq. in. section being employed. The following results were obtained:—

1. Nitric nitrogen *versus* ammoniacal nitrogen.—When potassium chloride and soluble phosphate of lime were supplied as well, sodium nitrate was slightly better than its equivalent of ammonium sulphate, the respective yields of grain being in the ratio of 64·3 to 55·4.

2. Whereas the omission of potash reduced the yield in the ammonium sulphate pots in the proportion of 26 to 10, where sodium nitrate was employed, the reduction in yield by omitting potash was only in the proportion of 13 to 10. Potash increased the weight of the individual grain from 10 to 17 in the ammonium sulphate pots, from 10 to 14 in the sodium nitrate pots.

3. The addition of magnesium sulphate to the other chemical manures produced no effect.



4. Arable soil—containing $CaCO_3$, 5·515; P_2O_5, 0·220; K_2O, 0·297; MgO, 0·297; and N, 0·139—was tried against the sterile sand. The soil pots were manured, once only, with sodium nitrate, containing 0·100 gram N, and superphosphate, containing 0·100 gram P_2O_5.

The sand pots were manured 20 times during the season, each receiving in the aggregate sodium nitrate containing 2 grams nitrogen and superphosphate containing 2 grams P_2O_5. Under these conditions the yield of grain in the soil was only 57 per cent., and of straw 68 per cent., of that in the manured sand. The grain grown in soil contained 12·93 per cent. proteïds, that in manured sand 15·77 per cent.

In the ammonium sulphate experiments the ratio of grain to straw was 55 to 100, and in the sodium nitrate experiments 64 to 100. These are both high yields, due to the abundance of soluble phosphate supplied in the manure. J. M. H. M.

Analytical Chemistry.

Extraction Apparatus. By J. T. Willard and G. H. Failyer (*Chem. Centr.*, 1892, i, 4; from *J. anal. Chem.*, **5**, No. 8).—The apparatus is easily understood from the figure. D is the lower end of the condenser, which is widened and ground to fit the upper part of the extractor; the lower end of the latter is ground to fit the flask.

The substance is placed in the side "pocket" C, and the siphon is loose. This must be bent as indicated, in order to prevent the extracting liquid from passing up the inner side by capillarity, and so over the bend and into the receiver before the "pocket" is full.

J. W. L.

Use of Bromic Acid in Quantitative Analysis. By W. Feit and K. Kubierschky (*Chem. Zeit.*, **15**, 351—352).—The authors have found that bromic acid, or, what amounts to the same thing, a solution of potassium bromate in dilute sulphuric acid, from which any free bromine may be expelled by boiling, is a very handy laboratory reagent. It acts as a powerful oxidiser, and the liberated bromine may be very readily expelled by boiling. The authors proceed in the following manner:—An accurately-measured excess of the bromate solution, which must contain excess of sulphuric acid, is put into a 200-c.c. flask, the substance is added, and the whole gradually

heated to boiling. After about five minutes, the bromine will be practically expelled, and no notice need be taken of a trace of a yellow colour. After cooling, the liquid is made up to the mark, and the excess of undecomposed bromic acid is estimated in an aliquot part of the liquid by means of potassium iodide and sodium thiosulphate. The authors communicate some very successful quantitative experiments. Hydrogen sulphide is oxidised to sulphuric acid and water. Sulphurous anhydride and hydrogen thiosulphate are also completely oxidised to sulphuric acid and water. Nitrous acid is oxidised to nitric acid, and oxalic acid is oxidised to carbonic anhydride and water.

The process may also be applied to ferrous salts. As the ferric compound obtained would interfere with the iodometric estimation, it must first be removed by a cautious addition of sodium carbonate. After making up to the mark and allowing to settle, the bromate may be estimated as usual after acidifying with sulphuric acid.

The authors have every reason to believe that bromic acid may become a useful reagent in the synthesis of organic compounds.

L. DE K.

Estimation of Fluorine. By A. CARNOT (*Compt. rend.*, **114**, 750—753).—The substance is heated with sulphuric acid and a large excess of silica in a carefully dried apparatus, and the silicon fluoride evolved is absorbed in a 10 per cent. solution of potassium fluoride, the end of the delivery tube being under mercury at the bottom of the vessel containing the fluoride solution. Potassium silicofluoride forms, and its precipitation is made more complete by adding an equal volume of alcohol of 90 per cent.; the precipitate is washed with alcohol and dried at 100° on a weighed filter.

The quantity of substance taken should not contain more than 0·100 gram of fluorine, and it must be intimately mixed with not less than 10 times as much finely-divided silica as there is fluorine present. About 40 c.c. of pure concentrated sulphuric acid is added, and the mixture is heated at about 160° in a carefully dried flask of 150 c.c. capacity, a slow current of dry carbonic anhydride being passed through the apparatus. The exit tube is furnished with a bulb to arrest any drops of sulphuric acid that may be spurted over, and if the substance contains chlorine, a tube containing anhydrous copper sulphate must be attached. Care must be taken that all the materials are free from fluorine, and, if necessary, a blank experiment may be made.

In order to estimate silica as well as fluorine, a known weight of pure silica is added to the substance, and the silica is determined partly by calculation from the weight of silicon fluoride and partly by direct separation from the residue in the flask, the weight of silica added being of course deducted. C. H. B.

Precipitation of Phosphorus from Solutions of Iron and Steel. By R. HAMILTON (*J. Soc. Chem. Ind.*, **10**, 904—906).—Shimer (Abstr., 1889, 76) suggested that the incomplete precipitation of phosphorus was due to incomplete oxidation, and proposed to render all the phosphorus precipitable by oxidising the solution with

potassium permanganate. The experiments recorded in this paper would appear to show that this view has much to commend it. They show (1) that the carbonaceous matter in a solution of iron does not prevent the complete precipitation of properly oxidised phosphorus as ammonium phosphomolybdate; (2) that the reason of the incomplete precipitation of phosphorus from a nitric acid solution of iron, which has not been evaporated to dryness and roasted, is that the phosphorus has not all been properly oxidised; and (3) that in such solutions all the phosphorus can be completely oxidised and rendered precipitable, in the wet way, by means of certain oxidising agents.

D. B.

Estimation of Phosphorus in Pig-iron by means of Braun's Centrifugal Apparatus. By C. Reinhardt (*Chem. Zeit.*, **15**, 410—412).—The author has found it quite possible to obtain, by this process, results which favourably compare with the gravimetric methods; but there is a great deal of personal equation in the matter, and every analyst should therefore fix his own coefficient, namely, the factor to be used in reducing the volume of the phosphomolybdate precipitate to percentage of phosphorus.

L. de K.

Volumetric Estimation of Phosphoric Acid. By M. Spica (*Gazzetta*, **22**, i, 117—123).—The author employs the following process for estimating phosphoric acid in chemical manures. The weighed sample is cautiously heated with concentrated sulphuric acid in a small porcelain capsule until almost all the sulphuric acid is driven off; all the phosphoric acid is now in the free state, and is extracted from the residue by absolute alcohol, the metals remaining as sulphates insoluble in alcohol. The alcoholic solution is now filtered and evaporated on the water-bath to expel the alcohol. The residue is dissolved in water, rendered exactly neutral with soda, made up to a known volume, and an aliquot part taken for the titration. The solution is titrated in the cold with standard potassium ferric alum solution. On running in the ferric solution, a white precipitate of ferric phosphate separates. Aqueous salicylic acid solution is used as the indicator; an amethyst colour is produced when excess of iron is added. The solution must be exactly neutral when titrated, for if it be alkaline, ferric hydroxide will be precipitated, whilst, if acid, part of the ferric phosphate will be dissolved. 1 c.c. of the ferric solution may conveniently be made equivalent to 1 milligram of P_2O_5. The results are very good.

W. J. P.

Analysis of Phosphates. By J. H. Vogel (*Chem. Zeit.*, **15**, 495—499).—The author, who has made a thorough investigation of the matter, comes to the conclusion that, in order to get a trustworthy estimation of iron and alumina in phosphates, Glaser's process should be used in conjunction with Stutzer's method. The first process generally gives the results too high, on account of co-precipitated magnesia; the second process gives the results too low, on account of the slight solubility of the phosphates in acetic acid.

The author first throws down the aluminium and ferric phosphates according to Glaser's directions, but does not boil the ammo-

niacal fluid to redissolve the magnesium phosphate. The precipitate is now treated according to Stutzer's plan, namely, separation of the phosphoric acid with molybdate and precipitation of the joint ferric and aluminium hydroxides with ammonia. The magnesia remains in solution. A second precipitation frees the precipitate from any molybdate. In this way, absolutely correct results may be obtained.

L. DE K.

Estimation of Carbon in Iron and Steel. By W. THÖRNER (*Chem. Zeit.*, **15**, 149).—The author strongly objects to Rürup's proposal of using india-rubber connections when oxidising the well-known copper carbon mixture with sulphuric acid and potassium dichromate. If the operator wishes to use a flask which may be readily disconnected from the condenser, an ingenious contrivance devised by the author may be employed. L. DE K.

Detection and Estimation of Potassium Spectroscopically. By F. A. GOOCH and T. S. HART (*Amer. J. Sci.*, **42**, 448—459).—The authors have endeavoured to improve the delicacy of the spectroscopic potash test by making use of more powerful flames, and by substituting hollow coils of platinum wires for the single loop. Such coils are easily made by winding the wire somewhat obliquely around a rod of suitable size, pressing the coils close together, and joining the free ends into a twisted handle. The size of the coils is adjustable without difficulty, so that each coil may be made to hold almost exactly any appropriate amount and to take up this amount with very little variation in successive fillings, provided only that the precaution be taken in the process of filling to plunge the coil while hot into the liquid and to keep its axis inclined obliquely to the surface of the liquid while withdrawing it. In these coils we have simple means of taking up known amounts of solution, and this may be evaporated with little danger of loss of solid material by holding the handle of the coil across the flame with the coil proper at a safe distance outside. The burner used in heating the coils is of the Muencke pattern, and gives a powerful flame 3 cm. wide at its base. The authors generally adjust the flame to a height of 20 cm., and introduce the dried coil just within the outer mantle on the side next the spectroscope, with the axis transverse to the slit of the spectroscope and the handle across the body of the flame.

The spectroscope recommended is a well-made single-prism instrument provided with a scale and a movable observing telescope, so that different portions of the spectrum may be viewed or cut off at will. The slit is adjustable, but, for measuring its width, the authors have been obliged to have recourse to the device of closing it upon wires of known gauge. If a quantitative estimation is intended, a standard solution of potassium chloride, containing 0·002 milligram of potassium to the coilful, is tested in the apparatus, and the liquid under examination is diluted until its potassium line is of the same brightness as that given by the same quantity of the standard solution. The calculation presents, of course, no difficulty. If the substance contains sodium, this causes a remarkable increase in the

brightness of the potassium line, the maximum effect being reached when it exceeds the potassium by 100 to 1. In this case, a judicious quantity of sodium chloride should be added to the standard solution. Too large a proportion of sodium chloride in the sample is, however, undesirable, and may be got rid of by precipitation with alcohol.

To ensure success, it is essential that the eye of the observer should be kept as near as possible in the same condition of sensitiveness and in the same position in making the comparisons, and to accomplish this it is best to hold the eye at the observing telescope during the entire interval between the exposures, to shade it carefully by the hand or otherwise, to cover the eye not in use, to cut off all direct sunlight from the work-table, and to light the comparison scale of the spectroscope to the faintest possible visibility in order to fix exactly the position in which the line is to be sought.

The test analyses are encouraging. Though not accurate to a very high degree when large amounts of potassium are to be estimated, the method offers great advantage, without much sacrifice of exactness, in the estimation of small quantities. L. DE K.

Estimation of Small Quantities of Calcium. By M. KRÜGER (*Zeit. physiol. Chem.*, **16**, 445—452).—It is shown that Hempel's method of estimating calcium by titration of its oxalate with potassium permanganate solution is one which is applicable to such small quantities of calcium as often have to be dealt with in the operations of physiological chemistry. W. D. H.

Solubility of Calcium and Strontium Chromates in Dilute Alcohol, and the Separation of these two Alkaline Earths as Chromates. By W. FRESENIUS and F. RUPPERT (*Zeit. anal. Chem.*, **30**, 672—680).—An aqueous solution of the chlorides (containing preferably not more than 3 per cent.), mixed with potassium chromate, warmed to 60—70°, and mixed with one-third of its volume of strong alcohol, gives a precipitate almost instantly when strontium is present, but none in its absence, or only after a long time a trifling one, which cannot be mistaken for the strontium precipitate. About 0·0004 gram of strontium chloride per c.c. appears to be the lower limit of detection, in the presence of six times as much calcium chloride (see Lüdeking, Abstr., 1891, 364). A larger proportion of alcohol should be avoided; with 6 vols. of alcohol to 10 of the aqueous solution, calcium chromate began to precipitate. The method can be used only for rough quantitative separation; 50 c.c. of alcohol of 29 vols. per cent. dissolve 0·0066 gram of strontium chromate, or 0·608 gram of calcium chromate. In alcohol of 53 vols. per cent., the solubility is 0·44 gram of calcium chromate and 0·001 of strontium chromate in 50 c.c.

For qualitative analysis, the two bases should be precipitated as carbonates, the precipitate dissolved in hydrochloric acid, the excess of acid evaporated off, and the dilute aqueous solution mixed with potassium chromate and one-third its volume of alcohol, and shaken. M. J. S.

Separation of Strontium and Calcium Nitrates by means of Amyl Alcohol. By P. E. Browning (*Amer. J. Sci.*, **43**, 50—56).—The author, having found that calcium nitrate is completely soluble in amyl alcohol, whilst strontium nitrate is practically insoluble, has based on this fact a quantitative separation of the two metals. To ensure success, the operation must be conducted as follows:—About 0·5 gram of the mixed nitrates is dissolved in the smallest possible quantity of water and boiled with 30 c.c. of amyl alcohol until this reaches its normal boiling point, showing that all moisture has evaporated. The solution is then filtered from the undissolved strontium nitrate through asbestos, and this is washed with anhydrous amyl alcohol contained in a wash-bottle, the mouth-piece of which consists of a small calcium-chloride tube passing through the stopper and drawn out and plugged at the lower end with cotton-wool. To make sure of a complete separation, it is advisable to dissolve the residue in water and a drop of nitric acid, to evaporate to dryness, and to treat the nitrate again with amyl alcohol, in the manner described.

The strontium is finally converted into sulphate, and weighed as such. The united alcoholic filtrates containing the calcium are evaporated to dryness, and the residue is then also converted into sulphate.

In accurate analysis, it must be remembered that strontium nitrate is not absolutely insoluble in amyl alcohol. The author therefore proposes to add 0·001 gram of strontium oxide for every 30 c.c. of amyl alcohol employed. A corresponding amount of strontium sulphate must, of course, be deducted from the weight of the calcium sulphate. L. de K.

Separation of Barium from Calcium. By P. E. Browning (*Amer. J. Sci.*, **43**, 314—317).—The fact that strontium can be separated quantitatively from calcium by boiling the nitrates with amyl alcohol (compare preceding abstract) naturally suggested a similar separation of barium from calcium by the same general treatment. The author found that barium nitrate is totally insoluble in amyl alcohol, so no correction for slight solubility is required, as in the case of strontium. In the separation of the latter substance from calcium, it is necessary to have recourse to a double treatment with amyl alcohol, in order to effect a complete separation, because the strontium nitrate separates in plate-like masses, whilst the barium salt is much more granular and less liable to include foreign matter, and is, therefore, obtained pure by a single treatment.

The rapidity of execution and satisfactory character of the test analyses seem to place the process among the good analytical methods for the separation of barium and strontium from calcium.

L. de K.

Estimation of Zinc by the Ferrocyanide Process. By F. Moldenhauer (*Chem. Zeit.*, **15**, 223—224).—The estimation of zinc by means of potassium ferrocyanide, with copper sulphate paper as indicator, is gradually superseding the old process with sodium sulphide, but certain precautions should be taken to avoid errors.

The standard solution of ferrocyanide is best made of such a strength that 1 c.c. equals 0·005 gram of zinc. This solution does not keep well, but decomposition may be retarded by the addition of 1 gram of potassium hydroxide per litre, and keeping the liquid in the dark. The author has investigated the influence of the presence of some other metals which are often associated with zinc. Of the alkaline earths and the lighter metals, there exist only two whose ferrocyanides are quite insoluble in ammonia, namely, zinc and manganese, whilst magnesia is sparingly soluble. In the presence of these two metals, the amount of zinc may be found from 3 to 6 per cent. too high. The author has therefore modified the process as follows:—2·5 grams of the zinc ore is dissolved in hydrochloric acid, oxidised with nitric acid, and, without filtering, diluted to 250 c.c. 50 c.c. of this solution is heated and mixed with 10 c.c. of ammonia and 5 c.c. of a solution containing, in 100 c.c., 5 grams of ammonium chloride, 5 grams of ammonium carbonate, and 10 c.c. of ammonia. While the mixture is cooling, 50 c.c. of the original liquid is mixed with 10 c.c. of ammonia and carefully titrated with the ferrocyanide.

When cold, 1 c.c. of a 10 per cent. solution of disodium hydrogen phosphate is added, which will precipitate any manganese or magnesia as phosphate. The titration is now most carefully repeated, and will, of course, often give a lower result than the first.

The test analysis, made on an artificial zinc ore, is very satisfactory.

L. DE K.

Estimation of Manganese in Iron and Steel. By L. RÜRUP (*Chem. Zeit.*, **15**, 149—150).—The author has modified the process as follows:—6 grams of the sample is dissolved in acid as usual, and, after oxidation, introduced into a litre flask. After the addition of some sodium sulphate, water is added up to the mark, and, after settling, the liquid is filtered through a double quick filter. 500 c.c. of the filtrate (= 3 grams of substance) is put into a 1-litre Erlenmeyer flask, mixed with zinc oxide, heated, and titrated with permanganate.

The advantage of the process is supposed to consist in the large quantity of material operated on. L. DE K.

Separation of Iron, Manganese, and Calcium by the Acetate and Bromine Methods. By R. B. RIGGS (*Amer. J. Sci.*, **43**, 135—140).—The author, after conducting a great number of experiments, concludes that, in precipitating iron as a basic acetate, it is probably better to avoid a large excess of alkaline acetate, and the precipitate should not be digested too vigorously or too long. When the solution is neutralised previous to the acetate separation, there is always a danger of some of the manganese separating out as a higher oxide, but the amount is generally trifling, and may be completely recovered by redissolving and reprecipitating the iron.

In the subsequent separation of the manganese from the calcium, the filtrate from the iron should be mixed with excess of ammonia and heated, before adding the bromine, as, if the solution is cold, the oxidation is slow and incomplete. The addition of ammonia after the bromine has been added causes a less uniform oxidation. To free the manganese from co-precipitated calcium, it must be re-

dissolved in hydrochloric acid, and again precipitated with ammonia and bromine. The calcium is finally precipitated as oxalate.

L. DE K.

Electrolytic Separation of Iron. By E. F. SMITH and F. MUHR (*Chem. Centr.*, 1892, i, 75; from *J. Anal. Chem.*, **5**, 488).—If a solution of ammonio-ferrous tartrate be subjected to the action of a feeble voltaic current (equivalent to the liberation of about 3 c.c. of oxyhydrogen gas per minute), the iron separates in a very compact form, but contains some carbon. In one experiment, 0·161 gram of iron as ferrous sulphate, with 1 gram of tartaric acid and 10 c.c. of ammonia in 150 c.c., was subjected to such a current for 20 hours, when the precipitated iron weighed 0·165 gram. After dissolving in sulphuric acid, titration with potassium permanganate showed 0·161 gram of iron to be present. The method may be employed for the separation of iron from aluminium. Nickel, cobalt, zinc, copper, and cadmium are precipitated quantitatively under the above conditions.

J. W. L.

Estimation of Cobalt in Manganese Ores. By T. MOORE (*Chem. News*, **65**, 75—77).—Two grams of ore is fused in a covered platinum crucible with 4 or 5 grams of potassium hydrogen sulphate; when the fusion becomes quiet, in 15—20 minutes, ammonium carbonate is added in successive small quantities, replacing the cover after each addition until sulphuric anhydride is emitted but feebly; the mass is then poured on to a metal slab, and when cool is put along with the rinsings from the crucible into 400 c.c. of boiling water. After boiling for 20 minutes, and boiling and washing the insoluble residue several times with hot water, the combined filtrates are heated, 30 c.c. of acetic acid added, hydrogen sulphide passed in, and, when the iron still remaining in solution is reduced, a strong solution of ammonium acetate is added. The precipitated sulphides of nickel and cobalt, after being well washed, are calcined at a temperature just sufficient to destroy the filter, and are dissolved in a few c.c. of hydrochloric acid, and converted into sulphates by evaporation with sulphuric acid. The two metals are then deposited together electrolytically in the usual manner, and, their weight having been determined, they are redissolved and separated, preferably by precipitating the cobalt as phosphate.

A second method, based on the fact that cobalt alone absorbs oxygen to any appreciable extent in the presence of citric acid, is conducted by evaporating 2 grams of ore to dryness with hydrochloric acid, then mixing with 3 grams of citric acid dissolved in 3 or 4 c.c. of ammonia, and, if necessary, acidifying with hydrochloric acid; after heating with 2 or 3 c.c. of water and allowing it to cool, the solution is transferred to and agitated in a modified Bunte's gas burette, the amount of oxygen absorbed being subsequently noted with every precaution.

D. A. L.

Estimation of Molybdenum. By E. PÉCHARD (*Compt. rend.*, **114**, 173—175).—Hydrogen chloride is passed over the molybdate at 440°. The base remains in the boat as chloride, and the molybdenum collects in the tube in white needles, having the composition

$MoO_3,2HCl$; this is dissolved in water, and the solution evaporated to dryness, when the residue consists of molybdic anhydride. A small quantity of a bluish sublimate, insoluble in water, is easily dissolved by adding a little nitric acid to the wash water, and is then weighed, with the main residue, as trioxide. The trioxide is obtained directly from ammonium molybdates by simply heating at 440°. As tungstates do not give a volatile compound similar to the above, the determination of molybdenum, in presence of tungsten, can be carried out by this method. The results of trial analyses quoted show the method to be trustworthy. The volatile compound is formed, even in the cold, by passing hydrogen chloride over a molybdate. The ethereal extract of the residue deposits white crystals, consisting of the volatile compound and ether. W. T.

Detection of Tin, Antimony, and Arsenic. By E. Pieszczek (*Arch. Pharm.*, **229**, 667—669).—After separating the sulphides of arsenic, antimony, and tin from the other sulphides of the hydrogen sulphide group by means of ammonium or potassium sulphide solution, the author precipitates the mixed sulphides with hydrochloric acid, and then separates the arsenic sulphide with ammonium carbonate. The antimony and tin sulphides are then dissolved in concentrated hydrochloric acid (without addition of potassium chlorate), and to a drop of the solution placed on a platinum crucible lid, a small piece of tin is added; any antimony is precipitated on the platinum as a brown or black deposit. If a trace of copper should be present, it is likewise precipitated, but the deposit is red, and has a metallic lustre, which is readily distinguishable from the antimony.

For the detection of tin, a piece of iron wire is placed in another portion of the solution of antimony and tin; any antimony which is present is precipitated, whilst the tin is reduced to stannous chloride, and may be detected by means of mercuric chloride. J. W. L.

Assay of Antimony Minerals. By A. Carnot (*Compt. rend.*, **114**, 587—590).—The antimony is dissolved in hydrochloric acid, precipitated by tin, and weighed in the metallic state. In the case of sulphuretted minerals, a quantity containing about 1 gram of antimony is heated with successive quantities of strong hydrochloric acid until the whole of the sulphide is decomposed. The last quantity of acid is mixed with a small quantity of nitric acid, and the residue is washed with dilute acid. The extraction is effected on a water-bath, but actual ebullition should be avoided. The decanted or filtered solution is diluted with an equal volume of water, a piece of sheet tin is added, and the liquid is heated at about 80° or 90°. The precipitated antimony is washed with dilute hydrochloric acid, then with warm water, and, finally, alcohol, and is weighed on a tared filter.

Oxidised minerals are placed in a flask with a flat bottom, heated at a temperature not exceeding 300°, and subjected for about an hour to the action of a current of hydrogen sulphide. The antimony is thus converted into sulphide, which is then dissolved (in the same flask) in the manner just described.

Iron and zinc do not interfere with the estimation. Lead is

partially precipitated with the antimony, but, after weighing, it may be separated and estimated by treating the metals at 50—60° with a yellow solution of sodium polysulphide (obtained by boiling a solution of the monosulphide with sulphur), which dissolves the antimony, and leaves a residue of lead sulphide. The latter is washed, dried, and weighed: 0·9 of the weight of the precipitate gives the quantity of metallic lead present in the mixture of metals.

C. H. B.

Estimation of Bismuth in Silver Slags. By W. Hampe (*Chem. Zeit.*, **15**, 410).—1 gram of the finely powdered slag is digested in a platinum dish, first with 15 c.c. of nitric acid, then with 10 c.c. of strong hydrofluoric acid; if everything is dissolved, a few drops of sulphuric acid is added, and the whole evaporated to dryness. The residue is again dissolved in nitric acid, filtered from any graphite, and after neutralising the filtrate with ammonia, ammonium carbonate is added, and the liquid heated to boiling. The precipitate is then collected, redissolved in dilute nitric acid, and treated with hydrogen sulphide. The precipitate, which consists of lead and bismuth sulphides, is again dissolved in nitric acid, filtered from any sulphur, once more precipitated with ammonium carbonate, the precipitate dissolved in hydrochloric acid, and the liquid evaporated to dryness. On treating the residue with boiling water, the lead chloride is gradually dissolved, whilst the bismuth remains as oxychloride; this is then dissolved in nitric acid, and precipitated with ammonium carbonate. The precipitate is afterwards carefully detached from the filter and temporarily put aside; the filter is extracted with nitric acid, and this is evaporated to dryness in a weighed porcelain crucible. The precipitate is now added, the whole carefully ignited, and finally weighed as bismuth oxide.

L. de K.

Use of Cadmium in Assaying Gold. By C. Whitehead (*Proc. Chem. Sect., Franklin Inst.*, **3**, 94—98).—An approximate assay of the silver in the gold bullion is first made by cupellation. 500 milligrams of the bullion is then placed in a porcelain crucible, covered with 10 grams of potassium cyanide, and heated until the cyanide is in a state of quiet fusion. 1 gram of cadmium is then added; it forms a bright, homogeneous alloy with the gold; if no copper is present in the bullion, about 50 milligrams is added, in order to make the resulting alloy brittle. The contents of the crucible are poured on to a porcelain slab, the alloy is washed, dried, placed in a diamond mortar, and reduced to a powder by a few sharp blows with a hammer. The powder is then transferred to an assay bottle, sufficient pure silver is added to make the total amount present 1004 milligrams (the amount in the bullion itself has been approximately determined by the preliminary cupellation), and 10 c.c. of nitric acid (32° Baumé) added. To this solution 100 c.c. of normal salt solution is added, and the precipitation is finished with a decinormal salt solution. The assay is accompanied by another "proof" assay, in which 1004 milligrams are dissolved in the same amount of acid. The difference in the amounts of salt solution used gives the excess of silver in the assay over that in the "proof." Adding this to 1004 milligrams, the

amount in the "proof," we get the total amount in the assay; subtracting from this the weight of pure silver added in the assay, we get the weight of silver in the 500 grams of bullion used. An actual assay gave 38 parts per thousand, as against 35 determined by cupellation. C. F. B.

Electrolytic Separations. By E. F. Smith and D. L. Wallace (*Ber.*, **25**, 779—785; compare Abstr., 1891, 1029).—The metal which is mentioned first in each of the following cases, is deposited on electrolysis:—

Gold from Arsenic.—The metallic salts were dissolved in potassium cyanide solution; the deposited gold is pale yellow. The results are satisfactory with currents evolving 1·8—2 c.c. of oxyhydrogen gas per minute.

Gold from Molybdenum.—Results excellent. The gold is deep orange-yellow in colour.

Gold from Tungsten.—Results fairly good, if the solution is free from potash; otherwise, as separate experiments have shown, the precipitation of the gold is very incomplete.

The separation of the above metals in potassium cyanide solution compares unfavourably with their separation from solution in alkaline sulphides, chiefly on account of the length of time required, 10—16 hours.

Gold from Osmium.—Results very satisfactory. A current evolving 2·4 c.c. oxyhydrogen gas per minute is required.

Cadmium from Osmium.—Results good; excess of potassium cyanide is to be avoided.

Silver from Osmium.—Results extremely satisfactory; time required about 7 hours.

Mercury from Osmium.—Results excellent; a current evolving 0·7—1·9 c.c. of mixed gases per minute is needed.

Cadmium from Nickel.—Results very good; the mixed solutions of cadmium and nickel sulphates are treated with potash, and a current evolving 2 c.c. of oxyhydrogen gas per minute is employed.

The fact noted above, that potash hinders the precipitation of gold, caused the authors to attempt to separate silver and mercury from gold, but the experiments were unsuccessful.

It was also found impossible to cause the complete deposition of gold from solution in ammonium sulphide, whilst attempts to separate gold from tin in ammonium sulphide solution were also fruitless.

J. B. T.

Assaying of Platinum. By F. Mylius and F. Foerster (*Ber.*, **25**, 665—686; see this vol., p. 789).

Estimation of the Dissolved Substances in Water. By A. Hazen (*Chem. Centr.*, 1892, i, 74; from *J. Anal. Chem.*, **5**, 140).—The author recommends the addition of sodium carbonate to the water before evaporating, in order to avoid the presence of water of combination in the magnesium and calcium chlorides, or the loss of hydrogen chloride, when heating the residue over the flame.

J. W. L.

Volatile Organic Matter in Potable Water and a Simple Method of Estimating Dissolved Fixed and Volatile Organic Matter in Water. By W. C. Young (*J. Soc. Chem. Ind.*, **10**, 883—889).—To determine the total organic matter, 1 litre of water, to which 0·5 gram of dried and ignited sodium carbonate is added, is distilled in a conical iron still of about 2 litres capacity, attached to a tin worm-condenser. The distillate is received in a graduated measure, and when 970 c.c. has been collected, the source of heat is removed, the still disconnected, the contents and washings placed in a platinum basin, and evaporated to dryness on a water-bath. The residue is then dissolved in a little pure distilled water, filtered through an asbestos plug into a platinum basin, dried on a water-bath, and subsequently heated for an hour in an air-bath at 150°. After cooling in a desiccator, the basin and contents are weighed. The residue is then ignited at a low temperature, cooled, and weighed, and the loss noted. The ignited residue is dissolved in water, excess of sulphuric acid added, and then standard solution of potassium permanganate (1 c.c. = 0·0001 gram O) until the colour remains permanent after five minutes. The weight of oxygen lost, thus ascertained, is deducted from the loss on ignition, and the difference is the organic matter. To determine the fixed organic matter, the same course is followed, except that the sodium carbonate is not added until the concentrated water is transferred from the iron still to a platinum basin. To determine the volatile organic matter, the distillate from the last-mentioned process is placed in the still, together with 0·5 gram of sodium carbonate, and distilled until about 25 c.c. remains in the still, afterwards proceeding as before, except that it is unnecessary to ascertain the oxygen lost by ignition. The result presents about two-thirds of the total volatile organic matter present; further small quantities can be recovered from the distillate by repeating the process.

By the employment of sodium carbonate the whole of the compounds of calcium, magnesium, and iron are precipitated, and any combined ammonia in the water is volatilised. There only remains sodium chloride, alkali nitrates, and uncombined silica to interfere with the loss on ignition being accepted as a measure of the organic matter present, and neither of these compounds being present in estimating volatile organic matter, the results may be accepted as free from objection on that account. As regards sodium chloride, the burning of the organic matter is so rapid (a few seconds suffices), and the temperature so low, that none is volatilised, or if a little is lost through excessive heating, the loss can be ascertained and due correction made. As regards alkali nitrates, provision is made in the process for ascertaining and correcting for loss of oxygen by reduction of nitrates, but it is seldom of any great importance, and has never exceeded, in ordinary drinking waters, the equivalent of 0·07 grain per gallon. The presence of nitrates assists the burning of the organic matter very materially, and in the case of very foul waters, such as sewage effluents or seriously polluted waters, which rarely contain any, the author finds it advisable to add a drop or two of solution of potassium nitrate before the final evaporation. With

regard to the uncombined silica, the author has never found it present, and if it should be, he does not think the heat required to burn off the organic matter is sufficiently great to cause it to decompose the sodium carbonate. D. B.

The Fermentability of Dextrins. By L. Medicus and C. Immerheiser (*Zeit. anal. Chem.*, **30**, 665—668).—Some specimens of wine, which the authors had condemned as adulterated with potato-starch sugar, were by other analysts described as genuine on the ground of the complete fermentability of their dextrorotatory constituents. The authors confirm the fact of this complete fermentation under the influence of pressed yeast. It takes place, however, very slowly. Specimens exhibiting originally a dextrorotation of 0·45—0·83° lost this entirely in from 25—28 days after mixing with pressed yeast. That the substances so fermented were dextrins was shown by the behaviour towards Fehling's solution after inversion, a much greater increase in the reducing power being found after treatment capable of saccharifying dextrin than after simple inversion of the cane sugar present. These results were confirmed by experiments on commercial potato-starch sugar. 250 c.c. of a 16 per cent. solution mixed with a little ammonium and potassium phosphates, and 2 grams of pressed yeast, fell off in rotating power from 17° to 7° in 11 days at ordinary temperatures, and on further addition of yeast and elevation of the temperature to 30°, the polarisation was finally reduced to about 1° in the course of 34 days. In a second experiment on solutions of the same strength without phosphates, but with more yeast, the rotation fell to 0 after the lapse of 32 days. In a third experiment, dextrin precipitated by alcohol from potato-starch sugar, and thoroughly washed with alcohol, was employed with a precisely similar result. The conclusion arrived at is that dextrin, although with difficulty, is yet completely fermentable under the influence of vigorous pressed yeast and at a favourable temperature.

M. J. S.

Recognition of Potato-starch Sugar in Wines. By W. Fresenius (*Zeit. anal. Chem.*, **30**, 669—672).—The statement of Neubauer that the substances precipitable from potato-starch sugar were not fermentable having been based on experiments with beer yeast, and the investigations of v. Raumer having shown that the behaviour of these substances was not identical with different kinds of yeast, the following further experiments were made:—A specimen of one of the dextrorotating wines examined by Medicus (see preceding abstract), and an optically inactive wine, were evaporated to syrups, and mixed, the former with a 10 per cent. solution of completely fermentable invert sugar, and the latter with a 10 per cent. solution of potato-starch sugar containing so-called "unfermentable substances." Under the influence of pressed yeast at 30°, both lost their rotating power completely in four days. In a similarly conducted experiment with a non-polarising wine mixed with potato-starch sugar and beer yeast, the solution still showed a rotation of 5° after 13 days. Specimens of the suspected wines were therefore evaporated, and mixed with fermentable invert sugar and beer yeast. The

observed result is not given, but it is stated that a thoroughly satisfactory proof was obtained that potato-starch sugar had been introduced into the wines. In the course of the experiments, it was observed that the wines were very apt to become mouldy on the surface, and after the growth of mould the dextrorotatory constituents were found to have disappeared. The same was the case with nitrates, which had been detected by Medicus and Immerheiser, but had disappeared by the time the samples were examined by the author (see also Borgemann, Abstr., 1888, 753). M. J. S.

Estimation of Cellulose. By S. Gabriel (*Zeit. physiol. Chem.*, **16**, 370—386).—Hönig's method of estimating cellulose (*Chem. Zeit.*, 1890, 53) by dissolving out proteïd and starch with glycerol at 210° gives results which are too high, the residue being rich in ash and containing about 1 per cent. of nitrogen, as well as certain non-nitrogenous substances which are not cellulose. A number of comparative experiments were made with different agricultural products, and the commonly used Weender method was found to give more trustworthy results. A solution of potassium hydroxide in glycerol, heated to 150°, was, however, found to give approximately correct results.
W. D. H.

Detection of Resin Oil in Terebenthene. By Zune (*Compt. rend.*, **114**, 490).—The terebenthene is fractionated, and the refractive index of the various fractions determined. In the absence of resin oil, the difference between the indices of the extreme fractions should not exceed 0·004, whilst in the presence of even 1 per cent. of the oil it is at least 0·006. Jn. W.

Detection of Resin in Beeswax. By H. Röttger (*Chem. Zeit.*, **15**, 45).—If a sample of wax contains not less than 5 per cent. of resin, it will, on heating it to 110°, emit a strong odour of turpentine, but pure wax collected in the neighbourhood of pine woods also gives this test. If the amount of resin is large, any expert will notice this from the very appearance of the sample, but small quantities are best detected by a process recommended by Donath. A piece of the suspected sample the size of a pea is put into a test-tube and boiled for 15 minutes with strong nitric acid. A little cold water is carefully added to solidify the wax, and the acid liquid poured into excess of dilute ammonia, which, if resin is present, will cause a blood-red coloration. Schmidt recommends boiling 5 grams of the wax for one minute with 25 grams of nitric acid (sp. gr. 1·33). He then adds an equal bulk of cold water, and afterwards a slight excess of ammonia. If the sample contains resin, the colour of the liquid will be reddish-brown. Hager boils the sample with 15 times its weight of dilute alcohol (2 vols. of alcohol, 1 vol. of water). After cooling, the liquid is filtered and diluted with an equal bulk of water, which, if resin be present, will cause a white emulsion. Stearic acid does not interfere with the test. The German Pharmaceutical Committee recommends boiling the sample for 15 minutes with 10 parts of water and 3 parts of sodium carbonate, when, if resin be present, a permanent emulsion will be obtained. Sedra dissolves 3 grams of the sample in 30 c.c. of

chloroform, and then shakes this with 200 c.c. of lime-water; pure wax forms an emulsion, but, if resin is present, a turbid, yellowish-brown liquid separates out.

The author, who carefully tried these processes, failed to detect an admixture of 20 per cent. of resin by Sedra's process. Hager's method gives satisfactory results if a weaker alcohol (1 vol. alcohol, 1 vol. water) is used. Donath's process is best applied to the spirituous extract of the sample. L. DE K.

Sodium Nitroprusside as a Reagent for Aldehydes and Ketones. By B. v. BITTÓ (*Annalen*, **267**, 372—379).—The author has investigated the behaviour of a large number of aldehydes and ketones towards sodium nitroprusside in alkaline solution, and gives his results in a table. It was found that a coloration is produced in the case of all aldehydes and ketones of the fatty series when the aldehyde or carbonyl group is in direct combination with at least one group composed only of carbon and hydrogen; acetaldehyde, acraldehyde, and chloracetone, for example, give a cherry-red, and paraldehyde a reddish-yellow, coloration, but formaldehyde, glyoxal, and chloral give no reaction. Aromatic aldehydes or ketones, in which the aromatic radicle is combined only with the aldehyde or carbonyl group, as, for example, in the case of benzaldehyde and benzophenone, do not give the reaction; when, however, the aromatic radicle is also united with a fatty hydrocarbon radicle, as in paracumaldehyde, a coloration is produced. More definite statements regarding the behaviour of the aromatic compounds cannot be made for want of experimental data. F. S. K.

Estimation of Cinnamaldehyde in Oil of Cassia. By SCHIMMEL (*Chem. Centr.*, 1892, i, 92—93; from *Schweiz. Wochenschr. Pharm.*, **29**, 403).—The authors recommend the following method as being more rapid than that usually employed:—10 c.c. of the oil is heated in a small flask on the water-bath, and solution of sodium hydrogen sulphite is added in small portions, time being allowed between each addition for the mass, which at first forms, to liquefy again. The time required amounts to 10—15 minutes. (Compare Abstr., 1891, 504.) J. W. L.

Estimation of Free Acids in Butter. By C. BESANA (*Chem. Zeit.*, **15**, 410).—The author extracts the butter with alcohol, which, at a gentle heat, easily dissolves the free acids, but scarcely touches the glycerides. 10 grams of the clarified fat is treated three times in succession with 15 c.c. of rectified spirit at a temperature of about 50°. The mixed alcoholic liquids are afterwards titrated with N/10 sodium hydroxide, with phenolphthaleïn as indicator.

From the author's experiments, it is made plain that rancid, unsaleable butter does not necessarily contain the largest proportion of free acids. L. DE K.

Estimation of Gallic Acid in Urine. By C. T. MÖRNER (*Zeit. physiol. Chem.*, **16**, 255—267).—See this vol., p. 904.

Estimation of Homogentisic Acid in the Urine. By E. Baumann (*Zeit. physiol. Chem.*, **16**, 268—270).—Mörner (see this vol., p. 904) having proved that it is advisable to use more concentrated ammonia in the estimation of gallic acid in the urine than was previously suggested, the author has found it advisable to modify his method of estimating homogentisic acid in cases of alcaptonuria. The amended method is now as follows:—

10 c.c. of urine is mixed in a flask with 10 c.c. of 3 per cent. ammonia; this is then titrated with decinormal silver nitrate solution; the mixture, after the addition of 5 drops of calcium chloride solution and 10 drops of ammonium carbonate solution, is filtered, and the filtrate tested with silver nitrate; if any reduction occurs, another quantity of urine is similarly treated, only more standard silver solution is employed. This is repeated as often as necessary, excess of silver being recognised by hydrochloric acid. 1 c.c. of the silver solution corresponds with 0·004124 gram of homogentisic acid.

W. D. H.

Assay of Commercial Toluidine. By F. F. Raabe (*Chem. Zeit.*, **15**, 116, 179—180). The author remarks that, in order to prevent as much as possible analytical differences, it will be necessary for the buyers to agree with the manufacturers on a definite method of testing. The process should, however, be such a one as can be readily mastered by anybody who has a sufficiency of the sample at his disposal. In testing toluidine, particular notice must be taken of its appearance, which should be as clear as good ale, although the colour is spoiled to some extent when the sample has been stored in iron barrels. The presence of higher homologues may be ascertained by taking the boiling point. 100 c.c. of the sample is fractioned in a retort holding about 180 c.c., the heat being so regulated that about two drops distil over every second. The specific gravity is best taken by means of Lunge's hydrometer. To get the temperature exactly at 15°, the oil is put into a cylinder, which is then surrounded by another cylinder filled either with warm or, if necessary, with iced water.

These simple tests are, however, hardly sufficient now-a-days, when the buyers demand a specified percentage of paratoluidine. Of the various methods from time to time proposed, the author has most faith in Lorenz's oxalic acid process, which is carried out as follows:—A definite volume of an ethereal solution of dry oxalic acid is added to a known quantity of pure paratoluidine mixed with a few drops of orthotoluidine, and after some time the liquid is filtered off, the ether expelled, and the excess of acid titrated with solution of sodium carbonate, with delicate litmus-paper as indicator. In this way we get a standardised solution of oxalic acid, which may then be used for testing any given sample. The author has tried to estimate the paratoluidine gravimetrically as oxalate by simply adding a large excess of an aqueous solution of oxalic acid, and has obtained very satisfactory results when analysing samples containing from 25 to 40 per cent. of paratoluidine. A process, which he believes to be a very suitable one for daily use by manufacturers, and on which he is still engaged, consists in taking the solidifying point of the sample after first fusing it

with a definite amount of pure dried paratoluidine. The operator must, however, be in possession of a large number of standard mixtures containing, say, 82·5, 83, 83·5, 84, 84·5, and 85 per cent. of pure paratoluidine for comparison. L. DE K.

Test for Guanidine. By E. SCHULZE (*Ber.*, **25**, 661—662).—Many salts of guanidine (the nitrate, sulphate, hydrochloride, and carbonate were examined) give with Nessler's reagent a white or faintly yellowish precipitate, at first flocculent and bulky, but collecting together after a time. The reaction is very delicate; a 0·05 per cent. aqueous solution of guanidine nitrate gives an appreciable precipitate; a 0·01 per cent. solution is rendered turbid. C. F. B.

Assay of Opium. By D. B. DOTT (*Pharm. J. Trans.* [3], **51**, 746).—The paper points out some sources of possible error in Teschemacher and Smith's gravimetric process of opium assay, and recommends the following method:—10 grams of the opium in powder is exhausted with spirit (sp. gr. 0·92), one or two drops of ammonium oxalate added, and then ammonia, until the spirit is only slightly acid. The extract is evaporated to one-third, cooled, filtered, the filtrate concentrated to 5 c.c., and transferred to a small flask with the aid of 4 c.c. of water and 3 c.c. of spirit; 2·2 c.c. of aqueous ammonia (sp. gr. 0·96) and 25 c.c. of ether are added. After 18 hours, the precipitate is collected on a tared filter, washed with morphiated water, dried, washed with benzene, dried, weighed, and finally titrated with N/10 sulphuric acid. R. R.

Analysis of Tea. By A. DOMERGUE and C. NICOLAS (*J. Pharm.*, **25**, 302—306).—For the estimation of the theïne, 5 grams of coarsely-powdered leaves was boiled some minutes in 50 to 60 c.c. of water. To the boiling liquid is added 100 c.c. of a 3 per cent. solution of mercuric acetate; after boiling a little longer, all is passed into a moistened filter, and washed with hot water, until the washings become colourless. The solution, about 300 c.c., is concentrated to about 20 c.c., and is mixed with 2 grams of calcined magnesia, and 15 grams of powdered glass or calcined and washed quartz. The mixture is completely dried on the water-bath, and is extracted in a Soxhlet apparatus, with a mixture of equal weights of benzene and chloroform. The solution, on evaporation, yields the theïne only very slightly contaminated with a little waxy matter, which may be neglected. To estimate the manganese, the sulphated ash from 2 grams of tea is boiled with 1 gram of lead peroxide, and 5 c.c. of nitric acid, the solution made up to 50 c.c., and the colour compared with typical solutions of titrated permanganate.

Black teas only of ascertained purity were examined. The amount of theïne varies with the commercial value of the sample. The ash may slightly exceed 6 per cent. The green solution of the soluble part passes rapidly through violet-red before losing its colour. The quantity of soluble matter in tea is very variable. The three last samples had probably been previously extracted; the ashes of these three were not green, and, when treated with water, the solutions ob-

tained were colourless. Evidently the manganese is contained in tea in a soluble form; for spent leaves yield a grey ash, which again gives a colourless solution. A black tea may be considered to be bad in quality if it contains less than 2 per cent. of theïne, and gives an ash not green in colour, the aqueous extract of which is colourless, and if the insoluble part of the ash equals or exceeds the soluble.

J. T.

Analysis of Gambier. By H. R. Procter (*J. Soc. Chem. Ind.*, **10**, 681—683).—The author has been in communication with English and Continental chemists interested in the analysis of tanning materials, asking their opinion as to the possibility of agreeing on a standard method for the analysis of gambier, in order to avoid the serious discrepancies which arise in consequence of all the present processes being anything but perfect. His correspondents are unanimously in favour of the indirect gravimetric method, in which equal quantities of the infusion of the tanning material are evaporated, in the one case after careful filtration through paper only, and in the other after complete removal of the tanning matter by treatment with purified hide powder; and the tanning matter is calculated from the difference of weight of the dried residues. There is, however, considerable diversity of opinion as to the details, both of making the infusion and of carrying out the absorption of the tannin, and in the present paper the author has briefly summarised the points still requiring discussion, and the respective advantages of the various modifications, in the hope that some chemists may be induced to make independent investigation where it is required, and communicate with him, so as to enable him to outline at an early date, a method which will represent as nearly as possible the average of chemical opinion.

D. B.

A Sensitive Reaction for Albumin in Urine. By E. Spiegler (*Ber.*, **25**, 375—378).—The urine is acidified with a little concentrated acetic acid, filtered if necessary, and cautiously dropped by a pipette into a test tube half filled with a solution of mercuric chloride (8 parts), tartaric acid (4 parts), and sugar (20 parts), in water (200 parts) in such a manner that the two liquids do not mix; the presence of albumin is indicated by the formation of a white ring at the point of contact of the two liquids. The solution prepared as above described has a sp. gr. 1·06; the sugar plays no part in the reaction, but is merely added to raise the density of the solution, and prevent its mixing with the urine; with dense diabetic urines, a further addition of sugar is needful. The acidification of the urine with acetic acid is necessary to precipitate mucus, and to decompose carbonates and alkali phosphates, which interfere with the reaction; urines which are turbid through bacteria need not be clarified. Several samples of urine, free from albumin, from women after parturition, in which the presence of peptone was indicated by biuret, were found not to give the above-described reaction; propeptone (hæmialbumose), however, does give it. By the new reaction, 1 part of albumin in 225,000 can be detected, whereas the potassium ferrocyanide reaction is only sensitive to 1 part in 50,000.

A. R. L.

General and Physical Chemistry.

Refractive Indices of Saline Solutions. By P. Bary (*Compt. rend.*, **114**, 827—830).—The refractive indices of solutions of various strengths were determined, and the results plotted in curves, the abscissæ representing the quantity of anhydrous salt in 100 parts of the solution, whilst the ordinates represent the refractive indices. The general result is that the curve representing the variation of the refractive index with the concentration of the solution is not continuous, but is made up of several right lines with different inclinations to the axis of the ordinates. Each break indicates a sudden change in the molecular condition of the medium, and most probably corresponds to the formation of a new compound, or, in other words, a new hydrate in the solution. The composition of the solutions at the points where the breaks occur can be represented by molecular formulæ. The following table gives the composition of the solutions and their refractive indices at the breaks :—

Sodium thiosulphate.—$Na_2S_2O_3 + 40H_2O$, 1·3658; $Na_2S_2O_3 + 20H_2O$, 1·3097.

Potassium dichromate.—$K_2Cr_2O_7 + 250H_2O$, 1·3438; $K_2Cr_2O_7 + 170H_2O$, 1·3478.

Potassium chloride.—$KCl + 80H_2O$, 1·3423.

Sodium chloride.—$NaCl + 30H_2O$, 1·3528; $NaCl + 15H_2O$, 1·3686.

Lithium sulphate.—$Li_2SO_4 + 150H_2O$, 1·3415; $Li_2SO_4 + 30H_2O$, 1·3610.

Ferrous sulphate.—$FeSO_4 + 70H_2O$, 1·3570.

Silver nitrate seems to be an exception, but it is possible that the variations are within the limits of the error of experiment, and that the exception is only apparent. C. H. B.

Determination of the Molecular Refraction of Solid Chemical Compounds in Solutions of the same. By F. Schütt (*Zeit. physikal. Chem.*, **9**, 349—377).—Continuing his researches (Abstr., 1890, 1033) on the molecular refraction of solutions, the author has examined the behaviour of mixtures of ethylene bromide and propyl alcohol. The results obtained are, generally speaking, similar to those in the case of sodium chloride solutions.

The discrepancy between the observed and calculated values led the author to a further examination of the formulæ employed in the calculations. The formula used for calculating the molecular refractions of mixtures from those of the components has been hitherto $100K/d = pK_1/d_1 + (100 - p)K_2/d_2$, in which $K = (n - 1)/1$. For this Pulfrich's formula may be substituted,

$$K\frac{1 - aC}{1 - C} = v_1K_1 + v_2K_2,$$

where C is the contraction which takes place on mixing the volumes v_1 and v_2 of the two solutions and a is a variable factor. This last quantity the author finds is proportional to the percentage composition $a = \alpha + \beta p$, and therefore the above formula becomes

$$K = \left(\frac{v_1}{v} K_1 + \frac{v_2}{v} K_2\right) \frac{1}{1 - C(\alpha + \beta p)},$$

where $v = 1/(1 - C)$. The author finds that results calculated with this formula show a most excellent agreement with those obtained by observation, both in the case of the sodium chloride solutions and the mixtures of ethylene bromide and propyl alcohol. To determine the molecular refraction of a solid or liquid substance from those of its solutions, since $K/d = R$, $K_1/d_1 = R_1$, and $K_2/d_2 = R_2$,

$$R_1 = R\left[\frac{1 - C(\alpha + \beta p)}{1 - C}\right]\frac{100}{p} - R_2\frac{100 - p}{p}.$$

The molecular refraction of solid sodium chloride can be calculated to within the third decimal place of the observed value, from solutions containing even less than 1 per cent. of the salt, with the aid of this formula. H. C.

Spectra of Gallium. By L. de Boisbaudran (*Compt. rend.*, **114**, 815—818).—When the non-condensed spark from a coil with a long wire is allowed to impinge on the surface of a solution of gallium chloride, the spectrum consists of a band at λ 509·04—λ 495·50, with a maximum at λ 502·33, a strong, narrow band at 417·04, and a well-marked narrow band at 403·19. If the coil is connected with a condenser, or if the spark passes between poles of metallic gallium, a more complex spectrum is obtained, although the band with a maximum at λ 502·33 is no longer visible. Bands are observed at 645·27, 641·24, 639·23, 632·67, 599·49, 585·15, 580·14, 542·89, 536·95, 533·97, 521·26, 499·33, 486·46, 438·22, 425·58, 417·04, 403·19. A Demarcay coil with a short wire gives a spectrum very different in the number and relative intensities of the lines. Bands are seen at 641·24, 639·23, 632·67, 535·51, 417·04, 403·19. The remarkable variations in the spectrum of gallium caused by variations in the nature of the spark illustrate the great importance of defining precisely the conditions under which electric spectra are obtained. C. H. B.

Changes of E.M.F., Volume, and Temperature by Mixing Electrolytes. By G. Gore (*Chem. News*, **65**, 145—147).—In a former communication (this vol., p. 257), the author has shown the effects of dilution on the temperature and total volume of liquids and on the mean amount of E.M.F. of a voltaic couple immersed in them; he has now examined in a similar manner the effects of mixing electrolytes on the same phenomena, and in order to obtain some new information respecting the chemical substitution of acids and the double decomposition of salts, pairs termed "isomeric mixtures" were employed, and were divided into two groups, acids + acids and salts + salts. The equivalent weight of each substance in grains

being dissolved in 1800 grains of water, the various data were recorded before and after admixture in the manner described in the previous paper.

With regard to the changes of mean E.M.F., total volume, and temperature attending the expulsion of one acid from a salt by means of another acid; in 15 isomeric couples of mixed liquids every mixture suffered a change of either one or all of these during the mixing, but in every instance each of the two mixtures of an isomeric couple gave the same amount of E.M.F., demonstrating that whatever change took place during the mixing, the final result was the same; in fact, a counter-balancing of forces appears to take place. With regard to the question of substitution of one acid by another, as exemplified by these experiments, sulphuric is observed to expel nitric, hydrochloric, and acetic; whilst hydrochloric expels nitric and hydrobromic more readily than the reverse. With mixtures of salts, changes were observed, as in the above experiments, during mixing, but the amount of E.M.F. produced in duplicate mixtures was the same; the three series of changes of volume, temperature, and E.M.F. in these cases largely agree with each other, but the agreement is generally less distinct than with the series of mixtures of acids + salts. Generalising on the results obtained in these investigations, it is pointed out that whenever admixture produces an increase of velocity and freedom of molecular motion there is a proportional gain in the mean E.M.F. and *vice versâ;* this considered in conjunction with the distinct connection also exhibited between changes of total volume, total heat, and mean amount of E.M.F., helps to confirm the existence of a mechanical basis of voltaic and chemical action.

D. A. L.

Correction in the Calculation of the Heat of Dissociation of Electrolytes. By S. Arrhenius (*Zeit. physikal. Chem.*, **9**, 339—342).—Van der Waals (Abstr., 1891, 1309), Nernst, Jahn, and Trevor have all pointed out an error which occurs in the author's calculation of the heat of dissociation of electrolytes. In this paper the necessary correction is made, and the heats of dissociation of a number of electrolytes recalculated.

H. C.

Persulphuric Acid and its Salts. By Berthelot (*Compt. rend.*, **114**, 875—883).—The author prepared potassium and ammonium persulphates by Marshall's method (Trans., 1891, 772), but placed the sulphate solution inside the porous cell, and used a platinum wire as the anode. He states that, under these conditions, the yield is greater than when the anode has a large surface. The potassium or ammonium sulphate is dissolved in sulphuric acid diluted with six to eight times its volume of water. Barium persulphate is obtained by adding barium hydroxide to a solution of the ammonium salt, expelling the ammonia at the ordinary temperature in a vacuum, and precipitating excess of barium by carbonic anhydride.

Heat of dissolution,	$K_2S_2O_8$ at 9·7°	−14·36 Cal.
„ „	$K_2S_2O_8$ at 5·6°	−15·34 „
„ „	$(NH_4)_2S_2O_8$ at 10·5°.....	− 9·72 „
„ „	$BaS_2O_8 + 4H_2O$ at 12° ..	−11·80 „

The heat of neutralisation was determined by precipitating the barium salt with dilute sulphuric acid; the value per equivalent is +13·8 Cal., identical with the heat of neutralisation of thiosulphuric, nitric, and hydrochloric acids. The heat of neutralisation with potassium or sodium hydroxide is +13·7 Cal., and with ammonia +12·4 Cal. Sulphuric acid does not completely displace persulphuric acid from its salts, but a condition of equilibrium is established.

In order to measure the heat of formation of persulphuric acid, the heat developed by the action of persulphates in presence of sulphuric acid on ferrous sulphate was compared with the heat developed by the action of hydrogen peroxide on the same reducing agent under similar conditions, matters being so arranged that the final composition of the solution was the same in both cases. As a mean result, the reduction of persulphuric acid was found to develop +13·2 Cal. more than the reduction of hydrogen peroxide. From this result the following values can be calculated:—

S_2 (octahedra) + O_8 + H_2 + water = $H_2S_2O_8$ dil.	develops	+316·2 Cal.
$S_2 + O_7 + H_2O$ + water = $H_2S_2O_8$ dil.	,,	+247·2 ,,
$K_2S_2O_8 + H_2O = SO_4H_2$ dil. + K_2SO_4 diss. + O	,,	+ 36·3 ,,
$K_2S_2O_8$ sol. + H_2O sol. = $2KHSO_4$ sol. + O	,,	+ 28·1 ,,
$K_2S_2O_8$ sol. + $K_2S_2O_7$ + O	,,	+ 19·5 ,,
$K_2 + S_2 + O_8$ + water = $K_2S_2O_8$ diss.	,,	+453·6 ,,
$K_2 + S_2 + O_8 = K_2S_2O_8$ sol.	,,	+439·2 ,,
$(NH_4)_2S_2O_8$ diss. + $H_2O = H_2SO_4$ dil. + $2NH_4HSO_4$ diss. + O	,,	+ 37·1 ,,
$(NH_4)_2S_2O_8$ sol. + H_2O sol. = $2NH_4HSO_4$ sol. + O	,,	+ 27·0 ,,
$N_2 + H_8 + S_2 + O_8$ + water = $(NH_4)_2S_2O_8$ diss.	,,	+383·0 ,,
$N_2 + H_8 + S_2 + O_8 = (NH_4)_2S_2O_8$ sol.	,,	+392·7 ,,
$BaS_2O_8 + H_2O = BaSO_4$ ppt. + H_2SO_4 dil. + O	,,	+ 44·2 ,,

The difference between the heats of formation of potassium and ammonium persulphates from their elements is the same as the difference in the case of the sulphates.

The fact that barium persulphate decomposes more readily than the alkaline salts is explained by the fact that the liberation of heat accompanying the change is greater in the first case. The anhydrous potassium salt undergoes practically no alteration when kept; the hydrated barium salt gradually decomposes into sulphate and sulphuric acid.

The formation of persulphuric acid and the persulphates from free oxygen and sulphuric acid or sulphates is endothermic, but the necessary energy may be supplied by the electric current, the heat of hydration of strong sulphuric acid, &c. The author has previously observed that persulphuric acid is formed by the action of hydrogen

peroxide on concentrated sulphuric acid. If too much water is present, the sulphuric acid combines with it in preference to acting on the hydrogen peroxide; if the sulphuric acid is too concentrated, it decomposes the persulphuric acid.

When barium peroxide is added to well-cooled concentrated sulphuric acid, persulphuric acid is formed, but if the addition of the peroxide is continued, at a certain point the mixture evolves a quantity of thick vapour, with a strong odour, and all the persulphuric acid decomposes, probably because it has passed the maximum concentration consistent with stability. C. H. B.

Sugars. By J. Fogh (*Compt. rend.*, **114**, 920—922).—

	Heat of combustion, 1 gram.	Heat of combustion, 1 molecule.		Heat of formation.
		Constant volume.	Constant pressure.	
	Cal.	Cal.	Cal.	Cal.
Glucoheptite, $C_7H_{16}O_7$	3966·5	840·9	841·2	370·9
Glucoheptose, $C_7H_{14}O_7$	3732·8	783·9	783·9	359·2
Glucoheptonic lactone, $C_7H_{12}O_7$	3494·8	726·9	726·6	347·5
Glucooctonic lactone, $C_8H_{14}O_8$	3518·7	837·5	837·2	400·2
Dextromannonic lactone, $C_6H_{10}O_6$	3477·8	619·0	618·7	292·1
Lævomannonic lactone, $C_6H_{10}O_6$	3465·7	616·9	616·6	294·2
Lævogulonic lactone, $C_6H_{10}O_6$	3456·8	615·3	615·0	295·8
Allomucic acid, $C_6H_{10}O_8$	2358·8	495·3	494·5	416·3
Inactive trihydroxyglutaric acid, $C_5H_8O_7$	2163·7	389·5	388·7	358·2

In the first three, which represent an alcohol, an aldehyde, and a dehydrated monobasic acid, the heat of formation diminishes regularly by 11·7 Cal., in consequence of the successive loss of CH_2.

C. H. B.

Thermochemistry of Hydrazine and Molecular Refraction of some Nitrogen Compounds. By R. Bach (*Zeit. physikal. Chem.*, **9**, 241—263).—The author has obtained the following thermochemical data with regard to some of the derivatives of hydrazine and azoimide:—

$N_2H_5{\cdot}OH + Aq = N_2H_5{\cdot}OH,Aq$	+ 19·19	Cal.
$N_2H_5{\cdot}HSO_4 + Aq = N_2H_5{\cdot}HSO_4,Aq$	− 85·27	,,
$N_2H_5Cl + Aq = N_2H_5Cl,Aq$	− 54·40	,,
$N_2H_5Cl,HCl + Aq = N_2H_5Cl,HCl,Aq$	− 62·01	,,
$NH_3,N_3H + Aq = NH_3,N_3H,Aq$	+ 67·34	,,
$H_2SO_4,Aq + N_2H_5{\cdot}OH,Aq = N_2H_5{\cdot}HSO_4,Aq.$	+113·0	,,
$2HCl,Aq + N_2H_5{\cdot}OH,Aq = N_2H_5Cl,HCl,Aq$	+ 96·0	,,
$HCl,Aq + N_2H_5{\cdot}OH,Aq = N_2H_5Cl,Aq$	+ 96·5	,,
$2HNO_3,Aq + N_2H_5{\cdot}OH,Aq = N_2H_4,2HNO_3,Aq$	+ 97·0	,,
$HNO_3,Aq + N_2H_5{\cdot}OH,Aq = N_2H_5{\cdot}NO_3,Aq$	+ 97·0	,,
$NH_3,Aq + N_3H,Aq = NH_4{\cdot}N_3,Aq$	+ 83·0	,,

The heat of formation of hydrazine hydrate was determined by oxidising the hydrate with chromic acid, and also by decomposing it with an ammoniacal solution of silver nitrate. The first method gave for the heat of formation of the hydrate in solution 561 Cal., the second method gave the value 663 Cal. The author regards the latter value as the more probable, and from this the heat of formation of the anhydrous hydrate may be deduced.

$$N_2 + H_6 + O = N_2H_5{\cdot}OH \ldots\ldots\ldots \quad +644 \text{ Cal.}$$

The fact that the heat of formation is a positive quantity shows that hydrazine hydrate is not the analogue of the diazo-compounds. It therefore probably has the constitution $H_2N{\cdot}NH_3{\cdot}OH$, and not $H_3N{:}NH_2{\cdot}OH$.

It appears from the above table that the hydrazine salts N_2H_4,HR are not converted into N_2H_42HR salts in aqueous solution, as the heats of neutralisation of hydrazine hydrate by either one or two equivalents of the acid are the same. From this, it is probable that the salts $N_2H_4,2HR$ undergo hydrolytic dissociation in aqueous solution, and this, taken in conjunction with the electrolytic dissociation which takes place at the same time, would explain the fact that the molecular weights of these salts determined by the cryoscopic method are only one-fourth of those expressed by their formulæ (Abstr., 1891, 264).

The determination of the molecular refraction of hydrazine hydrate and some of its salts led to the unexpected result that the atomic refraction of nitrogen deduced from the molecular refraction of the hydrate is much smaller than the value obtained from the other hydrazine salts and other nitrogen compounds. The value for the two nitrogen atoms calculated for the formula $(n-1)/d$ is 9·5 in the case of the hydrate, and nearly 11 for the salts. In this behaviour, hydrazine resembles ammonia, as the latter in aqueous solution also gives a very much smaller value for the atomic refraction of nitrogen than that deduced from the ammonium salts or the amines.

H. C.

Determination of Vapour Density. By C. Schall (*Ber.*, **25**, 1490—1491).—A supplementary note to the previous papers on this subject (compare Abstr., 1890, 681, 1042). It is desirable to calculate the smallest quantity of substance which may be used for each determination, so as to secure the greatest possible accuracy.

J. B. T.

Determination of the Density of Liquefied Gases and of their Saturated Vapours. By E. H. Amagat (*Compt. rend.*, **114**, 1093—1098).—The method proposed for determining the density of liquefied gases and their saturated vapours is the following:—Starting with the gas, a portion of this, say one-tenth of its volume, is liquefied, and the volumes of liquid and vapour carefully determined. A further portion of the gas is then liquefied, so that the volume of the liquid may be three or four times increased, and the volume again determined. If ΔV and $\Delta V'$ represent the increase in the volume of the liquid and the decrease in the volume of gas, and D and D′ are the densities of the liquid and the gas, $\Delta V/\Delta V' = D'/D$. On the other

hand, if V and V′ be taken to represent the volumes of gas and liquid in one of the above experiments, VD + V′D′ = P, the weight of material used. From these equations, the values of D and D′ can be deduced.

The difficulty of making determinations by the above method increases as the critical point is approached. The author has, however, applied the method with success in the case of carbonic anhydride, even up to the critical point, at which the densities of liquid and vapour become the same. A table is given for the values of the densities of liquid carbonic anhydride and its saturated vapour for each degree from 0° to the critical point. H. C.

Liquid and Gaseous Mixtures. By J. A. Wanklyn (*Chem. News*, **65**, 122—123; compare Abstr., 1891, 1412, and this vol., p. 264).—In more recent experiments on the specific gravity of sugar solutions, the author and his collaborators, working with larger quantities ($\frac{1}{2}$ litres) of solution, find that the increment coefficient of cane sugar is 0·388, instead of 0·371, and is constant for solutions containing 1 gram, and up to as much as, and probably even more than, 105 grams per litre, but this number falls in very strong and viscid solutions, containing, for instance, 749·5 grams per litre; this is assumed as due to solution in these being imperfect, and to a physical variation in the condition of the sugar, by which its specific gravity approximates to 1·606, that of solid sugar, instead of to 1·634, the sp. gr. of fluid sugar in the more mobile solutions. Saline solutions are also regarded as mixtures of fluid hydrates with water, in which no change of volume of any kind obtains, and these investigators are of opinion that the volumes of either gaseous or liquid mixtures is equal to the sum of the volumes of the constituents separately measured. D. A. L.

Theory of Diffusion and Electrolysis. By M. Planck (*Zeit. physikal. Chem.*, **9**, 347—348).—The author shows that Wiedeburg's statement (*Zeit. physikal. Chem.*, **9**, 143) of an error in the theory of hydrodiffusion developed by himself and Nernst rests upon a mistaken assumption. H. C.

Applicability of Planck's Proof of the Law of Van't Hoff. By S. Arrhenius (*Zeit. physikal. Chem.*, **9**, 330—334).—The author raises some objections to recent observations of Planck with regard to the application of gaseous laws to dilute solutions, firstly on the ground of priority, and secondly with the view of showing that Van't Hoff's law cannot, as Planck maintains, be deduced *a priori* and without other assumptions from the laws of thermodynamics. H. C.

Determination of the Freezing Point of very Dilute Aqueous Solutions. By F. M. Raoult (*Zeit. physikal. Chem.*, **9**, 343—346).—The author has improved the apparatus which he formerly employed for the determination of the freezing points of solutions. The beaker containing the solution is immersed in a 40 per cent. glycerol solution, which is kept in constant motion and cooled by means of a copper worm tube, through which water at a temperature about 3°

below the freezing point of the solution under examination circulates. The thermometer used for taking the observations acts as the stirrer, as a network of platinum is situated round the bulb and attached to the stem, and the whole is rapidly rotated before taking an observation. With this apparatus, the freezing point of distilled water is found to correspond with the melting point of ice to within 1/500 of a degree.

The author has redetermined the freezing points of cane sugar solutions, and finds, in accordance with his former determinations, that the molecular reduction increases with increasing dilution when a certain limit is reached (this vol., p. 678). H. C.

Action at a Distance of Aqueous Solutions on Water Vapour. By M. W. Beyerinck (*Zeit. physikal. Chem.*, **9**, 264—266).—The author has observed that a drop of an aqueous solution placed upon a glass plate has the power of absorbing water vapour from its immediate neighbourhood, and thus surrounding itself with a sphere which is apparently free from moisture. The size of this sphere varies considerably with the nature of the solution taken, probably depending on its surface tension, and the method might, perhaps, be made available for determining the vapour pressures of aqueous solutions. H. C.

Velocity of Reaction in Mixtures of Isohydric and Non-isohydric Solutions of Acids. By B. Moore (*Zeit. physikal. Chem.*, **9**, 327—329).—Isohydric solutions of acids contain hydrogen ions in equal concentration, and Arrhenius has shown (Abstr., 1887, 415) that when such solutions are mixed the concentration remains unaltered. If in two acid solutions the concentration of the hydrogen ions is not equal, the one solution will influence the degree of dissociation of the other, in such a manner that the concentration of the ions in the mixture is not the arithmetical mean of the concentrations in each solution. From this it follows that mixtures of non-isohydric solutions will bring about reactions with a velocity which is not the mean velocity of their components. In order to test this view, methyl acetate was hydrolysed by isohydric and non-isohydric solutions of hydrochloric, and di- and trichloracetic acids, and the velocity of the different reactions measured. The results obtained were in perfect accordance with the general theory. H. C.

Labile Conditions of Equilibrium in Mixtures of Two Substances at a Temperature below the Melting Point of either. By A. Blümcke (*Zeit. physikal. Chem.*, **9**, 323—326).—The object of the experiments described in this paper was to test some of the theoretical conclusions which have been arrived at in former communications (Abstr., 1891, 375; this vol., p. 259). With mixtures of sodium thiosulphate with potassium nitrate, of sodium acetate with potassium nitrate, and also of sodium thiosulphate with acetate, it has been found possible to obtain labile conditions of equilibrium below the melting points of either substance. The experiments are only of a qualitative character, but serve, as far as they can at present be extended, to

confirm the author's conclusions with respect to the isothermals of mixtures of two substances. H. C.

Equilibrium of Chemical Systems under Unequal Pressures. By H. Le Chatelier (*Zeit. physikal. Chem.*, **9**, 335—338).—The case is considered of a solid substance in contact with either a liquid or a gas being brought under a different pressure. If this takes place without chemical change, then the sum of the chemical energy expended during the alteration of the pressure or temperature must be zero. If L is the latent heat of the reaction and N the latent work of each different element in the system which accompanies the volume change v, p the pressure, and t the absolute temperature, $L\,dt/t + \Sigma N dp/p = 0$. The formula is applied with satisfactory results to some of the changes of water in contact with ice.

H. C.

Influence of Foreign Substances on the Form, Purity, and Size of Crystals separating from a Solution. By J. W. Retgers (*Zeit. physikal. Chem.*, **9**, 267—322).—The author points out that very little is at present known with regard to the conditions which determine the form, purity, and size of crystals separating from a solution. The form is often influenced in a totally unexplained manner by the presence of a foreign substance in the solution from which the crystals are separating. Thus, ordinary salt, which usually crystallises in cubes, will separate out in octahedra from a solution which contains urea. This may be due to the difference in physical character of the cube and octahedron faces, this difference inducing a difference in the capillary attraction between the faces and the different solutions into which the crystal may be introduced, so that in one case the attraction may be greater for the cube, in the other greater for the octahedron faces, and thus the growth of the one or the other favoured as the case may be. The purity of crystals is subject to similar unexplained influences. Lead nitrate can only be obtained in opaque crystals from a pure, aqueous solution, but in the presence of free nitric acid the crystals which separate are perfectly clear and transparent. With regard to the size, the author believes that there is a distinct maximum limit of size for every crystal, beyond which the crystal is incapable of further growth. The maximum varies with the same crystal, somewhat, with the bulk of the solution from which it is crystallised, but there is a particular maximum limit when the bulk of the solution ceases to exercise any influence. Crystals of alum and magnesium sulphate, which had apparently reached such a maximum size, have been kept for days in strongly supersaturated solutions without undergoing the least change, although the solutions, when disturbed, gave copious separations of smaller crystals. This maximum in size is also, in certain cases, influenced by the presence of foreign substances, salt crystals being obtained of larger size from solutions containing cupric chloride than from pure aqueous solutions.

In order to obtain some further evidence on the above points, the author has examined crystals of the different haloïd salts of the alkali metals and ammonium, obtained from solutions containing a

number of foreign impurities. The chief results with regard to the influence of these impurities on the form of the crystals are given in the following table :—

Salt.	From water.	With urea.	With $CrCl_3$.	With $FeCl_3$.	With $PbCl_2$.
NaCl.....	Cubic	Octahedral	Octahedral	Cubic	Cubic
KCl.....	,,	Cubo-octahedral	Cubic	,,	Octahedral

KI.....	,,	,,	,,	,,	,,
NH_4Cl ...	Trapezoidal	,,	,,	,,	Trapezoidal
NH_4Br ...	,,	,,	,,	Trapezoidal	Cubic
NH_4I	Cubic	,,	Octahedral	Octahedral	Octahedral

H. C.

Relations between Atomic Weights. By H. Adkins (*Chem. News*, **65**, 123—124).—It is shown that numbers representing all the atomic weights may be obtained by additive combinations of the numbers 7, 9, 11, and 12, being the atomic weights of lithium, glucinum, boron, and carbon respectively. D. A. L.

Inorganic Chemistry.

Slow Combustion of Gaseous Mixtures. By P. Askenasy and V. Meyer (*Annalen*, **269**, 49—72).—The authors have continued the experiments, commenced by Krause and Meyer (Abstr., 1891, 1153), on the rate of combination of oxygen and hydrogen, in order to try and ascertain the cause of the irregularity of the previous results, and, if possible, to get rid of all disturbing influences, so that the relation between time and amount of water formed could be determined.

The electrolytic gas was prepared as already described, and purified with the greatest care ; in addition to the precautions previously observed, it was passed through a glass tube, heated to 518° in the vapour of phosphorus pentasulphide, in order to ensure the decomposition of any ozone or hydrogen peroxide which might be present, then through solutions of potassium iodide (from which, however, no liberation of iodine took place) and concentrated potash and finally dried with concentrated sulphuric acid.

In some preliminary experiments, the electrolytic gas was passed through potassium permanganate in order to free it from hydrogen peroxide ; it was found, however, that the potassium permanganate was reduced by the hydrogen in the mixture, and, also, that absolutely pure hydrogen is completely absorbed by potassium permanganate with formation of a brown precipitate (compare Wanklyn and Cooper, *Phil. Mag.* [5], **6**, 288, and Jones, Trans., 1878, 95).

When electrolytic gas, purified in the manner described, is passed at a moderate rate for 10 hours through a glass tube heated to 518°, only a very small quantity of water (0·7—1·7 milligrams) is produced (compare Meyer, this vol., p. 562); when the glass tube is heated to 606°, a somewhat larger quantity of water is formed, but only a very small proportion of the two gases enter into combination.

The authors then describe in detail a number of experiments which were made in order to determine the amount of water formed on heating electrolytic gas in glass bulbs at 518° for two hours; although various devices were adopted, such as etching the inside of the bulbs, protecting the bulbs from the light, passing electrolytic gas for many hours through the bulbs heated at 518°, in order to obtain an unchangeable surface previous to their employment in the quantitative experiments, constant results could not be obtained. The effect of coating the inner surfaces of the bulbs with silver has been already referred to by Meyer (*loc. cit.*); further experiments have shown that when such silvered bulbs are employed, and the heating is continued for two hours, complete combination takes place at temperatures above 218°; at 183° about 70 per cent. of the electrolytic gas is converted into water, but at 155° only a comparatively very small quantity of water is formed, and at 100° no appreciable combination takes place, even after heating for four hours. The quantity of water produced on heating pure electrolytic gas in the silvered bulbs for two hours at 183° was just as variable as in the experiments with unsilvered vessels.

The conclusion to be drawn from this investigation is, that it is impossible to establish any relation between the quantity of water produced on heating electrolytic gas and the duration of the experiment, even when every imaginable precaution is taken to ensure equality of conditions, and this, probably, owing to the irregular action of the surface of the containing vessels; further experiments on the subject are in progress. F. S. K.

Photochemical Notes. By P. Askenasy and V. Meyer (*Annalen*, **269**, 72—73; compare preceding abstract).—Pure, dry electrolytic gas underwent no change when it was exposed to direct sunlight from May to October, in sealed glass bulbs; on opening the bulbs under water, no change in the original volume of the gas was observed. Even when moist electrolytic gas was exposed to the concentrated light of a July sun, and at the same time heated to 606°, no explosion occurred.

Chlorine and hydrogen, both of which had been separately exposed for three to four hours to bright sunlight, did not combine when mixed together in the dark immediately afterwards; this conclusion confirms that previously come to by Bunsen and Roscoe, and proves that Draper's statement to the contrary is untrue. F. S. K.

Preparation of Nitric Oxide. By F. Emich (*Monatsh.*, **13**, 73—77).—In order to obtain this gas in a very pure condition, the author employs the reaction which obtains in a Lunge's nitrometer, namely, treating mercury with a mixture of sulphuric acid and nitric acid.

The purity of the gas was placed beyond question by the results obtained on leading it over glowing copper; the increase in weight of the metal giving the weight of oxygen, whilst the gas evolved, which was collected and measured, gave the weight of nitrogen. In the reaction between copper and nitric oxide, which is attended by the liberation of much heat, the metal is quantitatively converted into cuprous oxide. G. T. M.

Behaviour of Nitric Oxide at High Temperatures. By F. Emich (*Monatsh.*, **13**, 78—85).—According to Gay-Lussac (Gmelin-Kraut's *Handbuch*, **1**, **2**, 452), nitric oxide is resolved into nitrogen and nitrous oxide when passed over glowing platinum; whilst Berthelot (*Compt. rend.*, **77**, 1448) states that, besides these gases, free oxygen is also formed. The author has further investigated this question, and finds that ruddy fumes are produced when the gas, which has been previously passed through a porcelain or platinum tube heated to the highest temperature obtainable in a Fletcher tube-oven, is allowed to come into contact with the air. When, however, the gas is submitted to the very high temperature obtained by the electrical ignition of nets of platinum, platinum-iridium, platinum-rhodium, and palladium wire, it is completely decomposed into nitrogen and oxygen.

The author also finds that, contrary to the statement of Calberla (*J. pr. Chem.*, **104**, 232), silver at a bright red heat exercises no specific action on nitric oxide. He has exactly repeated the experiments made by that author, but in every case considerable quantities of the oxides of nitrogen could be recognised in the escaping gas.

G. T. M.

Reaction between Nitric Oxide and Oxygen. By F. Emich (*Monatsh.*, **13**, 86—89).—The author finds that these gases, in a state of perfect purity and carefully dried by long-continued exposure to phosphorus pentoxide, when mixed, rapidly react, with the production of brown fumes. This observation refutes Traube's tenet, "that no substance, when in a perfectly dry state, unites directly with oxygen" (compare *Ber.*, **18**, 1881). G. T. M.

Action of Potassium Hydroxide on Nitric Oxide. By F. Emich (*Monatsh.*, **13**, 90—97).—Gay-Lussac found (Gmelin-Kraut's *Handbuch*, **1**, **2**, 454) that when nitric oxide is allowed to remain over potassium hydroxide for some months, a diminution in volume of about 75 per cent. occurs, and the residual gas is nitrous oxide, whilst potassium nitrite is present in the solution. Russell and Lepraik (this Journal, 1877, ii, 37) further studied the interaction between the two substances. They allowed them to remain together for 11—12 months, whereby a condensation of 75 per cent. occurred, and observed that when the compounds reacted at 100°, the residual gas contained nitric oxide (1·5 to 2·5 per cent.) and nitrogen (6·5 to 15·1 per cent.) as well as nitrous oxide. The author has investigated the behaviour of nitric oxide with anhydrous potassium hydroxide at a higher temperature (125°), and finds that, under the circumstances, a diminution occurs of 83·3 per cent. in the volume of the gas, which,

after the action, appears to consist entirely of nitrogen. This volume corresponds with the equation $6NO + 4KOH = N_2 + 4KNO_2 + 2H_2O$.

G. T. M.

Manufacture of Nitric Acid. By C. W. Volney (*Chem. Centr.*, 1892, i, 348—349; from *J. Amer. Chem. Soc.*, **13**, 246—251).—The author explains the sudden frothing which frequently takes place when nitric acid is prepared from sodium nitrate and sulphuric acid on the assumption that the first portions pass over at 84°, and that the heating must be commenced cautiously, and the temperature only allowed to rise after the first reaction abates. After the temperature has risen above 109°, no acid passes over until the temperature 117° is reached, when the last portions pass over. The latter acid has a sp. gr. 1·42, and corresponds with the hydrate, $2HNO_3 + H_2O$, which distils at 120—121°, without decomposition.

J. W. L.

Crystallised Anhydrous Sulphates. By P. Klobb (*Compt. rend.*, **114**, 836—838).—When nickel, cobalt, zinc, and copper sulphates are mixed with excess of ammonium sulphate and carefully heated, out of contact with flame gases in a partially covered crucible, until the whole of the ammonium sulphate is volatilised, care being taken not to decompose the metallic sulphate, the anhydrous sulphates remain in a distinctly crystallised condition. Zinc sulphate forms colourless, elongated, and truncated octahedra, rapidly soluble in warm water. Copper sulphate forms grey, slender, prismatic needles, easily soluble in water, especially if hot. Cobalt sulphate forms purplish-red, truncated octahedra, very stable in air, and only slowly dissolved by boiling water. Nickel sulphate forms yellowish-green octahedra, soluble, with difficulty, in boiling water.

C. H. B.

Colloïdal Silver. By E. A. Schneider (*Ber.*, **25**, 1440—1448; compare this vol., p. 775).—The fact that hydrochloric acid precipitates a mixture of silver chloride and silver from colloïdal silver solutions may be explained by supposing either that the solution contains small quantities of oxygen compounds of silver, or that the silver decomposes the hydrogen chloride with formation of silver chloride and hydrogen. On evaporating a very pure colloïdal silver solution to dryness, and heating the residue to redness, only a negligible quantity of oxygen was obtained, showing, with certainty, that no oxygen compounds of silver were present in the colloïdal solution. If silver chloride and hydrogen are formed on treatment with hydrochloric acid, the hydrogen must be occluded by the silver, as no gas escapes, and, on electrolysis in a properly arranged apparatus, it would be expected to reveal its presence by the effect of the polarisation current on the E.M.F. of the solution. From such measurements the author concludes that the silver particles contain occluded hydrogen, which they slowly lose. The quantity of hydrogen present must, however, be very small, no appreciable liberation of gas being observed on amalgamation with mercury under water. The deficiency in the quantity of hydrogen produced, as indicated by the equation $Ag + HCl = AgCl + H$, may be assigned to various causes.

Colloïdal silver solutions always contain a certain amount of ferric salts, and, on adding hydrochloric acid, the following reaction occurs:—$Ag + FeCl_3 = AgCl + FeCl_2$; the proportion of silver chloride present is thus increased. Oxygen is also dissolved in the solution, and, of course, combines with part of the hydrogen liberated. Hydrogen is also required to produce the silver subchloride, Ag_2Cl, which is formed. The presence of small quantities of easily reducible substances, such as citric acid, and the solubility of hydrogen in the solution are sufficient to account for the remainder of the missing hydrogen. W. J. P.

Decomposition of Silver Permanganate. By A. Gorgeu (*Compt. rend.*, **114**, 912—915).—Silver permanganate decomposes slowly at the ordinary temperature, rapidly at 100°, or in hot water, and very rapidly at 135°. The black product, obtained by decomposition in water at 75°, the permanganate being always in excess, has the composition—

MnO.	O (active).	Ag_2O.	O (inactive).	H_2O.	Loss.
32·71	7·33	53·38	2·75	3·29	0·54

The active oxygen is present exactly in the proportion required to form manganite. The quantity of inactive oxygen does not vary with the method of analysis. No similar excess of inactive oxygen is found in other combinations of silver oxide with higher oxides of manganese, but it occurs in the deposit formed on the positive pole during the electrolysis of silver nitrate. This inactive oxygen seems to be united with the silver, but its exact condition has yet to be determined; it seems to exist neither in occlusion nor in true combination. C. H. B.

Occlusion of Hydrogen by Lead. By J. Shields (*Chem. News*, **65**, 195—197).—Bellati and Lussana's method for showing the diffusion of hydrogen through an iron plate, and also Helmholtz and Root's method of showing the occlusion of hydrogen by platinum, when applied to show the occlusion of hydrogen by lead, gave negative results. It is pointed out, moreover, that even Neumann and Streintz's most recent results (this vol., p. 567) can scarcely be regarded as proving the occlusion of hydrogen by lead, considering that the amount of absorption shown by them amounts only to about 0·13 of its volume. D. A. L.

Behaviour of Copper and of the Noble Metals towards some Gases and Vapours. By G. Neumann (*Monatsh.*, **13**, 40—48; compare Neumann and Streintz, this vol., p. 567).—According to Thudichum and Hake (this Journal, 1876, ii, 251), the hydrogen which is retained in copper reduced from the oxide may be perfectly removed by passing over the glowing metal, for some time, a stream of carbonic anhydride. The author finds, however, that the carbonic anhydride does not remove all the hydrogen, and that the process has a further disadvantage, inasmuch as the carbonic anhydride itself, or carbon obtained from it, may be absorbed by the copper. In one

set of experiments, a coil of copper gauze, weighing 29 grams, was found to give, on combustion, from 0·00114 to 0·0079 gram of water, and from 0·0055 to 0·0196 gram of carbonic anhydride. Copper gauze which has been reduced by means of methyl and ethyl alcohols, or by coal gas, and dried at 220°, always retains carbonic anhydride and water; but in quantity so small that the effect produced is usually within the limits of experimental error.

At a temperature of 450°, silver gauze was found to absorb 4·09 to 5·43 times its volume of oxygen, whilst, at the same temperature, gold absorbed from 32·78 to 48·49 times, and platinum from 63 to 77 times respectively their volume of the gas. Palladium, at 450°, is converted into the suboxide Pd_2O.

In the above-described experiments, the temperature was controlled by employing such conditions that zinc (m. p. 412—433°) melted easily, and antimony (m. p. 432—450°) only just melted.

G. T. M.

Aluminium Sulphide. By H. N. Warren (*Chem. News*, **65**, 135—136).—Pure alumina, prepared by dissolving the metal in hydrochloric acid and drying and igniting the product, when exposed, at a full red heat, to a current of carbon bisulphide vapour, neither fuses nor does it yield any aluminium sulphide. But alumina prepared from alum under similar treatment yields, as usually asserted, a glassy mass, evolving hydrogen sulphide when thrown into water; but the author finds the source of both this gas and the glassy appearance is not aluminium sulphide, but a small quantity of potassium sulphide derived from potassium sulphate retained by the alumina. Aluminium sulphide is obtained when aluminium is subjected, at a red heat, to the action of sulphur vapour. D. A. L.

New Iron Salts. By Lachaud and C. Lepierre (*Compt. rend.*, **114**, 915—918).—When ferrous sulphate or ferrous ammonium sulphate is added gradually to fused ammonium sulphate, products are obtained which differ in composition with the time of heating and the temperature. The excess of ammonium sulphate is separated from the crystalline products by treatment with alcohol.

$Fe_2(SO_4)_3,FeSO_4,4Am_2SO_4 + 3H_2O$ forms colourless, prismatic needles; sp. gr. at $-10° = 2·02$. It dissolves slowly in cold water, and is converted into a basic sulphate by boiling water. It is formed when the quantity of sulphuric acid present is insufficient to convert the whole of the ammonia into ammonium hydrogen sulphate.

$Fe_2(SO_4)_3,3Am_2SO_4$ is obtained by heating the preceding compound in presence of the ammonium salt. It forms white, prismatic needles; sp. gr. = 2·31 at 14°.

$Fe_2(SO_4)_3,Am_2SO_4$ crystallises in hexagons; sp. gr. at 14° = 2·45. It is obtained when the heating is prolonged.

$Fe_2(SO_4)_3$ is obtained in yellow, hexagonal lamellæ (sp. gr. 3·05 at 14°) when any of the preceding compounds is subjected to prolonged heating in presence of ammonium sulphate.

Ferric oxide is obtained by heating the two preceding salts, and forms hexagonal lamellæ of sp. gr. 4·95 at 14°. C. H. B.

Action of Hydrogen Peroxide on the Oxides of Molybdenum, Tungsten, and Vanadium. By J. B. Cammerer (*Chem. Zeit.*, **15**, 957—959).—The author prepared a pure molybdic acid from its ammonium salt by repeated ignition and treatment with nitric acid. On boiling this product with a solution of hydrogen peroxide, it gradually dissolves with evolution of oxygen. The resulting liquid is clear yellow, but yields on spontaneous evaporation a thickish, orange-red mass, which may be further dried, and then yields a yellow powder. It is difficultly soluble in cold, but readily so in hot water, and does not again precipitate on cooling. The solution has a strongly acid reaction, combines, however, with acids to form nearly colourless products, and decomposes alkaline carbonates with the formation of colourless salts. Analysis showed it to be not a mixture, but a chemical compound of molybdic acid with hydrogen peroxide of approximately the formula $2MoO_3,H_2O,H_2O_2$. The hydrogen peroxide cannot be expelled by prolonged heating at 100°.

Action on Tungstic Acid.—The acid was prepared in a similar manner to the molybdic acid, and boiled with the solution of hydrogen peroxide, in which it dissolved with evolution of oxygen. The solution behaves like that of the molybdate compound, and cannot be made to crystallise even after the addition of alcohol and ether. On analysis, it proved to be a compound of tungstic acid with hydrogen peroxide, and had the formula WO_3,H_2O,H_2O_2.

Action on Vanadic Acid.—The acid was prepared in the same manner as the two previous compounds, and then boiled with the peroxide. The liquid is first of a dirty-green colour, but evolves oxygen, and then changes to a reddish-brown. On spontaneous evaporation, blackish-brown crusts are obtained, which occasionally show a metallic lustre. The powder is brown and amorphous. Attempts at crystallisation failed. It is but partly soluble in cold water, and on warming, it is gradually decomposed. In dilute acids, it is freely soluble, and loses in colour, especially on warming. Its solution, which is intensely acid to blue litmus-paper, gives with an alkaline carbonate a brown precipitate, which dissolves on warming with evolution of carbonic anhydride.

Analysis, however, showed such a wide variation in the amount of hydrogen peroxide, and the compound is so readily decomposed, that it may be considered more like a mixture than a true chemical combination. L. de K.

Reduction of Potassium Platinum Thiostannate: Potassium Thioplatinosate. By R. Schneider (*J. pr. Chem.* [2], **45**, 401—411).—Potassium platinum thiostannate, $K_2S,3PtS,SnS_2$ (*Annalen*, **138**, 612), is best prepared by melting 1 part of platinum sponge with 2 parts of stannic sulphide (mosaic gold), 6—8 parts of dry potassium carbonate, and 6—8 parts of sulphur. When this salt is heated to dark redness in a current of hydrogen, it loses sulphur as hydrogen sulphide and a mixture of *potassium thioplatinosate*, K_2PtS_2 with platinum and tin is left. When the residue is treated with water in absence of air, the solution contains $K_2PtS_2 + 4KOH$, and there are left undissolved a double salt, $K_2PtS_2,2H_2PtS_2$, platinum,

and tin. When the solution is exposed to the air, the potassium thioplatinosate is partially oxidised according to the equation $3K_2PtS_2 + 3O = K_2PtO_3 + 2K_2PtS_3$, and when this oxidised solution is treated with hydrochloric acid, platinum bisulphide is precipitated. When the insoluble matter left by the treatment of the residue from the heating in hydrogen with water is attacked by dilute hydrochloric acid in absence of air, the K_2PtS_2 becomes H_2PtS_2; in presence of air, this latter is oxidised to H_2O and PtS_2.

Attempts to isolate potassium thioplatinosate failed.

Mineralogical Chemistry.

Allotropism of Amorphous Carbon. By W. Luzi (*Ber.*, **25**, 1378—1385).—A graphitite is found in the chalk at Wunsiedel, in the Fichtelgebirge, which has been examined by Fuchs, who came to the conclusion that it is amorphous (*J. pr. Chem.*, **7**, 353), and by Sandberger, who also concluded that it is amorphous and identical with the graphitoïd or schungite of Sauer and Inostranzeff. The author considers it to belong to the class of graphitites. He has received from Stugard, in Finuland, a graphitite which is exactly like that of Wunsiedel. It marks paper like graphite, has no plane of cleavage, and has a conchoïdal fracture; sp. gr. = 2·255—2·26 at 17·5°. It gives 0·67 per cent. of pale-yellow ash on combustion in oxygen, and is quite amorphous.

The mineral from Wunsiedel has a sp. gr. = 2·007, is similar to the above in other properties, and is free from hydrogen and nitrogen. When oxidised with potassium chlorate and concentrated, red, fuming nitric acid, it does not behave like ordinary amorphous carbon, but like graphite and graphitite, and yields a graphitite oxide similar to that obtained from magnetic graphitite. After five treatments with the oxidising mixture, the product has an orange-brown colour. It decomposes on heating with hissing and glowing, and leaves a black, powdery, heavy residue. It is insoluble in water and nitric acid, under the microscope is seen to consist of minute leaflets, is doubly refractive, and gave on analysis 51·99 per cent. C, 1·93 per cent. H, 46·08 per cent. O.

From these results, the author concludes that the mineral contains amorphous carbon, which is not identical with the ordinary amorphous modification of this element. E. C. R.

Fractional Analysis of Silicates. By F. W. Clarke (*Chem. News*, **65**, 188–189, 199—200).—The author realises the desirability of furnishing experimental data upon which to base the structural composition of silicates, and, with this object in view, gives the results of some experiments on minerals mainly belonging to the mica and chlorite group, and a few other magnesian silicates such as talc, serpentine, and olivine, the last being the only anhydrous

mineral used. First of all, by ascertaining the loss of weight at 100°, 250°, 300°, and at a full red heat, and when there was fear of oxidation also taking a total water directly, the vermiculite micas, kerrite, jefferisite, and protovermiculite are found to correspond with an ordinary mica, *plus* 3 mols. H_2O, and with hydrogen equivalently replacing the alkali metals of the original mineral; the water is expelled, 2 mols. at 100°, the third at 250°. In the true micas and chlorites the water is not expelled in fractions, but is stable up to or near redness, and is regarded as constitutional. Such results can be turned to account, in many instances, for ascertaining the character and distribution of the hydroxyl, and for finding whether it is in combination with silica, alumina, or magnesia, &c. For instance, in the above minerals all except talc are decomposable by aqueous hydrochloric acid, but by dry hydrogen chloride they are differently affected; this, the following experiments tend to show, is due to the character of the hydroxyl. Each silicate was heated to constant weight in a current of dry hydrogen chloride, at about 400°, a temperature at which the water of constitution is retained. Olivine, which does not contain hydroxyl, was practically unattacked; talc, the true micas, and the vermiculites were not acted on, or only slightly; serpentine and the chlorites, however, were strongly affected, with the production of magnesium chloride, in which the magnesia was estimated, and the numbers obtained lead to the assumption that the group Mg·OH is present in those minerals, which are vigorously attacked by dry hydrogen chloride. It is therefore presumed that talc, which is not attacked either by wet or dry hydrochloric acid, does not contain this group; therefore, of the two suggested formulæ for that mineral, $Mg_3H_2(SiO_3)_4$ and $Mg(Si_2O_5{\cdot}Mg{\cdot}OH)_2$, the former, the acid metasilicate formula, is preferable. This is also supported by the fact that when talc is sharply and quickly ignited one-fourth of its total silica is set free, as represented by the equation $Mg_3H_2Si_4O_{12} = 3MgSiO_3 + SiO_2 + H_2O$; this could not well be explained from the pyrosilicate point of view. Moreover, the acid character of the hydroxyl agrees well with the stability towards acids.

Another method of obtaining further information as regards the composition of these silicates is based on the fact that even if they are readily decomposed by hydrochloric acid, yet by ignition they are transformed into soluble and insoluble portions, for instance, three chlorites of similar type and xanthophyllite (waluewite from Siberia), all of which had been analysed, were strongly ignited over a blast, in a covered platinum crucible, for several hours, digested with strong hydrochloric acid, evaporated to dryness, heated with weak acid, filtered, the silica removed by boiling with solution of sodium carbonate, and the insoluble residue washed, weighed, and separately analysed. In each of the four cases it proved to have the composition of spinel, and in quantity bore a definite relation to the formulæ of the original minerals, which were:—

Ripidolite (West Chester, Pa.), $Al_{38}Mg_{85}H_{140}(SiO_4)_{50}O_{113}$.
Clinochlore (Slatoust., Urals), $Al_{38}Mg_{87}H_{143}(SiO_4)_{52}O_{113}$.
Leuchtenbergite (Slatoust., Urals), $Al_{42}Mg_{86}H_{143}(SiO_4)_{50}O_{121}$.
Waluewite (Slatoust., Urals), $Al_{86}Ca_{24}Mg_{52}H_{50}(SiO_4)_{28}O_{174}$.

In each case there is an excess of oxygen over the silica, and the amount of spinel formed by ignition is almost quantitatively proportional to that excess. Such decompositions give strong evidence of the relative constitution of the minerals. The three examples of chlorites all reduce to the general formula $Mg_2(SiO_4)_2R'_4$, in which R′ is partly hydrogen, partly Mg·OH and partly ·AlH_2O_2; the juxtaposition of the two latter groups would explain the formation of spinel on ignition, whilst the soluble portions of the decomposed material are apparently mixtures of olivine and magnesian garnet, minerals which are common sources of chlorites in nature. Tschermak suggested that these particular chlorites were mixtures of amesite and serpentine; as, however, the latter mineral when ignited yields insoluble enstatite, that view, in face of the present results, is untenable. Waluewite, the most basic known member of the clintonite group, appears to be a mixture of isomorphous molecules, among which the compound $(AlO_2Mg)_4SiO_4$ is predominant; such a compound might easily split up into olivine and spinel, $Mg_2SiO_4 + 2MgAl_2O_4$, and the quantity of spinel actually formed, when waluewite is decomposed by heat, is almost exactly the amount required by this theory. The association of spinel and members of the olivine group with clintonite micas in nature is very suggestive in this connection.

D. A. L.

Native Iron from Cañon Diablo. By Mallard and by Daubrée (*Compt. rend.*, **114**, 812—814).—A specimen of native iron, collected by Foote in 1891 near the Cañon Diablo, in Arizona, was found by Koenig to contain cavities filled with black matter, and containing diamonds of 0·5 mm. diameter (this vol., p. 284). In other samples collected by Eckley Coxe, Mallard finds cavities filled with black matter and containing rounded grains of carbonado, 0·5 to 1·0 mm. in diameter. This native iron seems to be of meteoric origin, but Foote observed, about 3 kilom. to the north-west of the locality where the larger fragments are found, an abrupt elevation which seems to be an extinct volcano. It is not improbable, therefore, that the native iron is of terrestrial and volcanic origin.

Daubrée points out that the native iron of Greenland has been shown to be of terrestrial origin, and to be connected with basaltic eruptions. He considers that the determination of the origin of the native iron of the Cañon Diablo would probably throw much light on the general question of the formation of diamonds. C. H. B.

Organic Chemistry.

Boiling Point Curves for the Normal Paraffins. By G. Hinrichs (*Compt. rend.*, **114**, 1015—1018).—In a former paper (*Compt. rend.*, **112**, 998), the author has shown that the boiling point depends on the atomic weight and on the pressure separately. In the present paper, he shows that in an homologous series, that of the normal paraffins, the boiling points are determined by the same

function when the pressure or molecular weight is altered. This is first demonstrated by construction of the isobaric lines for 15, 30, 50, 100, and 760 mm. for the paraffins containing from 11 to 19 carbon atoms. The form of the curves is the same, and they can all be expressed generally by the equation $t = \eta + k_1(\log a - \xi)$, where a is the molecular weight. A like similarity is noticed in the isosomatic curves, where the boiling point is given for each separate paraffin as a function of the pressure. H. C.

Mechanical Determination of the Boiling Points of Compounds with Simple Terminal Substitution. By G. Hinrichs (*Compt. rend.*, **114**, 1113—1115).—The substitution of a simple atom such as that of chlorine, bromine, or iodine for one of the terminal hydrogen atoms in an organic compound will have the effect of increasing the mass and the moment of inertia of the molecule. The boiling point is, as the author has shown, a function of the moment of inertia, and it should be possible from the increase in the latter to calculate the increase of the former. The author shows that this is possible, making use of relationships which he has established in former papers, and that the rise in the boiling point is directly proportional to the increase in the mass, and inversely proportional to the number of carbon atoms in the hydrocarbon molecule. That this result is in keeping with experiment is shown by reference to the bromides and iodides of the C_4, C_5, and C_6 paraffins. H. C.

Establishment of Fundamental Formulæ for the Calculation of Moments of Inertia. By G. Hinrichs (*Compt. rend.*, **114**, 1064—1066).—The author obtains general expressions for the moment of inertia of molecules of the C_nH_{2n+2} hydrocarbons round their natural axes of rotation in terms of the number of carbon atoms contained in the molecule. H. C.

Composition of Ant Oil. By C. Schall (*Ber.*, **25**, 1489—1490). The author has succeeded in separating a hydrocarbon from a specimen of ant oil; it boils at 192—194° under a pressure of 720 mm., and appears to be identical with normal undecane. J. B. T.

Acetylated Lactose and the Optically Different Modifications of Lactose. By M. Schmoeger (*Ber.*, **25**, 1452—1455).—Herzfeld (Abstr., 1880, 619) prepared an octacetyllactose by Liebermann's method, and stated that it melts at 87°; the author finds that, if slowly crystallised from a mixture of alcohol and chloroform, it melts at 95—100°. When separated from its boiling alcoholic solution, it melts at 85°. Its specific rotatory power is $[\alpha]_D = -3{\cdot}5°$.

An acetyllactose was prepared by Schützenberger (*Annalen*, **84**, 74) by the action of acetic anhydride on lactose dissolved in acetic acid. The product of the action is a horny mass melting at about 80°, and containing about 40 per cent. of acetyl. By fractional crystallisation from water, the author succeeded in separating a small quantity (4 per cent.) of the crystalline octacetyllactose from it, the remainder was an amorphous mass consisting, probably, of acetylated decomposition products. On attempting to prepare a hydrazone and

osazone from this, only acetylphenylhydrazine was obtained. No crystalline product was formed with hydroxylamine.

The author has previously pointed out the existence of two optically different modifications of ordinary lactose (Abstr., 1882, 157). The one exhibiting semi-rotation is obtained by rapidly evaporating a solution of 2·6 grams of lactose on a water-bath. The modification showing slight bi-rotation is prepared by evaporating not more than 7 c.c. of a 10 per cent. sugar solution to dryness. The two modifications are crystalline, and contain no water of crystallisation; they eventually change into the variety showing constant rotatory power. Cryoscopic determinations and observations of their refractive indices and dispersions in aqueous solution afford no explanation of their existence. W. J. P.

Allyltrimethylammonium Chloride and Iodide. By E. Schmidt and J. Weiss (*Annalen*, **268**, 143—151; compare this vol., p. 905, and Bode, this vol., p. 806).—*Allyltrimethylammonium chloride*, $NMe_3Cl{\cdot}C_3H_5$, is formed when allyl chloride is treated with methylamine in alcoholic solution; it is a colourless, very hygroscopic, crystalline compound, which seems not to be reduced on treatment with tin and hydrochloric acid. The *platinochloride*, $(NMe_3Cl{\cdot}C_3H_5)_2PtCl_4$, separates from dilute hydrochloric acid in well-defined octahedra, and melts at 215°; when its aqueous solution is boiled for a long time and then allowed to cool, a lemon-yellow salt of the composition

$$NMe_3Cl{\cdot}C_3H_5,PtCl_2,$$

is deposited. The *aurochloride*, $NMe_3Cl{\cdot}C_3H_5,AuCl_3$, crystallises in golden plates, and melts at 210°.

Propyltrimethylammonium iodide, NMe_3IPr, prepared from normal propyl iodide in like manner, is a colourless, crystalline compound. When treated with silver chloride, it yields a chloride from which an *aurochloride* of the composition $NMe_3ClPr,AuCl_3$ is obtained; this crystallises in long, golden needles, melts at 215°, and is quite different in properties from the aurochloride which is obtained from the allyl base after the latter has been treated with tin and hydrochloric acid.

When allyltrimethylammonium chloride is treated with bromine in alcoholic solution, it is converted into a *perbromide* of the composition $NMe_3Br{\cdot}C_3H_5Br + Br_2$; this compound forms well-defined, reddish-yellow crystals, and is converted into dibromopropyltrimethylammonium bromide (m. p. 173°) by warm alcohol.

Allyltrimethylammonium iodide, $NMe_3I{\cdot}C_3H_5$, prepared from allyl iodide and trimethylamine, separates from boiling alcohol in well-defined, colourless needles, and melts at 104°.

Experiments on frogs and rabbits showed that the physiological action of allyltrimethylammonium salts is quite different from that of neurine, the former being far less poisonous than the latter. F. S. K.

Note by Abstractor.—The melting points of some of the compounds described above are not given by the author, but are taken from Partheil's paper (compare following abstract) to avoid repetition.

Derivatives of Allyltrimethylammonium Hydroxide. By E. Schmidt and A. Partheil (*Annalen*, **268**, 152—197; compare Abstr., 1890, 356, and Schmidt, this vol., p. 905).—These experiments were instituted in order to compare the chemical behaviour of allyltrimethylammonium hydroxide with that of the corresponding vinyl compound, and also with the object of preparing and studying the physiological action of homologues of isomuscarine and of acetenyltrimethylammonium hydroxide; practically the whole of the subject matter of the present paper has already been published (Abstr., 1890, 356).

Tetramethylammonium bromide, prepared as already described (compare Schmidt, this vol., p. 805), crystallises from glacial acetic acid in prisms, and from water and alcohol in octahedra; it is insoluble in ether and acetone, and only very sparingly soluble in cold alcohol.

When *dibromopropyltrimethylammoninm bromide*, $NMe_3Br{\cdot}C_3H_5Br_2$, (m. p. 173°) is decomposed with silver chloride, and the hydrochloric acid solution of the product mixed with auric chloride, an *aurochloride* of the composition $NMe_3Cl{\cdot}C_3H_5Br_2,AuCl_3$ is deposited in lemon-yellow needles, melting at 148°; by directly precipitating a solution of the bromide with auric chloride, the same aurochloride is obtained, mixed, however, with some other bromo-derivative.

When γ-iodopropyltrimethylammonium iodide (*loc. cit.*) is treated with moist silver oxide at the ordinary temperature, it is converted into the corresponding hydroxide, the *platinochloride*,

$$(NMe_3Cl{\cdot}C_3H_6I)_2,PtCl_4,$$

of which crystallises from hot, dilute hydrochloric acid in brownish-red needles, melting at 237°; if, however, the treatment is carried out at 100°, or alcoholic potash is employed instead of silver oxide, allyltrimethylammonium hydroxide is produced with liberation of hydriodic acid; when boiled with silver nitrate, the iodide is converted into γ-hydroxypropyltrimethylammonium hydroxide (γ-homocholine), identical with the compound described by Weiss (*Zeitschr. f. Naturw.*, **60**, 275).

When trimethylenechlorhydrin is heated at 100° for six hours with an alcoholic solution of trimethylamine, there is formed a salt which seems not to be identical with homocholine hydrochloride.

F. S. K.

Picric Acid as a Reagent for Guanidine. By O. Prelinger (*Monatsh.*, **13**, 97—100; compare Emich, Abstr., 1891, 1180).—*α-Triphenylguanidine picrate*, $CH_2Ph_3N_3,C_6H_2(NO_2)_3{\cdot}OH$, is readily formed on shaking together equivalent quantities of the base and acid dissolved in hot alcohol. It is of a deep-yellow colour; melts at 176—178°; dissolves in 12,200 parts of water at 15°; is only sparingly soluble in ether, benzene, and carbon bisulphide, but may be readily recrystallised from chloroform or acetone.

Phenylguanidine picrate is obtained in the form of deep-yellow, slender, microscopic needles on adding picric acid to a solution of phenylguanidine. It melts partly at 208°, completely at 214°, is nearly insoluble in water, but dissolves readily in acetone.

The relative insolubility in water of the compounds described above, leads the author to suggest that picric acid may be employed with advantage as a reagent for the detection of guanidine and its derivatives. G. T. M.

Action of Nitric Acid on the Amidines. By A. P. N. Franchimont (*Rec. Trav. Chim.*, **10**, 231—235).—Guanidine nitrate dissolves in an excess of nitric acid with development of heat, but without the production of any gas. The product, recrystallised from boiling water, forms slender needles which decompose at 222°.

Nitroguanidine, suspended in absolute alcohol and subjected to the action of a current of dry ammonia, dissolves after some time. From the solution, by diluting with water and neutralising, a substance which appears to be nitroguanidine is re-obtained. After some time, the solution yields a well-crystallised residue which is soluble in water, but only slightly in alcohol. Nitroguanidine dissolves easily in aqueous ammonia; the solution gives off nitrogen monoxide at the ordinary temperature. The reaction may be written $C(NH_2)_2{:}N{\cdot}NO_2 + H_2O = CO(NH_2)_2 + NH_2{\cdot}NO_2$; the carbamide decomposes in presence of a base into ammonia and carbonic anhydride; the nitramine immediately forms water and nitrogen monoxide.

Attempts to prepare the sodium derivative of this, the simplest, nitramine by the action of sodium alkyl oxides on nitroguanidine failed. Propionamidine appears not to form a nitro-derivative even when evaporated with 10 times its weight of nitric acid. Its nitrate crystallises in colourless, deliquescent prisms melting at 132°. W. T.

Action of Sulphuric Acid on Methylethylacraldehyde. By E. Ludwig (*Ber.*, **25**, 1409—1410).—Methylethylacraldehyde is entirely resinified when suspended in water and treated with concentrated sulphuric acid. If, however, it is added to an ice-cold mixture of alcohol and sulphuric acid, only a small quantity of resin is formed, together with a *hexenylsulphuric acid* of the composition $CH_2Me{\cdot}CH_2{\cdot}CMe[CH(OSO_3H)_2]{\cdot}OSO_3H$. Methylethylacraldehyde (5 grams) is added drop by drop to an ice-cold mixture of alcohol (20 grams) and sulphuric acid (30 grams). The solution is separated from the resin, calcium carbonate added, and the mixture filtered. On concentrating the filtrate, the easily soluble *calcium* salt of the acid is obtained, and crystallises when placed in a vacuum over sulphuric acid. The *barium* salt, obtained by adding barium hydrate to the crude product, is very easily soluble, and is crystalline. When the acid is heated with potassium hydroxide at 100°, sulphuric acid is not eliminated. When distilled with potassium hydroxide, slight carbonisation takes place, an alcoholic liquid distils over, and potassium sulphate remains.

The author is engaged in the further investigation of these reactions. E. C. R.

Acetaldoxime. By A. P. N. Franchimont (*Rec. Trav. Chim.*, **10**, 236—237).—Acetaldoxime has been described by V. Meyer and by Petraczek (Abstr., 1883, 569) as a liquid boiling at 114—115°. The

author finds it to be a solid substance, distilling constantly at 114·5°, melting at 47°, and solidifying, even in a capillary tube, immediately on taking from the bath. It is an inodorous substance, crystallising in acicular crystals sometimes a decimetre in length. It dissolves easily in ether, chloroform, acetone, and benzene, less easily in petroleum ether and carbon bisulphide. There seems no reason to believe that this substance is an isomeride of the ordinary acetaldoxime. The author suggests that a trace of impurity prevents the crystallisation of the ordinary substance. (Compare Dunstan and Dymond, Trans., 1892, 470, and Proc., 1892, 135.) W. T.

Preparation of Symmetrical Dichloracetone. By A. Erlenbach (*Annalen*, **269**, 46—48).—In preparing symmetrical dichloracetone by the method described by Grimaux and Adam (*Bull. Soc. Chim.*, **36**, 19), the yield is increased from 15 to 57 per cent. of the oxidised dichlorohydrin by proceeding as follows:—Dichlorhydrin (100 grams) and very finely divided potassium dichromate (80 grams) are placed in a litre flask, and a mixture of concentrated sulphuric acid (120 grams) and water (150 grams) is added in small quantities at a time in the course of a day to the ice-cold solution, which is frequently and vigorously shaken; after keeping over night, the oil is extracted with ether, and the dichloracetone separated from unchanged dichlorhydrin with the aid of sodium hydrogen sulphite. F. S. K.

Diamidoacetone. By L. Rügheimer and E. Mischel (*Ber.*, **25**, 1562—1568).—Rügheimer (Abstr., 1889, 249 and 1210) has obtained diamidoacetone from several compounds, and has described the sulphate and the platinochloride. The base cannot be isolated, and its aqueous solutions decompose on remaining; the *hydrochloride* $CO(CH_2{\cdot}NH_2,HCl)_2 + 1\frac{1}{2}H_2O$, which forms lustrous crystals soon becoming dull, the *nitrate*, the picrate, and the aurochloride have all been obtained in the crystalline form.

Benzenyldiamidoacetone, $CO<\begin{matrix}CH_2{\cdot}NH\\CH_2-N\end{matrix}>CPh$, is produced when an aqueous solution of diamidoacetone sulphate is rendered slightly alkaline and benzoic chloride (1 mol.) gradually added with vigorous shaking; it crystallises from alcohol in colourless leaflets, and melts at 190—191°. It is a neutral compound, and reduces ammoniacal silver and Fehling's solutions. When suspended in absolute alcohol, and treated with hydrazine hydrate, the *compound* $N_2(C<\begin{matrix}CH_2{\cdot}NH\\CH_2-N\end{matrix}>CPh)_2 + 2H_2O$ is obtained; the phenylhydrazone,

$$N_2HPh{:}C<\begin{matrix}CH_2{\cdot}NH\\CH-N\end{matrix}>CPh,$$

crystallises from alcohol in needles which are sensitive towards light and heat, and melt at 173—175°. *Phenylethenyldiamidoacetone*, $CO<\begin{matrix}CH_2{\cdot}NH\\CH_2-N\end{matrix}>C{\cdot}CH_2Ph$, prepared from diamidoacetone sulphate and phenylacetic chloride, forms colourless, lustrous leaflets, and melts at 189·5—190·5°, being fairly soluble in hot water, but insoluble in ether;

it reduces ammoniacal silver solution on heating, and Fehling's solution at the ordinary temperature.

When a concentrated solution of diamidoacetone sulphate (1 mol.) is mixed with potassium carbimide (2 mols.) crystals separate, but redissolve after a time, and at the end of some days an amorphous compound separates which is insoluble in alcohol, but readily soluble in water, melts at about 224°, and is perhaps the *biuret*,

$$CO<^{CH_2\cdot NH\cdot CO}_{CH_2\cdot NH\cdot CO}>NH.$$

Ethyl chlorocarbonate reacts with diamidoacetone forming a white crystalline compound, probably $CO<^{CH_2\cdot NH}_{CH_2\cdot NH}>CO$. A. R. L.

Cuprammonium Acetobromide. By P. W. Richards (*Ber.*, **25**, 1492).—*Cuprammonium acetobromide*, $CuBr,Ac,2NH_3$, is prepared by mixing together cupric bromide (5 grams), alcohol (10 c.c.), and saturated alcoholic ammonia (10 c.c.); the precipitate which forms is immediately dissolved in a mixture of acetic acid (16 c.c.) and alcohol (70 c.c.); on allowing the solution to evaporate spontaneously in the air, or on cooling it to −5°, lustrous, prismatic crystals separate which probably belong to the monosymmetric system; the compound is almost insoluble in alcohol, but decomposes in presence of water. J. B. T.

Ethyl Acetoacetate. By P. C. Freer (*J. pr. Chem.* [2], **45**, 414—416).—Brühl (this vol., p. 583) admits that the behaviour of ethyl acetoacetate with phenylhydrazine (Nef, this vol., p. 142) is one of the instances in which this ethyl salt behaves as a hydroxycrotonic derivative. Inasmuch as phenylhydrazine is a base, its behaviour to ethyl acetoacetate should resemble that of sodium; the author has experimented with phenylhydrazine hydrochloride, expecting to obtain some different result.

Phenylhydrazine hydrochloride was added to a solution of ethyl acetoacetate in absolute alcohol, together with some chalk to keep the liquid neutral; carbonic anhydride was evolved, and the reaction was over in the course of 6—8 hours. When the product was poured into water, a yellow oil separated; this was dissolved in ether, the ethereal solution was washed successively with sodium hydroxide, dilute hydrochloric acid, and water, dried, and distilled. The residual yellow oil, $C_{10}H_{10}N_2O$, boiled at 220° (30 mm.), and became brown in air; its empirical formula is identical with that of 1-phenyl-3-methyl-5-pyrazolone; the hydrochloride, $C_{10}H_{11}N_2OCl$, was prepared.

By acidifying the alkaline washings of the above ether extract with hydrochloric acid, a difficultly crystallisable acid was isolated, but not further investigated; when this was filtered off, and sodium carbonate added to the filtrate, 1-phenyl-3-methyl-5-pyrazolone (m. p. 127°) was precipitated. A. G. B.

Action of Sodium on Ethyl Chloracetate. By A. Erlenbach (*Annalen*, **269**, 14—48).—*Ethyl ethoxychloracetoacetate*,

$$OEt\cdot CH_2\cdot CO\cdot CHCl\cdot COOEt,$$

or $CH_2Cl{\cdot}CO{\cdot}CH(OEt){\cdot}COOEt$, is formed, together with at least two other compounds, when ethyl chloracetate (100 grams) is added in the course of $1\frac{1}{2}$ days to ice-cold ether (200 grams) containing shavings of sodium (27 grams) in suspension; two days after the commencement of the experiment, the greater part of the sodium has disappeared, the evolution of hydrogen is almost at an end, and from the dark red ethereal solution a light yellow powder has been deposited. The unchanged sodium is then separated by filtration through a coarse metallic sieve, the solution containing the solid in suspension is mixed with water and dilute hydrochloric acid, the ethereal layer separated, dried, evaporated, and the ethyl ethoxychloracetoacetate isolated from the oily mixture by fractional distillation, under a pressure of 40—60 mm., during which process hydrogen chloride is evolved; the weight of the pure compound is, on the average, half that of the ethyl chloracetate employed. It is a yellowish liquid, and boils at 157° under a pressure of 45 mm., and at 162° under a pressure of 55 mm., but it cannot be distilled under the ordinary atmospheric pressure; it is only sparingly soluble in water, but it dissolves in dilute soda, and in sodium carbonate, with partial decomposition, yielding a dark brown solution. When boiled with dilute hydrochloric acid, it is decomposed into alcohol, carbonic anhydride, and symmetrical dichloracetone. The *sodium* derivative, $C_8H_{12}ClO_4Na$, is a colourless powder, and is decomposed by water. The *copper* derivative is a green, crystalline compound.

Ethyl ethoxyacetoacetate, $C_8H_{14}O_4$, can be obtained by treating the chloro-derivative just described with zinc dust and acetic acid in the cold; the product is purified by means of its copper derivative. It is a colourless liquid, boils at 105° under a pressure of 14 mm. with very slight decomposition, and just above 200° under the ordinary atmospheric pressure with considerable decomposition; it is moderately easily soluble in water, more readily in dilute hydrochloric acid. The *sodium* derivative is a colourless, gum-like substance. The *copper* derivative $(C_8H_{13}O_4)_2Cu$, prepared by shaking the ethereal salt with a concentrated solution of copper acetate, crystallises from alcohol in long, green needles, melts at 143°, and is insoluble in water, but readily soluble in ether, benzene, chloroform, and carbon bisulphide; when an alcoholic solution of a mixture of the copper derivatives of ethyl ethoxyacetoacetate and ethyl ethoxychloracetoacetate is heated for some time at 80°, a yellow basic substance, consisting principally of the decomposition products of the copper derivative of the chloro-compound, is deposited. The *aluminium* derivative crystallises from cold dilute alcohol in small, colourless needles, and dissolves freely in ether, benzene, chloroform, and light petroleum. When ethyl ethoxyacetoacetate is warmed for a short time with dilute hydrochloric acid, it is decomposed into carbonic anhydride, alcohol, and acetol ethyl ether, $COMe{\cdot}CH_2{\cdot}OEt$, identical with the compound described by Henry (*Compt. rend.*, **93**, 422).

Acetol ethyl ether is a colourless, mobile oil of sp. gr. 0·9204 at 21·7°, boils at 128°, and is miscible with alcohol, ether, and water in all proportions; it reduces solutions of copper acetate and ammoniacal solutions of silver, and when treated with potassium dichromate and

dilute sulphuric acid it is oxidised to acetic acid, carbonic acid and formic acid being also produced in small quantities. It combines very readily with sodium hydrogen sulphite, forming a very readily soluble crystalline compound, and on reduction with sodium amalgam in acid solution, it yields approximately equal quantities of acetone and ethyl alcohol, together with traces of isopropyl alcohol. The *hydrazone*, $N_2HPh{:}CMe{\cdot}CH_2{\cdot}OEt$, is a yellowish oil, boils at 165° under a pressure of 16 mm., and at 267° with decomposition under the ordinary atmospheric pressure; it turns brown on exposure to the air, and dissolves freely in ether and alcohol, but is insoluble in water.

Ethoxymethylindole, $C_{11}H_{13}NO$, is formed when the hydrazone just described is heated with sodium acetate, a little sodium chloride, and a few drops of acetic acid in dilute alcoholic solution; it separates from alcohol in large, colourless, rhombic crystals, $a : b : c = 0{\cdot}5635 : 1 : 0{\cdot}7445$, melts at 143·5°, and is readily soluble in ether, alcohol, benzene, and chloroform, but more sparingly in light petroleum and cold water; it is not acted on by dilute soda, and is only very slowly decomposed by dilute hydrochloric acid.

Ethyl diethoxyacetoacetate, $OEt{\cdot}CH_2{\cdot}CO{\cdot}CH(OEt){\cdot}COOEt$, can be obtained by gradually adding ethyl ethoxychloracetoacetate to a cold alcoholic solution of sodium ethoxide, and then boiling the mixture for three hours. It boils at 131—132° under a pressure of 11 mm., and is identical with the compound prepared by Conrad from ethyl ethylglycollate (*Ber.*, **11**, 58); when boiled with dilute potash, it is converted into diethoxyacetone (compare Grimaux and Lefèvre, Abstr., 1889, 235), the *sodium* derivative of which is a yellow, hygroscopic substance of the composition $C_7H_{13}O_3Na$.

A compound of the composition $C_{12}H_{14}O_7$, which the author names *ethyl ketacetate*, is deposited in yellow needles when ethyl ethoxychloracetoacetate is mixed with a solution of sodium acetate, and the mixture kept at the ordinary temperature for many days, with frequent shaking. It melts at 140·5°, and is readily soluble in warm alcohol, benzene, chloroform, and carbon bisulphide, but only sparingly in ether, very sparingly in light petroleum, and insoluble in cold water; when a trace of the substance is warmed with water, the latter is coloured an intense bluish-violet, the colour changing to yellow on prolonged boiling. It dissolves freely in ammonia and in soda, and is reprecipitated unchanged on immediately adding dilute hydrochloric acid; the soda solution quickly turns reddish-brown, and after keeping for some time, only a small quantity of a resinous substance is precipitated on the addition of dilute hydrochloric acid; it reduces ammonical silver solutions in the cold. The molecular weight of the compound was determined in glacial acetic acid solution with results which agreed well with those required by a compound of the molecular formula given above. The *sodium* derivative, $C_{12}H_{12}O_7Na_2$, is an almost colourless powder, stable in the air, and soluble in alcohol, yielding a dark green solution. The *barium* derivative, $C_{12}H_{12}O_7Ba + H_2O$, and the *calcium* derivative $C_{12}H_{12}O_7Ca$, are amorphous. The *cuprous* derivative, $C_{12}H_{12}O_7Cu_2$, crystallises in slender, yellow needles. The instability of these metallic derivatives, and the fact that they are decomposed by carbonic anhydride with

regeneration of ethyl ketacetate, renders it highly improbable that the last-named compound is a true carboxylic acid; a number of experiments were made with the object of determining the constitution of the compound, but without success; the most important results bearing on this question are the following:—When ethyl ketacetate is boiled with concentrated hydriodic acid, the quantity of ethyl iodide liberated, determined by Zeisel's method, corresponds with the theoretical quantity for two ethoxy-groups; when treated with soda at the ordinary temperature, it yields an amorphous compound, which seems to have the composition $C_{10}H_{10}O_7$. The *diacetyl* derivative, $C_{12}H_{12}O_7Ac_2$, is formed when ethyl ketacetate is heated with excess of acetic anhydride for 10 hours at 120°, or, better, warmed with acetic chloride at 70—80° for two hours; it crystallises from moderately dilute alcohol in yellow prisms and in colourless needles, melts at 106—107°, and is readily soluble in warm ether, benzene, alcohol, carbon bisulphide, and acetic acid, but insoluble in cold water; it dissolves freely in dilute soda, yielding a yellow solution, from which ethyl ketacetate is precipitated on adding dilute hydrochloric acid. The *dihydrazone*, $C_{24}H_{26}N_4O_5$, prepared by heating ethyl ketacetate with phenylhydrazine, is a red, amorphous compound, readily soluble in ether, benzene, alcohol, and chloroform, but insoluble in light petroleum and water. The *anilide*, $C_{18}H_{19}NO_6$, crystallises from alcohol in golden needles, melts at 137—138°, and dissolves freely in ether and alcohol, but is insoluble in water. The *bromo*-derivative, $C_{12}H_{13}BrO_7$, is formed when ethyl ketacetate is suspended in carbon bisulphide and treated with one molecular proportion of bromine; it separates from a mixture of chloroform and light petroleum in transparent, well-defined, prismatic, colourless or rose-red crystals, melts at 125—130°, and is readily soluble in chloroform and ether, but only sparingly in cold carbon bisulphide and light petroleum; it is decomposed by alcohol, and it becomes sticky on exposure to the air. When ethyl ketacetate is dissolved in ice-cold concentrated nitric acid, and the solution poured into water, a colourless, crystalline compound is deposited after a short time. This product separates from a mixture of ether and light petroleum in large, colourless, well-defined crystals, which melt at 80—95°, decompose at 102°, and have the composition $C_{12}H_{13}NO_{10} + 2H_2O$; when the crystals are kept over sulphuric acid under reduced pressure, they lose water and then melt at 40—45°; the anhydrous substance is very hygroscopic and crystallises from a mixture of ether and light petroleum in radially-grouped needles. F. S. K.

Lactonic Acids, Lactones, and Unsaturated Acids. By R. Fittig (*Annalen*, **268**, 1—7; compare this vol., p. 812).—The further investigation of the oxidation products of unsaturated acids (compare Fittig and Buri, *Annalen*, **216**, 171, **227**, 31, and Regel, Abstr., 1887, 488) has shown that $\alpha\beta$-unsaturated acids are oxidised to stable dihydroxy-acids, whereas the $\beta\gamma$-acids give unstable dihydroxy-acids, which, on liberation from their salts, are converted into neutral hydroxylactones. These lactones, just like the simple lactones, are either unacted on, or only very slowly decomposed by

water, but are readily converted into salts of the corresponding acids on boiling with strong bases; they are more readily soluble in water than the simple lactones, but separate from moderately concentrated solutions on the addition of potassium carbonate.

$\beta\gamma$- and $\gamma\delta$-unsaturated acids show no difference in behaviour on oxidation; allylacetic acid, $CH_2{:}CH{\cdot}CH_2{\cdot}CH_2{\cdot}COOH$, for example, resembles ethylidenepropionic acid, $CHMe{:}CH{\cdot}CH_2{\cdot}COOH$, not only in its behaviour on oxidation, but also in all other reactions, such as in its conversion into valerolactone and in the decomposition of its dibromide; if, therefore, allylacetic acid really is a $\gamma\delta$-unsaturated compound, it is impossible, at present, to distinguish such an acid from a $\beta\gamma$-compound by means of chemical reactions. Hydrosorbic acid gives, on oxidation, two isomeric hydroxylactones, of which one can be partially converted into the other by boiling its alkaline solution; whether this is due to the presence of two isomerides in the hydrosorbic acid, or whether the two lactones are geometrical isomerides, has yet to be determined.

Phenylisocrotonic acid, which is doubtless a pure $\beta\gamma$-unsaturated compound, also gives two hydroxylactones, which resemble one another very closely in chemical behaviour.

The two crotonic acids give, on oxidation, two different dihydroxyacids, that obtained from isocrotonic acid being identical with Hanriot's dihydroxybutyric acid.

In all the experiments, which are more fully described in the following abstracts (pp. 958, 959, 960, 986), the oxidation was carried out as follows:—The unsaturated acid (5 grams) is placed in a flask together with 400—500 c.c. of water, the solution rendered strongly alkaline with sodium carbonate or soda, and then a 2 per cent. solution of potassium (or barium) permanganate gradually added to the ice-cold solution; as a rule, molecular proportions of the acid and of potassium permanganate were employed. As bye-products, oxalic acid, succinic acid, and aldehydes are sometimes obtained, and in the case of some of the aromatic compounds benzoic acid is formed. F. S. K.

Oxidation of Crotonic Acid and Isocrotonic Acid. By R. Fittig and E. Kochs (*Annalen*, **268**, 7—22).—*Dihydroxybutyric acid*, $C_4H_8O_4$, is formed, together with aldehyde, acetic acid, and oxalic acid, when solid crotonic acid is oxidised with potassium permanganate in the manner already described (compare preceding abstract); as the acid is isolated only with difficulty, it is better to use barium permanganate ($\frac{1}{2}$ mol.) in place of the potassium salt. It separates from water in long, transparent, prismatic crystals, containing 1 mol. H_2O, which lose their water over sulphuric acid, and then melt at 74—75°; the anhydrous substance deliquesces in moist air. It is very readily soluble in water, alcohol, and acetone, but almost insoluble in hot ether, light petroleum, and chloroform; it is not volatile with steam, and is not changed by boiling, dilute hydrochloric acid. The *calcium* salt, $(C_4H_7O_4)_2Ca$, is a colourless, vitreous compound, very readily soluble in water, but insoluble in alcohol. The *barium* salt, with 2 mols. H_2O, separates from cold water in microscopic, prismatic crystals. The *silver* salt, $C_4H_7O_4Ag$, forms

microscopic, lance-shaped needles, and large, lustrous plates, and is only sparingly soluble in cold, but more readily in hot water, by which it is partially decomposed. This dihydroxybutyric acid is possibly identical with the compound obtained by Kolbe (*J. pr. Chem.*, **25**, 391) from $\alpha\beta$-dibromobutyric acid, and also with that prepared by Melikoff (Abstr., 1886, 1008) from β-methylglycidic acid.

Isodihydroxybutyric acid, $C_4H_8O_4$, obtained by the oxidation of pure isocrotonic acid, is a syrup, readily soluble in acetone, but insoluble in ether. The calcium salt, $(C_4H_7O_4)_2Ca$, and the barium salt, are brittle, vitreous compounds, readily soluble in water. The silver salt, $C_4H_7O_4Ag$, crystallises from pure hot water in small needles, quickly turns yellow on exposure to light, and is partially decomposed by boiling water; it is $3\frac{1}{2}$ times as readily soluble in water at 12—13·5° as the silver salt of the isomeric dihydroxybutyric acid described above. Isodihydroxybutyric acid is, in all probability, identical with the compound described by Hanriot (*Ann. Chim. Phys.* [5], **17**, 104) and by Melikoff (*Ber.*, **15**, 2587).

When either of the dihydroxybutyric acids is heated at 100° for eight days, an amorphous substance of the composition $C_8H_{10}O_5$ is formed, probably an anhydride of complex constitution.

F. S. K.

Oxidation of Ethylcrotonic Acid. By R. Fittig and R. Ruer (*Annalen*, **268**, 22—27).—*Isohexeric acid*, $C_6H_{12}O_4$, isomeric with the hexeric acid described by Fittig and Howe (*Annalen*, **200**, 38), is produced, together with a small quantity of oxalic acid, when ethylcrotonic acid is oxidised with potassium permanganate. It crystallises from a mixture of benzene and light petroleum in small plates, melts at 95—96°, and is readily soluble in water, but more sparingly in ether, chloroform, and benzene, and almost insoluble in light petroleum; it is not changed by boiling dilute hydrochloric acid, and it is not converted into an isomeride by boiling barium hydroxide. The *calcium* salt, $(C_6H_{11}O_4)_2Ca + 3H_2O$, forms small, nodular crystals, loses 2 mols. H_2O at 100°, and a third between 100° and 125°; it is readily soluble in water. The *barium* salt, $(C_6H_{11}O_4)_2Ba$, is an amorphous compound, very readily soluble in water, but only very sparingly in alcohol. The *zinc* salt separates from water in crystals containing 1 mol. H_2O.

F. S. K.

Oxidation of Allylacetic Acid. By R. Fittig and K. Urban (*Annalen*, **268**, 32—38).—*Hydroxyvalerolactone*,

$$\begin{matrix} CO—O \\ | \\ CH_2\cdot CH_2 \end{matrix} > CH_2\cdot CH_2\cdot OH,$$

obtained together with succinic acid, by the oxidation of allylacetic acid with potassium permanganate, is a colourless, moderately mobile liquid, boils at 300—301° with only slight decomposition, and is very readily soluble in water, but only sparingly in ether; it is slowly decomposed by cold, more quickly by boiling water, and it separates from moderately concentrated aqueous solutions on the addition of solid potassium carbonate.

Salts of dihydroxyvaleric acid are formed when the preceding compound is boiled with bases, but the acid cannot be isolated. The *barium* salt, $(C_5H_9O_4)_2Ba$, is a brittle, amorphous compound, but the *calcium* salt, $(C_5H_9O_4)_2Ca$, separates from concentrated aqueous solutions in crystalline crusts, and is very readily soluble in water, but insoluble in alcohol. The *silver* salt, $C_5H_9O_4Ag$, crystallises in colourless, lustrous plates or needles, and is decomposed by hot water. F. S. K.

Oxidation of Hydrosorbic Acid. By R. Fittig and J. Hillert (*Annalen*, **268**, 38—44).—When hydrosorbic acid is oxidised with potassium permanganate, a small quantity of succinic acid is formed, but the principal product is a neutral liquid which, when boiled with barium hydroxide, gives two barium salts, one of which is crystalline and insoluble in alcohol, the other amorphous and readily soluble in alcohol.

Hydroxycaprolactone, $C_6H_{10}O_3$, is obtained when the crystalline barium salt is decomposed with hydrochloric acid, and the solution immediately extracted with ether; on evaporating the ethereal solution at the ordinary temperature, a crystalline compound—doubtless dihydroxycaproic acid—is deposited, but the crystals quickly change into the liquid lactone. This compound dissolves in water in all proportions, yielding a neutral solution, from which it separates again as an oil on saturating with potassium carbonate; it distils under the ordinary atmospheric pressure, with partial decomposition. When boiled with water, it is only partially converted into dihydroxycaproic acid. *Barium dihydroxycaproate*, $(C_6H_{11}O_4)_2Ba$, prepared as already described, separates from hot water, in which it is very readily soluble, in colourless crystals. The *calcium* salt, $(C_6H_{11}O_4)_2Ca$, is much more readily soluble than the barium salt, and forms small, nodular crystals. The *silver* salt, $C_6H_{11}O_4Ag$, crystallises from warm water in lustrous, colourless needles.

Isohydroxycaprolactone, $C_6H_{10}O_3$, prepared from the amorphous barium salt referred to above, is a thick, colourless liquid, miscible with ether, and resembles the isomeride in its other properties. *Barium isodihydroxycaproate* and the corresponding *calcium* salt are amorphous, anhydrous compounds. The *silver* salt is very unstable.

When a solution of dihydroxycaproic acid is boiled with excess of soda for three hours, about one quarter of the acid is converted into the isomeric iso-compound. F. S. K.

Decomposition of Dibromides of Unsaturated Acids by Warm Water and Dilute Alkalis. By R. Fittig (*Annalen*, **268**, 55—60).—The study of the decomposition of a number of dibrom-additive products of $\beta\gamma$- and $\gamma\delta$-unsaturated acids by boiling water, or by cold dilute alkalis, has shown that they all behave in a similar manner, inasmuch as the first decomposition product is invariably a bromolactone of the constitution $CH_2<\begin{matrix}CO\cdot O\\CHBr\end{matrix}>CH\cdot CH_2X$ or $CH_2<\begin{matrix}CO\cdot O\\CH_2\end{matrix}>CH\cdot CHBrX$; if the treatment with boiling water, or

with dilute alkali, is prolonged, the bromolactone is decomposed into a hydroxylactone and an $\alpha\gamma$-ketonic acid, which are not convertible one into the other. Since the dibromide of allylacetic acid behaves just like the other dibromides, it follows that, assuming that this acid really is a $\gamma\delta$-dibromo-derivative, the position of the bromine atom in the bromolactone has no influence whatever on the manner in which the last-named compound undergoes decomposition. Although all the dibromo-acids behave in the manner just stated, there are certain respects in which they differ; in the case of the fatty compounds, the hydroxylactone is invariably the principal product, the ketonic acid being produced in comparatively small quantities; in the case of the aromatic acids, on the other hand, the ketonic acid is the principal product, and a hydroxylactone is not formed at all, when the decomposition is effected with boiling water, and only in one instance, namely, in the case of isocrotonic acid, when dilute alkali is employed.

The hydroxylactones produced in the manner described above are, as a rule, identical with the compounds obtained directly by the oxidation of the unsaturated acids (compare preceding abstracts) Although hydrosorbic acid yields two isomeric compounds on oxidation, only one hydroxylactone is obtained from its dibromide. The dibromide of phenylisocrotonic acid (phenyldibromobutyric acid) yields two bromolactones under certain conditions; the hydroxylactone obtained from the dibromide is, moreover, quite different from that produced by the oxidation of phenylisocrotonic acid. The author prefers not to attempt any explanation of these cases of isomerism.

The formation of the γ-ketonic acids from the bromolactones is easily explained by assuming that unsaturated lactones are first produced by the elimination of hydrogen bromide; these compounds are rather unstable, as has been shown by Wolff (*Annalen*, **229**, 249), and, by the addition of 1 mol. H_2O, they would be converted into γ-ketonic acids. This view was proved to be correct in the case of phenyldibromovaleric acid, since an intermediate product of this nature (phenylangelicalactone) was actually isolated.

The experimental part of this work is described in the following abstracts, and on p. 987. F. S. K.

Decomposition of Dibromovaleric Acid. By R. Fittig and K. Urban (*Annalen*, **268**, 60—67).—*Bromovalerolactone*, $C_5H_7BrO_2$, is easily obtained by dissolving dibromovaleric acid (m. p. 58°) in a slight excess of sodium carbonate, and, after a short time, extracting the precipitated oil with ether. It is a colourless, mobile liquid, and is only sparingly soluble in water; when boiled with water for several days, it yields hydroxyvalerolactone (compare Fittig and Urban, this vol., p. 958) and a small quantity of levulinic acid.

F. S. K.

Decomposition of Dibromocaproic Acid. By R. Fittig and J. Hillert (*Annalen*, **268**, 67—71).—Dibromocaproic acid (hydrosorbic acid dibromide) is readily decomposed by sodium carbonate, yielding an oily bromolactone; when boiled with water for a long

time, it is converted into hydroxycaprolactone (compare Fittig and Hillert, this vol., p. 959), and *homolevulinic acid*,

$$CH_2Me{\cdot}CO{\cdot}CH_2{\cdot}CH_2{\cdot}COOH.$$

This acid melts at 32—33°, or possibly at a higher temperature, and is very readily soluble in water, alcohol, and ether. The *calcium* salt, $(C_6H_9O_3)_2Ca + 1\frac{1}{2}H_2O$, crystallises in colourless plates, and has been previously erroneously described as the calcium salt of hydroxyhydrosorbic acid (*Annalen*, **200**, 57). The *silver* salt, $C_6H_9O_3Ag$, separates from boiling water in crystals, and is only sparingly soluble.

F. S. K.

Tetrolic Acid. By R. Fittig and M. C. Clutterbuck (*Annalen*, **268**, 96—110).—The authors find that, contrary to the statement of Aronstein and Hollemann (Abstr., 1889, 878), an aqueous solution of tetrolic acid is not reduced by sodium amalgam in acid solution, either at the ordinary temperature or at 100°; tetrolic acid is slightly volatile with steam.

In examining the behaviour of tetrolic acid with bromine, the authors have arrived at results quite different from those of Lagermark (*Ber.*, **12**, 854), Pinner (*Ber.*, **14**, 1081), and Michael and Pendleton (Abstr., 1888, 1176). When a carbon bisulphide solution of tetrolic acid is treated with the molecular quantity of bromine, under the conditions described by Fittig in the case of angelic acid (Abstr., 1891, 39), hydrogen bromide is evolved in large quantities, and a comparatively small quantity of a yellowish-brown, semi-solid substance is produced, but no well-defined compound can be isolated. In chloroform solution, however, other conditions remaining the same, the tetrolic acid is converted almost quantitatively into dibromocrotonic acid, only traces of hydrogen bromide are evolved, and the sole bye-product is a very small quantity of an oil having a very irritating odour.

Dibromocrotonic acid, $C_4H_4Br_2O_2$, separates from chloroform in transparent, monosymmetric crystals, $a : b : c = 1{\cdot}1907 : 1 : 1{\cdot}6692$, $\beta = 80° 55\frac{1}{2}'$, melts at 119·8—120·4°, and slowly volatilises at 100°; it is readily soluble in alcohol, ether, and warm chloroform, but more sparingly in light petroleum and hot water; it separates unchanged from boiling water in colourless needles. The *silver* salt, $C_4H_3Br_2O_2Ag$, crystallises from boiling water in transparent plates, and is very stable in the light. The *barium* salt, $(C_4H_3Br_2O_2)_2Ba + 3H_2O$, is readily soluble in boiling water, from which it crystallises in small prisms. When dibromocrotonic acid is treated with sodium amalgam in cold dilute sulphuric acid solution, it is converted into tetrolic acid, no crotonic acid being formed. It is only very slowly acted on by bromine at 100°, in chloroform solution, yielding hydrogen bromide, and a small quantity of *tribromocrotonic acid*, $C_4H_3Br_3O_2$; the last-named compound separates from chloroform in colourless, feathery crystals, and melts at 131·5—132°.

Tetrolic acid combines with concentrated hydrobromic acid at the ordinary temperature, yielding a monobromocrotonic acid, $C_4H_5BrO_2$, which crystallises from light petroleum in feathery plates, melts at 93·5°, and differs in appearance and in other physical properties from

the bromocrotonic acid (m. p. 91°) prepared by Kolbe from $\alpha\beta$-dibromobutyric acid (compare Michael and Brown, *Amer. Chem. J.*, **9**, 277). The barium salt of the acid (m. p. 93·5°) crystallises in plates containing 2 mols. H_2O, whereas that of the isomeride (m. p. 91°) forms prismatic needles containing $3\frac{1}{2}$ mols. H_2O. F. S. K.

Some New δ-Lactones. By R. Fittig and C. Christ (*Annalen*, **268**, 110—129).—*Ethyl α-ethylacetoglutarate*,

$$COOEt\cdot CEtAc\cdot CH_2\cdot CH_2\cdot COOEt,$$

can be obtained by treating ethyl sodethylacetoacetate with ethyl β-iodopropionate in alcoholic solution; it is a yellow liquid, and cannot be distilled even under reduced pressure.

γ-Ethyl-γ-acetobutyric acid, $CHEtAc\cdot CH_2\cdot CH_2\cdot COOH$, prepared by hydrolysing the preceding compound with dilute hydrochloric acid, is a thick, very hygroscopic oil, boiling at 173—174° under a pressure of 10 mm., and at 279—281° with slight decomposition under the ordinary atmospheric pressure; it is soluble in about 18 times its volume of water at the ordinary temperature, and is miscible with alcohol and ether in all proportions. The *barium* salt, $(C_8H_{13}O_3)_2Ba$, crystallises from hot alcohol in slender, lustrous needles, is very hygroscopic, and dissolves freely in water. The *calcium* salt, $(C_8H_{13}O_3)_2Ca$, separates from alcohol in small, colourless, nodular crystals, and is very readily soluble in water. The *silver* salt, $C_8H_{13}O_3Ag$, is a colourless compound, moderately easily soluble in cold water; it turns reddish on exposure to light.

γ-Ethyl-δ-caprolactone, $\begin{matrix} CHMe\cdot CHEt \\ | \\ O-CO-CH_2 \end{matrix}\!\!>\!CH_2$, is formed when ethylacetobutyric acid is reduced with sodium amalgam, and the product boiled with dilute hydrochloric acid for a short time. It is a colourless, transparent, mobile liquid, boils at 254—255°, and has a sp. gr. of 1·0804, 20°/4°; it is miscible with alcohol and ether in all proportions, and is soluble in 28 times its volume of water at the ordinary temperature, separating again from the solution on the addition of sodium carbonate. It is volatile with steam, and in its behaviour with boiling water it resembles Wolff's δ-caprolactone (*Annalen*, **216**, 127), equilibrium being established when the solution contains about 33 parts of lactone to 67 parts of acid.

Barium ethyl-δ-hydroxycaproate, $(C_8H_{15}O_3)_2Ba$, prepared by boiling the lactone with barium hydroxide, separates from cold water in colourless crusts, and is only sparingly soluble in cold water, and almost, or quite, insoluble in alcohol. The *calcium* salt, $(C_8H_{15}O_3)_2Ca$, forms colourless, nodular crystals, and is only sparingly soluble in cold water, and almost insoluble in alcohol. The *silver* salt, $C_8H_{15}O_3Ag$, forms moss-like crystals, and dissolves freely in hot water.

Ethyl α-benzylacetoglutarate,

$$COOEt\cdot CAc(CH_2Ph)\cdot CH_2\cdot CH_2\cdot COOEt,$$

was prepared by treating ethyl sodiobenzylacetoacetate with ethyl β-iodopropionate in alcoholic solution, but it was not obtained in a state of purity; on boiling the crude product with dilute hydrochloric

acid, *benzylacetoglutaric* acid is obtained as a thick, yellow oil, boiling at 254—256° under a pressure of 20 mm.

γ-Benzyl-δ-caprolactone, $C_{13}H_{16}O_2$, is formed in very small quantities when benzylacetoglutaric acid is reduced with sodium amalgam; it crystallises in small needles, melts at 54—56° (probably at a higher temperature), boils at 216—218° under a pressure of 15 mm., and is very readily soluble in alcohol and ether, but more sparingly in light petroleum, and only very sparingly in cold water, the aqueous solution remaining neutral, even after having been warmed. *Barium benzylhydroxycaproate*, $(C_{13}H_{17}O_3)_2Ba$, prepared by boiling the lactone with barium hydroxide, separates from alcohol in colourless, ill-defined crystals.

Ethyl dibenzylacetoacetate has been described by Ehrlich (*Annalen*, **187**, 24) as a yellow oil; it separates from light petroleum in well-defined, transparent crystals, melts at 57°, boils at 230—234° under a pressure of 12 mm., and is very readi y soluble in alcohol and ether, but more sparingly in light petroleum. The corresponding acid, $C_{16}H_{16}O_2$, separates from light petroleum in crystals, and melts at 89°, not at 85°, as stated by Sesemann (*Ber.*, **6**, 1085; and **10**, 785).

F. S. K.

Ethyl Chlorocarbonate. By B. Pawlewski (*Ber.*, **25**, 1449—1451).—Pure ethyl chlorocarbonate boils at 93·1° under 760 mm. pressure. Its sp. gr. is 1·14396 at 15°, and was determined in a dilatometer of special form; the number obtained by Dumas for this constant is 1·133. The author gives a table showing the specific gravity and coefficients of expansion at temperatures between 0° and 90°. The curve showing the rate of change of the coefficient of expansion shows points of inflexion at 40° and 80°. The observed molecular refraction $R_M = 37·98$, whilst the calculated value is 37·66. The vapour density was determined in a V. Meyer apparatus between 100° and 277°. The vapour density of the substance is normal at temperatures below 250°; above that temperature, decomposition into ethyl chloride and carbonic anhydride occurs gradually, not suddenly, as generally stated.

W. J. P.

Preparation of Maleïc Anhydride. By J. Volhard (*Annalen*, **268**, 255—256).—Maleïc anhydride can be conveniently prepared by gently heating an intimate mixture of fumaric acid (2 mols.) and phosphorus oxychloride (1 mol.) until the evolution of hydrogen chloride ceases, and then distilling the anhydride; the yield is about 84 per cent. of the theoretical, and any phosphorus oxychloride in the product can be easily got rid of by redistilling. Phosphoric anhydride may be employed in the place of phosphorus oxychloride; the yield is very good in this case also.

F. S. K.

β-Methylmalic Acid. By W. Wislicenus (*Ber.*, **25**, 1484—1488; compare this vol., p. 589).—Specimens of β-methylmalic acid, prepared from the pure sodium salt (see below), may be obtained in crystals which melt at 119—120°. The *sodium salt*, $C_5H_6O_5Na_2 + 1\frac{1}{2}H_2O$, is formed by neutralising the acid with soda, or by the action of sodium ethoxide on the ethyl sodium salt; on adding boiling

alcohol to its aqueous solution, it is deposited in colourless crystals. The *silver*, *lead*, and *mercurous salts* are amorphous, and insoluble in water. The *barium salt*, $C_5H_6O_5Ba + 2\frac{1}{2}H_2O$, crystallises from water in small, colourless, lustrous plates. The *zinc salt* crystallises from water with 6 mols. H_2O in lustrous prisms. β-Methylmalic acid yields mesaconic acid and citraconic acid when heated in a current of dry air at 170°.

A comparison of the properties of citromalic acid and α-methylmalic acid shows that these compounds are identical. J. B. T.

Aqueous Solutions of Tartaric and Racemic Acids. By L. Marchlewski (*Ber.*, **25**, 1556—1562).—Berthelot and Jungfleisch observed no thermic effect on mixing solutions of dextro- and lævo-tartaric acids, and Jahn subsequently confirmed this, employing 4 per cent. solutions. Ostwald found that solutions of tartaric and racemic acids have the same conductivity for all dilutions; assuming, therefore, that dextro- and lævo-tartaric acids have similar properties, racemic acid must in solution be dissociated into its components, at any rate in the concentrations investigated by Ostwald. Raoult examined the cryoscopic behaviour of solutions of tartaric and racemic acids, and concluded that in a solution containing 14·229 grams of racemic acid dissolved in 100 grams of water 1·037 grams of non-dissociated racemic acid existed, whilst in one containing 7·627 grams of racemic acid dissolved in 100 grams of water only 0·227 gram of the non-dissociated compound existed. The author has made a series of accurate determinations of the specific gravity of solutions of tartaric and racemic acids. He finds that the specific gravities of solutions of the two acids exhibit close agreement up to a concentration of 10 per cent. The following table illustrates his results above this concentration:—

Percentage of tartaric or racemic acid in solution.	Specific gravity of tartaric acid solution.	Specific gravity of racemic acid solution.	Specific volume of tartaric acid solution, d_1.	Specific volume of racemic acid solution, d_2.	$d_1 - d_2$.
10·666	1·04950	1·04969	0·95283	0·95266	0·00017
14·018	1·06600	1·06623	0·93809	0·93788	0·00021

Racemic acid solutions of a concentration 10—14 per cent. have therefore a smaller specific volume than those of tartaric acid of the same concentration, and it would appear that on mixing solutions of dextro- and lævo-tartaric acid of this concentration a contraction and thermic reaction occur. The specific gravities of 4 per cent. solutions of dextro- and lævo-tartaric acids were found to be 1·01770 and 1·01767 respectively, and therefore, within the limits of experimental error, identical. The solutions were then mixed, and gave in two determinations 1·01769 and 1·01766, showing that no alteration of volume had taken place. All the specific gravities were compared with water at 4° and reduced to a vacuum. A. R. L.

Tartrotartaric Acid. By M. E. Mulder (*Rec. Trav. Chim.*, **10**, 171—210).—By the action of ethyl chloride on ethyl disodium tartrate, two chief products are obtained, the one (*a*) soluble in alcohol, absolute ether, and ethyl chloride, the other (*b*) insoluble in these solvents. The soluble product is of a bright yellow colour, and has not been obtained in the pure state; the insoluble substance is an almost colourless solid. By the action of hydrogen chloride on these compounds dissolved or suspended in ethyl chloride, carbonic anhydride is eliminated, and thick liquid products are obtained apparently of the same composition. The aqueous solution of this product gives a cherry-red coloration with ferric chloride.

The aqueous solution of *a* does not give precipitates with aqueous solutions of copper sulphate, acetate, or chloride, with zinc sulphate or acetate, or with mercuric chloride or silver nitrate, but yields precipitates with calcium chloride and lead acetate. The same result is obtained with alcoholic solutions with the exceptions that lead acetate gives no precipitate and silver nitrate gives a reddish-brown coloration and afterwards a reddish-brown precipitate. With alcoholic solutions in presence of water, all these salts give precipitates.

An aqueous solution of *b* is not precipitated by cupric chloride; an alcoholic solution of cupric chloride gives an amorphous cupric compound with *b* insoluble in alcohol.

An alcoholic solution of the product *a* gives no precipitate with alcoholic cupric chloride, but, if the mixture is added to water, a substance is obtained which crystallises in prismatic needles of a bright green colour, soluble in alcohol or ether and almost insoluble in water. It gives a cherry-red coloration with ferric chloride, and a bluish-green solution with sodium hydroxide. Its formula is $C_{16}H_{24}CuO_{11}$; from its synthesis it must be ethyl ethylcoppertartrotartrate, $COOEt\cdot\dot{C}H-\dot{C}(COOEt)\cdot CO\cdot CH(OEt)\cdot\dot{C}H(OH)\cdot COOEt$.
$\quad\quad\quad

β-Methylamidocrotonanilide (Knorr and Taufkirch, this vol., p. 708) crystallises in colourless prisms, melts at 145°, and is very similar in solubility to β-amidocrotonanilide. A. G. B.

Derivatives of Thiocarbamide and Carbamide. By O. Probst (*J. pr. Chem.* [2], **45**, 416).—When phenylhydrazine acts on thiohydantoic acid, or, more simply, when an alcoholic solution of thiocarbamide, chloracetic acid, and phenylhydrazine is warmed, a *compound*, $C_9H_9N_3OS$, is formed; this crystallises in monoclinic prisms, and melts with decomposition at 175°.

Pinner's phenylurazole is easily formed by heating ethyl allophanate with phenylhydrazine. A. G. B.

Thiophenchlorophosphine and its Derivatives. By H. Sachs (*Ber.*, **25**, 1514—1518).—*Thiophenchlorophosphine*, $C_4SH_3{\cdot}PCl_2$, is obtained by passing the mixed vapours of thiophen and phosphorus chloride through a hard, glass tube packed with pieces of pumice and heated to a dull red heat. After continuing the treatment for eight days, 14 grams were obtained from 100 grams of thiophen, and 60 grams of thiophen were recovered. It boils at 218°, and is decomposed by water, yielding hydrochloric and thiophenphosphinous acids. It greatly resembles phosphenyl chloride, $C_6H_5{\cdot}PCl_2$. The PCl_2 group is probably in the 2-position.

Thiophentetrachlorophosphine, $C_4SH_3{\cdot}PCl_4$, is obtained by the addition of chlorine to the dichlorophosphine. It is a solid substance resembling phosphoric chloride, and is decomposed by water into the oxychloride and finally the phosphinic acid.

Thiophenoxychlorophosphine, $C_4SH_3{\cdot}POCl_2$, is best prepared by passing dry sulphurous anhydride over the tetrachloride, and distilling the resulting mixture of oxychlorophosphine and thionyl chloride. It boils at 258—260°.

Thiophenphosphinous acid, $C_4H_3S{\cdot}PO_2H_2$, is formed when the dichlorophosphine is decomposed with water. It forms needles melting at 70°, and is analogous in its properties and reactions to phenylphosphinous acid.

Thiophenphosphinic acid, $C_4SH_3{\cdot}PO(OH)_2$, is obtained by decomposing the tetrachlorophosphine with water. It crystallises from water in very small, short needles, melts at 159°, dissolves readily in water, alcohol, and ether, and is insoluble in water. It resembles phenylphosphinic acid. The *silver salt*, $C_4H_3S{\cdot}PO(OAg)_2$, forms a white precipitate which dissolves both in ammonia and in nitric acid.

Thiophendiethylphosphine, $C_4SH_3{\cdot}PEt_2$, is obtained by treating the dichlorophosphine with zinc ethyl in ethereal solution. It forms a colourless or light-yellow liquid boiling at 225° and having a phosphine-like odour. It unites with methyl iodide, best in ethereal solution, forming *thiophendiethylmethylphosphonium iodide*,

$$C_4SH_3{\cdot}PEt_2MeI,$$

as a white powder melting at 122°, and dissolving in alcohol and water, but not in ether. The chloride of the base forms a *platino-*

chloride, $(C_4SH_3{\cdot}PEt_2Me)_2PtCl_6$, a crystalline, yellow powder. Thiophentriethylammonium iodide can also be prepared, but not so easily as the diethylmethyl compound. C. F. B.

Action of Sulphuric Acid on Hydrocarbons with a Closed Chain. By MAQUENNE (*Compt. rend.*, **114**, 918—920).—Renard has stated that heptine, C_7H_{12}, is rapidly attacked by strong sulphuric acid with production of two isomerides $C_{14}H_{24}$, and a new hydride C_7H_{14}. The author has prepared pure heptine by the action of alcoholic potash on the nitrosochloride, $C_7H_{12}NOCl$. When agitated with its own volume of sulphuric acid of 66°, part dissolves with development of heat and evolution of sulphurous anhydride, whilst another part forms a layer of supernatant liquid which can be decanted off and distilled. The chief product is a hydrocarbon C_7H_{14}, which, after distillation over sodium, boils at 94—96°.

The unsaturated hydrocarbons derived from camphoric acid are attacked by strong sulphuric acid in much the same way as heptine. The hydrocarbon, C_8H_{14}, obtained by the destructive distillation of copper camphorate, is converted, under similar conditions, into xylene hexahydride, and this is true also of the hydrocarbon, C_8H_{14}, obtained by the destructive distillation of silver camphorate.

The hydration may be due to the sulphurous anhydride which is evolved as a product of the decomposition of part of the original hydrocarbon. C. H. B.

Halogen Derivatives of Methylbenzenes. By A. TÖHL (*Ber.*, **25**, 1521—1526).—*Iodomesitylene*, $C_6H_2Me_3I$ [$Me_3 : I = 1 : 3 : 5 : 6$], can be obtained from mesitylene and iodine in the presence of mercuric oxide, but is best prepared from mesidine by the diazo-reaction. It forms highly refracting crystals, melts at 30·5°, and boils at 248—250°.

Iododurene, C_6HMe_4I [$Me_4 : I = 1 : 2 : 4 : 5 : 6$], was obtained by adding durene and mercuric oxide to iodine in light petroleum allowing the mixture to remain for three weeks, and finally heating on the water-bath. It melts at 80°, boils at 285—290°, and dissolves readily in light petroleum, from which it crystallises in ill-defined prisms or in lustrous needles. It is better prepared by fusing together durene and iodine, and adding mercuric iodide until the iodine disappears.

When durene is dissolved in light petroleum, a little iodine added, and chlorine passed in, *dichlorodurene* separates out, and *monochlorodurene* remains dissolved. The latter melts at 48°, boils at 237—238° (uncorr.), and crystallises from alcohol in large, transparent tables. The former melts at 189—190°, boils at 275° (uncorr.), and dissolves in carbon bisulphide, chloroform, and carbon tetrachloride, sparingly in alcohol and light petroleum.

When prehnitene, $C_6H_2Me_4$ [$Me_4 = 1 : 2 : 3 : 4$], obtained from pentamethylbenzene and sulphuric acid, is chlorinated, it yields *monochloroprehnitene*, an oil boiling at 240° (uncorr.), and *dichloroprehnitene*, which melts at 195°, boils at 280°, and crystallises from chloroform in highly refracting prisms.

Chloropentamethylbenzene, C_6Me_5Cl, was prepared by chlorinating a solution of pentamethylbenzene in light petroleum. It melts at 155°, crystallises from light petroleum in ill-defined, apparently monoclinic prisms, from alcohol, in which it is but sparingly soluble, in plates, and is very slightly volatile with steam.

Several fluoromethylbenzenes were prepared by decomposing the corresponding diazopiperidides, themselves obtained from amido-derivatives, with strong hydrofluoric acid. Their melting points are but little higher than those of the hydrocarbons from which they are derived. *Fluorometaxylene*, $C_6H_3Me_2F$ [$Me_2 : F = 1 : 3 : 4$], boils at 143°, *fluoromesitylene* at 171—172°, while *fluoropseudocumene*, $C_6H_2Me_3F$ [$Me_3 : F = 1 : 2 : 4 : 5$], melts at 26°, and boils at 172°.

C. F. B.

Action of Sulphuric Acid on Monobromoprehnitene. By A. Töhl (*Ber.*, **25**, 1526—1527).—*Monobromoprehnitene* was prepared by adding an acetic acid solution of bromine to an acetic acid solution of prehnitene (prepared from pentamethylbenzene). It crystallises from light petroleum in large, transparent tables, melts at 30°, and boils at 265°. When allowed to remain with sulphuric acid in a warm place, it is completely decomposed in two days; solid dibromoprehnitene, melting at 210°, is formed, and the liquid contains prehnitenesulphonic acid. 2 mols. of monobromoprehnitene have thus, under the influence of sulphuric acid, yielded 1 mol. of prehnitene and 1 mol. of dibromoprehnitene.

C. F. B.

Action of Sulphuric Acid on Chlorodurene. By A. Töhl (*Ber.*, **25**, 1527—1530).—When monochlorodurene is heated for several hours at 60° with concentrated sulphuric acid, the mixture being frequently shaken, some solid chloropentamethylbenzene, melting at 155°, separates out, and in the solution is found the sulphonic acid of a chlorotrimethylbenzene, probably chloropseudocumene, $C_6H_2Me_3Cl$ [$Me_3 : Cl = 1 : 2 : 4 : 3$]. The *barium*, $(C_9H_{10}Cl{\cdot}SO_3)_2Ba + H_2O$, *sodium*, $C_9H_{10}Cl{\cdot}SO_3Na + \frac{1}{2}H_2O$, and *potassium*, $C_9H_{10}Cl{\cdot}SO_3K + H_2O$, *salts* of this acid were prepared. By the action of hydrochloric acid at 180° on this acid, a chlorotrimethylbenzene, melting at 213°, was obtained; this gave a dinitro-derivative which, on reduction, yielded an amido-derivative exhibiting the reactions of an orthodiamine. The chlorotrimethylbenzene was, therefore, probably the chloropseudocumene mentioned above. Sulphuric acid has thus converted 2 mols. of chlorodurene into 1 mol. of chloropentamethylbenzene and 1 mol. of chloropseudocumene, a "migration" of a methyl group having taken place, and not of the halogen atom, as is usually the case.

C. F. B.

Symmetrical and Unsymmetrical Ethylmetaxylene. By A. Töhl and A. Geyger (*Ber.*, **25**, 1533—1539).—When metaxylene is treated with ethyl bromide and aluminium chloride, both unsymmetrical and symmetrical ethylmetaxylene are formed, and are separated by means of their sulphonamides, which melt at 147—148° and 127—128° respectively. After these have been separated, there remains an uncrystallisable sulphonamide from which, by heating

with strong hydrochloric acid at 180°, a hydrocarbon can be obtained which boils at 183—185°, and is oxidised by nitric acid to paraxylylic acid [Me_2 : COOH = 1 : 2 : 4]; this acid, when distilled with lime, yields orthoxylene, so that the sulphonamide must have been derived from ethylorthoxylene, $C_6H_3Me_2Et$ [Me_2 : Et = 1 : 2 : 4], which had been formed from metaxylene and ethyl bromide, the aluminium chloride bringing about a molecular transformation. The symmetrical ethylmetaxylene was also prepared from symmetrical bromoxylene and ethyl bromide; it boils at 186°, and yields a dibromo-derivative melting at 216—217°, and a dinitro-derivative melting at 234—235°.

Unsymmetrical ethylmetaxylene, $C_6H_3Me_2Et$ [Me_2 : Et = 1 : 3 : 4], yields, with bromine, *monobromethylxylene*, $C_6H_2Me_2EtBr$ [Me_2 : Et : Br = 1 : 3 : 4 : 6]. This boils at 247—248°, and its constitution is proved by the fact that, when oxidised, it yields the bromoxylylic acid melting at 172—173°, which can be obtained by oxidising the solid bromopseudocumene. *Mononitroethylxylene*, obtained by dissolving the hydrocarbon in cold, strong nitric acid, boils at 270—272°, and when reduced with iron and acetic acid, yields *amidoethylxylene*, a colourless oil boiling at 144—145° under 20 mm. pressure, and turning brown in the air. The *sulphate* of this base, $(C_{10}H_{15}N)_2,H_2SO_4 + H_2O$, forms white plates, which turn red when exposed to light. The base is known to have the symmetrical constitution [Me_2 : Et : Br = 1 : 3 : 4 : 6], because, when the amido-group is displaced by bromine, and the resulting compound oxidised, bromoxylylic acid [Me_2 : COOH : Br = 1 : 3 : 4 : 6], melting at 172—173°, is formed. The *sulphonic acid* has the constitution [Me_2 : Et : SO_3H = 1 : 3 : 4 : 6], as the sulphonamide melting at 148°, when oxidised with alkaline permanganate, yields a sulphaminic acid [Me_2 : COOH : $SO_2{\cdot}NH_2$ = 1 : 3 : 4 : 6], identical with that obtained by oxidising pseudocumenesulphonamide.

Symmetrical ethylmetaxylene [Me_2 : Et = 1 : 3 : 5] was obtained from the sulphonamide melting at 128°. This has the constitution [Me_2 : Et : $SO_2{\cdot}NH_2$ = 1 : 3 : 5 : 2], since the sulphaminic acid obtained by oxidising it with permanganate yields mesitylenic acid when heated with hydrochloric acid, and is identical with the sulphaminemesitylenic acid [Me_2 : COOH : SO_2NH_2 = 1 : 3 : 5 : 2] melting at 276°. The hydrocarbon, when treated with bromine in the presence of iodine, yields monobromethylxylene [Me_2 : Et : Br = 1 : 3 : 5 : 2], which, when oxidised, yields the bromomesitylenic acid [Me_2 : COOH : Br = 1 : 3 : 5 : 2] melting at 214°. This monobromethylxylene, when heated with chlorosulphonic acid, yields the *sulphonic acid* [Me_2 : Et : Br : SO_3H = 1 : 3 : 5 : 2 : 6], whose *barium*, $(C_{10}H_{12}Br{\cdot}SO_3)_2Ba + 4H_2O$, and *cadmium* (with $3H_2O$) *salts* crystallise in plates, sparingly soluble in water. The sodium salt of this acid was treated with zinc-dust and ammonia to remove the bromine; the *barium salt*, $(C_{10}H_{13}{\cdot}SO_3)_2Ba + 6H_2O$, of the *ethylxylenesulphonic acid* [Me_2 : Et : SO_3H = 1 : 3 : 5 : 6] thus obtained crystallises in needles; the *sulphonamide* in white plates melting at 116—117°. The second *bromethylxylenesulphonic acid* [Me_2 : Et : Br : SO_3H = 1 : 3 : 5 : 6 : 2] was obtained by treating the sodium salt of the above-mentioned ethylxylenesulphonic acid [Me_2 : Et : SO_3H =

1 : 3 : 5 : 2] with bromine; the *calcium salt*, $(C_{10}H_{12}Br\cdot SO_3)_2Ca + 6H_2O$, crystallises in lustrous plates; the sulphonamide in yellowish needles melting at 156°. C. F. B.

Sodium Phenyl Sulphite. By C. Schall (*Ber.*, **25**, 1490).—By the action of sulphurous anhydride on anhydrous sodium phenoxide at ordinary temperatures, the author has prepared a compound which he believes to be unsymmetrical sodium phenyl sulphite, $NaSO_2\cdot OPh$. J. B. T.

Action of Bleaching Powder and of Hypochlorous Acid on Quinones. By T. Zincke (*Ber.*, **25**, 1493—1497; compare this vol., pp. 720 and 859).—Isocoumarincarboxylic acid, $C_6H_4<\begin{matrix}CO\cdot O\\ |\\ CH{:}C\cdot COOH\end{matrix}$, has recently been prepared by Bamberger and Kitschelt (this vol., p. 882); it may also be obtained by heating the acid $C_{10}H_8O_5$ for some time at 225—230°. The *methyl salt* crystallises from methyl alcohol in slender, lustrous needles melting at 172—173°.

Isocarbostyrilcarboxylic acid, $C_6H_4<\begin{matrix}CO\cdot NH\\ |\\ CH{:}C\cdot COOH,\end{matrix}$ can be obtained by the action of ammonia (25 per cent.) on the acid $C_{10}H_8O_5$ at 160—170°; the product is pure and the reaction proceeds quantitatively; on heating with zinc dust in excess, isoquinoline is formed. J. B. T.

Fluoresceïn. By R. Meyer and H. Hoffmeyer (*Ber.*, **25**, 1385—1390; see also Abstr., 1891, 1029).—The phenolphthaleïn anhydride obtained by Baeyer in the preparation of phenolphthaleïn has been further examined by the authors. They propose to name it fluoran, and consequently fluoresceïn would be a dihydroxyfluoran.

Fluoran, $\begin{matrix}CO\cdot O\\ |\\ C_6H_4\end{matrix}>C<\begin{matrix}C_6H_4\\ |\\ C_6H_4\end{matrix}>O$, crystallises with ½ mol. of alcohol, melts at 180°, and gives a dibromide melting at 254—258°. The authors have attempted to convert fluoran into fluoresceïn, or *vice versâ*, without success. They have, however, obtained the same acid, of the formula $C_{20}H_{14}O_3$, from both compounds.

In the hope of obtaining fluoran, fluoresceïn chloride was treated with reducing agents; a large quantity of unaltered material was obtained, together with compounds containing chlorine.

Phosphorus pentabromide acts on fluoresceïn in a similar way to the pentachloride; the product was not obtained pure, and, on analysis, gave numbers corresponding with a tribromofluoran, $C_{20}H_9Br_3O_3$. It crystallises from xylene in yellowish, microscopic needles, and melts at 298—300°. The bromide (15 grams) is boiled for 24 hours in a reflux apparatus with sodium hydroxide (60 grams), absolute alcohol (600 c.c.), and excess of zinc dust, and the product filtered, diluted with water, and the alcohol distilled off. An oily product is thus obtained, which dissolves in a large quantity of hot water, and, on acidifying with hydrochloric acid, the acid $C_{20}H_{14}O_3$ is precipitated. The latter is identical with the phenol-

phthalin anhydride obtained by Baeyer by reducing phenolphthaleïn anhydride with zinc dust.

By reducing fluoran in a similar way, the same acid is obtained. The authors give the formula $COOH{\cdot}C_6H_4{\cdot}CH<\begin{matrix}C_6H_4\\C_6H_4\end{matrix}>O$ to this acid. It crystallises from alcohol in rhombic prisms or tablets, melts at 226—228° (uncorr.), and dissolves in concentrated sulphuric acid with a yellow coloration; on warming, the solution turns cherry-red, and, on adding water, gives a brown precipitate which dissolves in ether with a yellowish-green fluorescence. E. C. R.

Dinitrosacyls. By A. F. Holleman (*Rec. Trav. Chim.*, **10**, 211—222; compare Abstr., 1889, 49).—Dinitrosacyls have the following properties:—

Alkalis dissolve them with a yellow colour; mineral acids precipitate the corresponding acids from the solution. They are dissolved by sulphuric acid with a reddish-brown colour, and, on the addition of water, the corresponding acids are obtained. With aniline or its homologues, the corresponding anilide is obtained. $(R{\cdot}CO{\cdot}CNO)_2$ yields $R{\cdot}CO{\cdot}NHR_1$. The substitution of the nitroso-group for hydrogen in the group $\cdot CO{\cdot}CH_3$ weakens the combination between the carbon atoms. By reduction with zinc powder and acetic acid, the dinitrosacyls lose nitrogen and give diketones. Boiling with concentrated hydrochloric acid causes dinitrosacyls to give acids of the type $R{\cdot}COOH$, together with oxalic acid, ammonia, and hydroxylamine.

Dinitrosacyls may be prepared by the oxidation of isonitrosoketones.

Attempts to prepare dinitrosacyls of the fatty series by the action of nitric acid on isonitrosoacetone and on isonitrosomethyl hexyl ketone have not been successful. Fine crystals of the hexyl ketone compound were prepared by Claisen's method (*Ber.*, **20**, 252; **22**, 526). They melt at 59°.

It is yet doubtful whether the formula of the isonitrosomethylhexyl ketone should be $C_6H_{13}{\cdot}CO{\cdot}CH{\cdot}NOH$ or $C_5H_{11}{\cdot}C(NOH){\cdot}CO{\cdot}CH_3$, as caproic acid is obtained on oxidising it with nitric acid, but no acetic acid is produced.

Dianisyldinitrosacyl.—Paracetylanisoïl is prepared by Gattermann's method. Resinification is avoided when 20 grams of anisoïl react with 25 grams of acetic chloride dissolved in 150—200 c.c. of carbon bisulphide. It melts at 38°.

Acetylanisoïl, in portions of 5 grams at a time, is introduced into a mixture of 50 grams of nitric acid of sp. gr. 1·4 with 5 grams of concentrated sulphuric acid and carefully heated. The dianisyldinitrosacyl which separates, after being washed with water and purified with acetic acid, melts at 138—139°. The yield is about 70 per cent. of the ketone used. Anisic acid is obtained from the alkaline and acid solutions. Reduction by zinc powder and acetic acid yields symmetrical dianisoylethane; 25 c.c. of glacial acetic acid diluted with 10 c.c. of water is raised to the boiling point, and zinc powder added in small portions with 1 gram of the dinitrosacyl in concentrated acetic solution; after each addition, the liquid is boiled until colourless. Water gives a

flocculent precipitate of the diketone; it is purified by extraction with boiling alcohol and crystallisation from glacial acetic acid. It crystallises in fine plates melting at 154°. By boiling with ammonium acetate solution, it yields α-α′-dianisylpyrroline, which crystallises from a mixture of alcohol and acetic acid in thin plates melting at 223°. This derivative dissolves in sulphuric acid with a reddish-brown colour, changing to intense, bluish-violet on heating.

Dianisyldinitrosacyl is also obtained by oxidation of sodiumisonitrosoacetylanisoïl with nitric acid. By the action of aniline on dianisyldinitrosacyl, two well-crystallised compounds are obtained. The anilide of anisic acid melts at 170°. The other compound is obtained in dark-brown needles, becoming white on purification; it is now under investigation.

Diparethoxydiphenylenedinitrosacyl. — Paracetylphenetoïl, which melts at 36—37° and not at 61°, is oxidised in like manner to the acetylanisoïl. The diparethoxydiphenylenedinitrosacyl fuses at 131° and yields, on reduction with zinc powder and acetic acid, diparethoxydiphenylenethylene diketone fusing at 132°. This compound gives 2 : 5-diparethoxydiphenylenepyrroline melting at 210°.

Dinaphthyldinitrosacyl was not obtained on oxidation of β-naphthyl methyl ketone with nitric acid of sp. gr. 1·4. Although some of the dinitrosacyl reactions were obtained with the mass resulting from the oxidation of sodiumisonitrosomethylnaphthyl ketone, the substance itself has not been isolated. W. T.

The Oxymethylene Group in Isosafrole. By G. Ciamician and P. Silber (*Ber.*, **25**, 1470—1477).—A mixture of isosafrole (10 grams), potash (10 grams), and methyl alcohol (10 c.c.), when heated in a closed tube for 6—8 hours at 160—170°, is converted into a viscid liquid with evolution of a little hydrogen. The product is extracted with ether; on evaporating the ethereal solution, a yellowish liquid remains, which, on repeated distillation under reduced pressure, yields a substance which boils at 173° under 16 mm. pressure. This compound has the composition $OH\cdot C_6H_3(OCH_2\cdot OMe)\cdot C_3H_5$, the methyl alcoholic potash having acted on the isosafrole as potassium methoxide.

On heating the phenol (22 grams) with methyl iodide (15 grams), potash (6 grams), and methyl alcohol (40 c.c.) under pressure on the water-bath for many hours, and evaporating the alcohol, a product is obtained which, on treatment with potash, partly dissolves. The soluble portion is a black, tarry mass, which is decomposed by distillation. The part insoluble in potash is dissolved in ether and the ethereal solution evaporated, when a substance is obtained which boils at 184—185° under 20 mm. pressure, and with slight decomposition at 285° under ordinary pressures; it is a thick, colourless, tasteless liquid, giving analytical numbers agreeing with the formula $OMe\cdot C_6H_3(O\cdot CH_2\cdot OMe)\cdot C_3H_5$, but this constitution is given with reserve. On suspending it (7·5 grams) in hot water (600 c.c.) containing a little potash and adding a hot aqueous solution (1750 c.c.) of potassium permanganate (35 grams), oxidation occurs, and is completed by evaporation on the water-bath. Isovanillic acid may be

extracted from the residue, but other acids, including vanillic acid, are probably also produced.

When the phenolic compound, $OH{\cdot}C_6H_3(O{\cdot}CH_2{\cdot}OMe){\cdot}C_3H_5$ (22 grams), is heated for six hours in a reflux apparatus with acetic anhydride (60 grams) and anhydrous sodium acetate (10 grams), it gives a product which, after evaporation of the acetic anhydride, is digested with dilute soda. The residue is extracted with ether, and, on evaporation of the ethereal solution, an oil is obtained which, on distillation under diminished pressure, yields *diacetylmetapropenylcatechol*, $C_6H_3(OAc)_2{\cdot}C_3H_5$ [$(OAc)_2 : C_3H_5 = 4 : 3 : 1$]; this forms pearly scales, melts at 96·5°, and boils with slight decomposition at 305—308°. On oxidation with a hot aqueous solution of potassium permanganate, it yields diacetylprotocatechuic acid melting at 155—156°, not at 150—153°, as previously stated.

In the fractional distillation of the diacetylmetapropenylcatechol, an oil boiling at 306—307° is obtained which, on oxidation with hot potassium permanganate solution, yields a mixture of diacetyl- and monacetyl-protocatechuic acids. The latter forms white needles melting at 197—199°. It is soluble in ether, alcohol, hot ethyl acetate, and water. A little protocatechuic acid is obtained at the same time. W. J. P.

Azobenzene-, Hydrazobenzene-, and Benzidinedisulphonamide. By H. Limpricht and F. Meyer (*Annalen*, **268**, 130—142). —Azobenzenedisulphonamide, $NH_2{\cdot}\overset{2}{S}O_2{\cdot}C_6H_4{\cdot}\overset{4}{N}{:}\overset{4}{N}{\cdot}C_6H_4{\cdot}\overset{2}{S}O_2{\cdot}NH_2$, is easily obtained by oxidising the hydrazo-compound described below (compare, also, Mahrenholtz and Gilbert, *Annalen*, **202**, 336); it crystallises in yellow needles or prisms, melts at 305°, and is insoluble, or only very sparingly soluble, in most ordinary solvents, but readily soluble in boiling aniline. The *potassium* derivative, $C_{12}H_{10}N_4S_2O_4K_2$, crystallises in yellowish plates and prisms, and contains 2 mols. H_2O when dried over sulphuric acid. The *sodium* derivative,

$$C_{12}H_{10}N_4S_2O_4Na_2,$$

crystallises in microscopic plates, and after having been dried over sulphuric acid, loses 7 mols. H_2O at 150°.

Hydrazobenzenedisulphonamide $C_{12}H_{14}N_4S_2O_4$ (compare Mahrenholtz and Gilbert, *loc. cit.*), prepared by reducing metanitrobenzenesulphonamide, or the azo-compound just described, with zinc-dust and ammonia, crystallises from boiling 50 per cent. acetic acid in long, colourless needles, melts at 248°, and is almost insoluble in water, ether, chloroform, and toluene, and only sparingly soluble in alcohol, but readily in acetone and aniline. It dissolves in, and is decomposed by, warm, concentrated sulphuric acid, yielding a deep yellow solution, but it separates unchanged from concentrated ammonia; it reduces ammoniacal silver solutions and Fehling's solution on warming. The *potassium* derivative, $C_{12}H_{12}N_4S_2O_4K_2 + 1\frac{1}{2}H_2O$, crystallises in colourless needles or plates. The *sodium* derivative, $C_{12}H_{12}N_4S_2O_4Na_2 + 2\frac{1}{2}H_2O$, crystallises in small, colourless, concentrically-grouped needles.

Benzidinedisulphonamide, $NH_2{\cdot}SO_2{\cdot}C_6H_3(NH_2){\cdot}C_6H_3(NH_2){\cdot}SO_2{\cdot}NH_2$, is formed, together with azobenzenedisulphonamide, amidobenzenesulphonamide, and a resinous base, the nature of which could not be determined, when hydrazobenzenedisulphonamide is heated with moderately concentrated hydrochloric acid for two to three days at 100°; it can also be prepared by warming the hydrazo-compound with stannous chloride. It crystallises from water in colourless, rhombic plates, and in long needles, melts at 278°, and is readily soluble in boiling acetone and boiling aniline, but only moderately easily in hot alcohol, and insoluble in ether, chloroform, and toluene; it dissolves in concentrated ammonia, yielding a yellow solution, from which a colourless, granular compound is precipitated on the addition of silver nitrate, and it is also readily soluble in dilute alkalis and dilute mineral acids. The *hydrochloride*, $C_{12}H_{14}N_4S_2O_4,2HCl$, crystallises in flat prisms which seem to contain 2 mols. H_2O after having been dried over sulphuric acid; it melts at 205°, and is readily soluble in water and alcohol. The *sulphate*, $C_{12}H_{14}N_4S_2O_4,H_2SO_4 + 2H_2O$, crystallises in prisms, and is readily soluble in water. F. S. K.

Oxyazo-compounds. By H. Goldschmidt and A. Pollak (*Ber.*, **25**, 1324—1347; see also Abstr., 1891, 1209).—Goldschmidt and Brubacher have shown that the acetyl and benzoyl derivatives of many hydroxyazo-compounds, when reduced with zinc-dust and acetic acid, yield acetanilide or benzanilide, and they maintain that this reaction is evidence that these compounds are hydrazones of quinones. The present paper deals with the reduction of other hydroxyazo-compounds, of disazo-compounds of the type of phenoldisazobenzene, of azo-compounds derived from resorcinol, and of the acetyl derivative of benzeneazoacetone.

Paratolueneazoparacresol was converted into the *acetyl derivative* $C_6H_3MeO{\cdot}N{\cdot}NAc{\cdot}C_6H_4Me$, and the latter reduced in alcoholic solution with zinc-dust and a few drops of acetic acid. After reduction, the excess of zinc-dust was filtered off, water added, and then dilute sulphuric acid, and the mixture extracted with ether. The ethereal solution contained paracetotoluidide; hence the reduction takes place in a similar way to that of the acetyl derivatives of other orthohydroxyazo-compounds. Benzoylparatolueneazoparacresol was reduced in the same way. An *hydrazo*-compound is first formed, and is precipitated on adding water. It melts at 144°, but is not pure. By further reduction, parabenzotoluidide is formed.

Parachlorobenzeneazoparacresol is obtained by the action of parachlorodiazobenzene chloride on an alkaline solution of paracresol. It crystallises from benzene in long, orange-red needles, and melts at 151—152°. The *acetyl* compound, obtained by the action of acetic anhydride and anhydrous sodium acetate, crystallises from alcohol in long, reddish-yellow needles, and melts at 118—119°. The acetyl compound, on reduction, first yields *acetylparachlorobenzenehydrazoparacresol*, $OH{\cdot}C_6H_3Me{\cdot}NH{\cdot}NAc{\cdot}C_6H_4Cl$, which is obtained as follows:—The acetyl azo-compound in well cooled alcoholic solution is treated with zinc-dust and just enough acetic acid to decolorise the solution. The liquid is then filtered into a flask filled with

carbonic anhydride, and precipitated with water in the presence of a current of carbonic anhydride. The precipitate is quickly collected, dried on a porous plate, and crystallised from hot petroleum. It forms long, colourless, four-sided prisms, melts at 99° with a red coloration, and is soluble in ether, benzene, and petroleum. It is as little soluble in alkali as the other hydrazo-compounds obtained by Goldschmidt and Brubacher from acetylparahydroxyazo-compounds. When left for some time in contact with concentrated sodium hydroxide, it is converted into the primary hydroxyazo-compound. By the further reduction of acetylparachlorobenzeneazoparacresol, the molecule is split and acetoparachloranilide is obtained.

Benzoylparachlorobenzeneazoparacresol is obtained by boiling the hydroxyazo-compound, dissolved in benzene, with benzoic chloride. It crystallises in long, orange-red prisms, melts at 115°, and is easily soluble in benzene, but only sparingly in alcohol and petroleum. On reduction, it yields the hydrazo-compound,

$$OH\cdot C_6H_3Me\cdot NH\cdot NBz\cdot C_6H_4Cl;$$

this crystallises in colourless needles, melts at 172° with a red coloration, and is easily soluble in alcohol and benzene, sparingly so in light petroleum. It does not yield benzoparachloranilide on further reduction.

Metachlorobenzeneazoparacresol is obtained by the action of metachlorodiazobenzene chloride on a strongly alkaline solution of paracresol. It crystallises from hot, dilute alcohol in long, orange-red needles, melts at 103°, and is easily soluble in alcohol, benzene, and ether; very sparingly so in cold petroleum. The *acetyl* derivative crystallises from hot alcohol in orange-yellow prisms, melts at 73—74°, and is easily soluble in cold benzene and ether, and in hot alcohol and petroleum. On reduction, it first yields the *hydrazo*-compound, which crystallises in long, colourless needles, and melts at 92° with a red coloration. By further reduction, the molecule is split up and acetometachloranilide (m. p. 75°) is obtained.

Benzoylmetachlorobenzeneazoparacresol crystallises from hot alcohol in long, orange-red needles, melts at 90°, and is soluble in cold benzene and ether, and in hot alcohol and petroleum. On reduction, it yields an impure *hydrazo-compound* which melts at 127—128°, and is probably mixed with benzometachloranilide.

Benzeneazo-orthocresol, $C_6H_3MeO{:}N\cdot NHPh$ [Me : O : N·NHPh = 1 : 2 : 5], a paroxyazo-compound, has been examined in conjunction with the foregoing orthoxy-compounds. The acetyl derivative, on reduction, yields *acetylbenzenehydrazo-orthocresol*. The latter crystallises in colourless needles, melts at 88—89°, and turns yellow on exposure to air; it is insoluble in alkalis, but, by the prolonged action of alkalis, is converted into benzeneazo-orthocresol. The acetyl derivative does not yield amidocresol and acetanilide on further reduction.

Benzoylbenzeneazo-orthocresol, on reduction, yields a *hydrazo-compound* which is precipitated, on adding petroleum to its solution in benzene, in clusters of colourless needles; it melts at 142°. The decomposition of the benzoyl compound into amidocresol and benzanilide could not be effected.

From these results the authors conclude that the hydrazo-derivatives of hydroxyazo-compounds of the ortho-series, with a few exceptions, can be further reduced to amidophenols and an anilide: the compounds of the para-series cannot be so reduced. They are, however, so alike in other respects, that a similar constitution must be assigned to both.

Monoxydisazo-compounds.—Phenoldisazobenzene, the simplest representative of this class, if expressed as a quinone hydrazone, can be either a para- or ortho-quinone derivative, as shown by the formulæ:

$$CO<\begin{matrix}CH\text{———}CH\\ C(N_2Ph):CH\end{matrix}>C:N\cdot NHPh. \qquad CO<\begin{matrix}CH\text{———}CH\\ C(N\cdot NHPh)\cdot CH\end{matrix}>C\cdot N_2Ph\cdot$$

I. II.

In favour of formula I is the production of the compound from oxyazobenzene, but against it is the loss of acid properties which are so distinctly characteristic of paroxyazo-compounds. The acetyl derivative, when reduced with zinc-dust and dilute sulphuric acid, yields acetanilide, aniline, and diamidophenol. Hence it behaves, on reduction, like the acetyl derivative of an orthoxyazo-compound, and the author concludes that its constitution is more correctly expressed by formula II.

Phenoldisazotoluene, $OH\cdot C_6H_3(N_2\cdot C_6H_3Me)_2$ [1 : 2 : 4], is obtained by the action of paradiazotoluene chloride on an alkaline solution of paratolueneazophenol. It crystallises from acetic acid in yellowish-brown, nodular aggregates, melts at 170°, and is sparingly soluble in cold alcohol, easily so in benzene and acetic acid. The *acetyl compound* crystallises from alcohol in yellowish-brown plates, melts at 128°, and gives acetoparatoluidide on reduction.

The constitution of phenoldisazo-compounds can be determined as follows:—If a diazo-salt $R'\cdot N:N\cdot Cl$ acts on a paroxyazo-compound $O:C_nH_m:N\cdot NHR$, then a compound of the constitution

$$O:C_nH_{m-1}(N:NR'):N\cdot NHR, \text{ or } O:C_nH_{m-1}(N:NR):(N\cdot NHR'),$$

is formed.

In the first case, a paraquinone derivative; in the second, an orthoquinone derivative is produced. If the disazo-compound is first acetylated and then reduced, in the first case the acetyl compound $Ac\cdot NHR$, and in the second case the compound $Ac\cdot NHR'$, will be obtained. Hence it is possible to distinguish between the para- and ortho-quinone formulæ. For this purpose, the authors have examined the behaviour of phenoldisazoparabenzeneorthotoluene, $OH\cdot C_6H_3(N_2\cdot C_7H_7)\cdot N_2Ph$ [1 : 2 : 4], which is prepared by the action of oxyazobenzene on paradiazotoluene chloride, and has been described by Griess as melting at 110°; the authors, however, find that, when pure, it melts at 121°. The *acetyl compound* crystallises in yellow prisms, and melts at 92°. When reduced in alcoholic solution with zinc-dust and dilute sulphuric acid, it yields acetoparatoluidide, unmixed with acetanilide. Hence the phenoldisazoparabenzeneorthotoluene is an orthoquinone derivative of the formula $CO<\begin{matrix}CH\text{———}CH\\ C(N\cdot NH\cdot C_7H_7)\cdot CH\end{matrix}>C\cdot N_2Ph.$

Phenoldisazo-orthobenzeneparatoluene is obtained by the action of

diazobenzene chloride on an alkaline solution of paratolueneazophenol. It crystallises in brownish-yellow, spherical aggregates, and melts at 115—116°. The *acetyl compound* crystallises from alcohol in transparent, golden prisms, melts at 130°, and yields acetanilide on reduction.

α-Naphtholdisazoparabenzeneorthotoluene.—On mixing an alkaline solution of α-naphtholazobenzene with a solution of paradiazotoluene chloride, a dark-coloured precipitate is obtained from which the disazo-compound cannot be separated by crystallisation. It is obtained pure by hydrolysing the acetyl compound with alcoholic potash, and then forms reddish-brown needles, melts at 165°, and dissolves in concentrated sulphuric acid with a bluish-green coloration. The *acetyl compound*, obtained by the action of acetic anhydride and anhydrous sodium acetate on the crude disazo-compound, is purified by crystallisation from alcohol, and melts at 150°. When reduced, it yields acetoparatoluidide, so that the disazo-compound is an orthoquinone derivative.

Azo-compounds of Resorcinol.—Resorcinoldisazobenzene

$$[(OH)_2 : (N_2Ph)_2 = 1 : 3 : 2 : 4]$$

is obtained by pouring an aqueous solution of diazobenzene chloride (2 mols.) and resorcinol (1 mol.) into a solution of sodium acetate. The product, after recrystallisation from chloroform and alcohol, was converted into the diacetyl derivative (m. p. 137—138°), and the latter reduced with zinc-dust and acetic acid. The products were acetanilide and diamidoresorcinol. Hence the authors express resorcinoldisazobenzene as the disphenylhydrazone of orthodiquinoyl.

Symmetrical resorcinoldisazobenzene, $[(OH)_2 : (N_2Ph)_2 = 1 : 3 : 4 : 6]$, is obtained by pouring a solution of diazobenzene chloride (2 mols.) and resorcinol (1 mol.) into a solution of sodium hydroxide, and precipitating with hydrochloric acid. The diacetyl derivative, on reduction, yields acetanilide.

Parabenzeneazoresorcinol $[(OH)_2 : N_2Ph = 1 : 3 : 4]$ was converted into the diacetyl compound; the latter, on reduction, yields acetanilide and amidoresorcinol.

Acetylbenzeneazoacetone, COMe·CH:N·NPhAc, is prepared according to the method of Japp and Klingemann (Trans., 1888, 525), and melts at 93°. Two preparations, however, gave a compound melting at 65°, which was apparently quite pure. On reduction, both compounds yield acetanilide and a ketine (dimethylaldine, C_6H_8N).

Benzoylbenzeneazoacetone is obtained by boiling a concentrated benzene solution of benzeneazoacetone with benzoic chloride. It crystallises in long, four-sided, colourless prisms, melts at 122°, and is easily soluble in alcohol, ether, benzene, and petroleum. On reduction, it yields benzanilide and a ketine.

Hence the acetyl and benzoyl derivatives of benzeneazoacetone, which is probably a hydrazone, behave on reduction similarly to the analogous derivatives of the orthoxyazo-compounds. E. C. R.

Diazoamido-compounds. By H. Goldschmidt and B. Bardach (*Ber.*, **25**, 1347—1378; see also Abstr., 1891, 1211).—The authors

have continued the cryoscopic experiments described by one of them on the conversion of diazoamido-compounds into amidoazo-compounds, with the view of determining the course of the reaction and to obtain the intermediate compounds formed. If known weights of diazoamidobenzene, paratoluidine, and paratoluidine hydrochloride are employed, then if the freezing point of the solution of the diazoamidobenzene in paratoluidine be determined before adding the hydrochloride, it is possible to calculate the depression of freezing point due to the elimination of 1 or 2 mols. of aniline, so that the reaction can be stopped when either of these points is reached and the products examined. The authors have examined the reaction which takes place between a series of diazoamido-compounds with paratoluidine hydrochloride in paratoluidine solution. The following results were obtained :—

Diazoamidobenzene (3 grams) is dissolved in pure paratoluidine (39·7 grams), and the freezing point of the solution determined with a Beckmann's thermometer, then paratoluidine hydrochloride (2·18 grams, corresponding with 1 mol. of diazoamidobenzene) is added, and the mixture stirred in a bath kept at 50°. At intervals of five minutes, the depression of the freezing point is determined. When the depression corresponding with the evolution of 1 mol. of aniline is reached, the melted mass is poured into water containing sodium hydroxide sufficient to neutralise the hydrochloric acid of the hydrochloride, and the paratoluidine is then brought into solution by the addition of acetic acid. A finely-divided, yellow powder (3·1 grams) is obtained, which, on crystallisation from petroleum, is split into paradiazoamidotoluene (m. p. 115°) and unaltered diazoamidobenzene. Diazoamidobenzenetoluene was not obtained. Other experiments under varying conditions gave similar results ; the diazoamidobenzene being converted into diazoamidotoluene, and this into amidoazotoluene. The first reaction takes place quickly, the second somewhat slowly.

Diazoamido-ψ-cumene crystallises from petroleum in large, yellow plates, and melts at 138° (Noelting and Baumann give the m. p. 130·5, *Ber.*, **18**, 1147). When treated with paratoluidine hydrochloride in paratoluidine solution as described above, it gave paradiazoamidotoluene.

Paradichlorodiazoamidobenzene, when treated in a similar way, gave some amidoazotoluene, and a compound melting at 123°, which is a crystalline mixture of paradiazoamidotoluene and paradichlorodiazoamidobenzene.

Metadichlorodiazoamidobenzene is obtained by the action of metadiazobenzene chloride on metachloraniline suspended in a solution of sodium acetate. On adding petroleum to its solution in benzene, it is precipitated in clusters of pale-yellow, microscopic needles, melts at 107°, and easily soluble in benzene, sparingly so in petroleum. With paratoluidine hydrochloride, it gives a crystalline mixture of metadichlorodiazoamidobenzene and diazoamidotoluene, which melts at 90°.

Mixed diazoamido-compounds which contain the group $C_7H_7{\cdot}NH-$, and those which contain the group $C_7H_7{\cdot}N{:}N-$, are both converted into paradiazoamidotoluene when treated as above with paratoluidine hydrochloride. Thus diazoamidobenzenetoluene, diazoamido-ψ-

cumeneparatoluene, diazoamidoparachlorobenzeneparatoluene, and diazoamidometachlorobenzeneparatoluene all yielded diazoamidotoluene.

Diazoamido-ψ-cumeneparatoluene, $C_6H_4Me{\cdot}N{:}N{\cdot}NH{\cdot}C_6H_2Me_3$, is obtained by the prolonged action of paradiazotoluene chloride on pseudocumidine suspended in a solution of sodium acetate. It crystallises from petroleum in bright yellow, radiating needles, and melts at 106°. The above constitution was proved by the cyanate method (*Ber.*, **21**, 1016 and 2557). With phenyl cyanate, it yields an additive compound, which melts at 102°, and when treated with 10 per cent. sulphuric acid and steamed, gives a compound melting at 211°. The authors, however, were unable to determine if this compound was tolylphenylcarbamide or pseudocumylphenylcarbamide. With paratolyl cyanate, it yields an additive compound which sinters at 120°, melts above 230°, and when mixed with sulphuric acid and distilled in a current of steam, it gives *pseudocumylparatolylcarbamide*. The latter crystallises in colourless needles, and melts at 218°.

Diazoamidoparachlorobenzeneparatoluene, $C_6H_4Me{\cdot}N{:}N{\cdot}NH{\cdot}C_6H_4Cl$, is obtained by the action of paradiazotoluene chloride on parachloraniline suspended in a solution of sodium acetate. It is precipitated by petroleum from benzene in long, radiating needles, and melts at 133°. With phenyl cyanate, it gives an additive compound melting at 122°, and then *parachlorodiphenylcarbamide*. The latter crystallises from alcohol in long, colourless needles, and melts at 237—238°.

Diazoamidometachlorobenzeneparatoluene, $C_6H_4Me{\cdot}N{:}N{\cdot}NH{\cdot}C_6H_4Cl$, is precipitated by petroleum from benzene solution in radiating, lemon-yellow needles, and melts at 103°. With phenyl cyanate, it yields an additive compound melting at 104° with frothing, and then *metachlorodiphenylcarbamide*. The latter crystallises from alcohol in white needles, and melts at 184°.

The authors have also examined the behaviour of diazoamido-compounds towards aniline hydrochloride in aniline solution.

Paradiazoamidotoluene, when treated with aniline hydrochloride in aniline solution, is first converted into diazoamidobenzenetoluene, and finally into toluneneazoaniline.

Diazoamidobenzenetoluene was dissolved in aniline, and treated under varying conditions with aniline hydrochloride. Toluneneazoaniline was obtained, and in no case was diazoamidobenzene formed.

Paradichlorodiazoamidobenzene, by the prolonged action of aniline hydrochloride in aniline solution, is converted into amidoazobenzene. A compound which melts at 118° and crystallises from benzene in yellow needles is also formed, but owing to the small quantity, was not examined.

The conversion of diazoamido-compounds into amidoazo-compounds has been stated to take place as follows:—The diazoamido-compound is converted into free amine and diazochloride, and then the latter unites with the amine to form the amidoazo-compound with evolution of hydrogen chloride. The authors find that this is not the course of the reaction. When diazobenzene chloride is added to pure, dry aniline, it at once yields a dark yellow solution, and on pouring this into dilute soda and examining the product, diazoamidobenzene was

obtained. Amidoazobenzene was not formed. Diazobenzene chloride and paratoluidine also unite directly to form a diazoamido-compound, as, on examining the product, diazoamidobenzenetoluene and diazoamidotoluene were obtained.

It has been shown above that by the action of primary amines on diazoamido-compounds, a new diazoamido-compound is first formed which then yields an amidoazo-compound. It has not been proved at which place in the group –NH·N:N– the split takes place in the formation of the amidoazo-compound. To settle this point tertiary amines have been employed in place of primary amines; for, in this case, the formation of a new diazoamido-compound is not possible. Noelting and Binder have stated that diazoamidobenzenetoluene, when treated with dimethylaniline hydrochloride in a solution of dimethylaniline, yields aniline and paratolueneazodimethylaniline, from which it would seem that the nitrogen chain –NH·N:N– is split at the double bond. The authors find that this is not a general reaction; in many cases the chain splits at the single bond, and in one case it splits partly at the double, partly at the single bond.

Diazobenzene-β-naphthylamine, $PhN{:}N{\cdot}NHC_{10}H_7$, was dissolved in six times the weight of dimethylaniline, the equivalent quantity of dimethylaniline hydrochloride added, and the mixture heated at 60° until a test on boiling with sulphuric acid no longer evolved nitrogen. The mass was then treated with dilute soda and steam distilled. The distillate contained dimethylaniline and aniline, the production of the latter showing that the molecule of the diazoamido-compound is split at the double bond. β-Naphthaleneazodimethylaniline, which ought to be contained in the residue, could not be separated.

Parabromodiazoamidobenzene treated in the same way yielded both parabromaniline and aniline. On account of the resinous properties of the non-volatile residue, the bromodimethylamidoazobenzene could not be isolated. *Parabromodimethylamidoazobenzene* is prepared by the action of parabromodiazobenzene chloride on a dilute alcoholic solution of dimethylaniline in the presence of sodium acetate. It crystallises from alcohol in beautiful, bright-red needles, and melts at 156°.

Metanitrodiazoamidobenzene and paranitrodiazoamidobenzene when treated with dimethylaniline hydrochloride, gave respectively metanitraniline and paranitraniline.

The authors put forward the following as the course of the reaction which takes place in the conversion of diazoamido- into amidoazo-compounds. The molecules of diazoamidobenzene and paratoluidine hydrochloride react together as expressed in the equation

$$NHPh{\cdot}N{:}NPh + C_7H_7{\cdot}NH_2,HCl = C_7H_7{\cdot}NH_2 + N(NHPh)_2Cl.$$

Then in the presence of excess of paratoluidine, aniline is eliminated and the compound $N(NH{\cdot}C_7H_7)_2Cl$ is formed. The latter then gives up its hydrogen chloride to the excess of paratoluidine and changes into diazoamidotoluene. When the diazoamidotoluene predominates, or when the diazoamidobenzene is entirely destroyed, the hydrogen chloride unites with the diazoamidotoluene, and the product $N(NH{\cdot}C_7H_7)_2Cl$ reacts with the excess of toluidine to form $N(NH{\cdot}C_7H_7)_2{\cdot}C_7H_6{\cdot}NH_2$, which then loses toluidine, and is converted

into the amidoazo-compound, $N(NH\cdot C_7H_7)_2\cdot C_7H_6\cdot NH_2 = C_7H_7\cdot NH_2 + C_7H_7\cdot NH\cdot N:C_7H_6:NH$. E. C. R.

Phenylhydrazine Acetate. By H. J. F. de Vries and A. F. Holleman (*Rec. Trav. Chim.*, **10**, 228—230).—Glacial acetic acid (1 mol.) is added to phenylhydrazine (1 mol.) dissolved in a little chloroform. Heat is developed, and white, crystalline plates form, which are separated by the pump and washed with chloroform. The compound melts at 68—69°. It is readily soluble in water, alcohol, ether, and chloroform. It is very unstable, and can only be recrystallised well from chloroform, which, in common with other solvents, causes some decomposition. It becomes brown in 24 hours even in a vacuum. It has an odour of mixed acetic acid and phenylhydrazine. Its aqueous solution reduces Fehling's solution at the ordinary temperature. Its analysis presents some difficulty; the nitrogen may be best determined by acting on the compound with boiling Fehling's solution in Schloesing's apparatus. W. T.

Acid Hydrazides. By F. Bölsing and J. Tafel (*Ber.*, **25**, 1551—1556; compare this vol., p. 710; also Gattermann and others, *ibid.*, 843).—*Isobutyric phenylhydrazide*, $C_4H_7O\cdot N_2H_2Ph$, obtained by heating together phenylhydrazine and isobutyric acid at 150°, and crystallising the product from water, forms colourless leaflets, melts at 140°, and is somewhat sparingly soluble in boiling water, readily so in boiling alcohol. It gives a reddish-brown coloration with concentrated sulphuric acid and potassium dichromate or ferric chloride, and reduces Fehling's solution when gently warmed with it. *Isobutyric diphenylhydrazide*, $C_4H_7O\cdot N_2HPh_2$, is prepared by boiling the last-described compound dissolved in alcohol with copper acetate; it crystallises from alcohol in colourless needles, melts at 171—172°, and distils almost without decomposition; it resembles the corresponding acetyl derivative (*loc. cit.*) in its reactions, and, like this, is without action on Fehling's solution.

Phenylacetic diphenylhydrazide, $CH_2Ph\cdot CO\cdot N_2HPh_2$, is produced by oxidising phenylacetic phenylhydrazide with copper acetate, and forms colourless needles melting at 188°.

Cinnamic diphenylhydrazide, $C_2H_2Ph\cdot CO\cdot N_2HPh_2$, crystallises from a mixture of alcohol and ether in small, faintly-yellow needles, and melts at 205°.

Ethyl oxalate diphenylhydrazide, $N_2HPh_2\cdot CO\cdot COOEt$, crystallises in small needles, melts at 131°, and gives *oxalic acid diphenylhydrazide*, $N_2HPh_2\cdot CO\cdot COOH$, when heated on the water-bath with 5 per cent. aqueous potash; the latter crystallises from dilute acetic acid in microscopic needles, melts at 171°, and, unlike the other acidyl diphenylhydrazines, is readily soluble in ether. When the last compound is heated at 180° in an oil-bath, formic diphenylhydrazide (m. p. 116°), see Gattermann and others (*loc. cit.*) is formed. Acetic diparatolylhydrazide (m. p. 170°), prepared by Gattermann and others (*loc. cit.*), dissolves in concentrated sulphuric acid forming a yellow solution which does not give a blue coloration on the addition of potassium dichromate. Coloured products are obtained when the last com-

pound is treated with alcoholic hydrochloric acid, and on addition of stannous chloride, and distillation of the faintly acidified solution, paraditolylamine passes over.

Acetylparabromophenylhydrazine, $C_8H_9BrN_2O$, prepared by boiling parabromophenylhydrazine with glacial acetic acid, crystallises from alcohol in brownish needles melting at 161°, and gives *acetylparabromodiphenylhydrazine*, $C_{14}H_{12}Br_2N_2O$, on oxidation with copper acetate. It is almost insoluble in hot water and in ether, crystallises from alcohol in delicate, colourless needles, and melts at 214°.

The oxidation of acetyl-α-naphthylhydrazine with copper acetate appears to proceed further than in the above cited cases, and with the exception of a small quantity of naphthalene, no crystalline products were isolated. A. R. L.

Mixed Acid Amides. By A. Pinner (*Ber.*, **25**, 1434—1438).—The author has shown that when acetic anhydride acts on imidoethers, the alkyl group is displaced by acetyl; the compounds obtained have been named imidoacetates, and the constitution OAc·CR:NH assigned to them. The same compounds are formed, to a greater or less extent, according to the conditions, by the action of acetic anhydride on the amidines. On the other hand, propionamidine, when treated with acetic anhydride, yields, as chief product, propionacetamide, $C_3H_5O{\cdot}NHAc$, together with propionamide.

Tafel and Enoch (*Ber.*, **23**, 103) have shown that, by the action of ethyl iodide on the silver compound of benzamide, ethylbenzimidoether, OEt·CPh:NH, is formed, and not ethylbenzamide, COPh·NHEt; that is, benzamide behaves as if it had the tautomeric form OH·CPh:NH. From this result the author is uncertain if the abovementioned imidoacetates have the constitution OAc·CR:NH or COR·NHAc, and if the mixed acid amides are of the type COR·NH·COR′. He has, therefore, attempted to prepare acetylbenzamide in various ways, but has been successful in only one method. Neither by shaking a solution of acetamide, mixed with sodium hydroxide, with benzoic chloride, nor by the direct action of benzoic chloride on acetamide, can benzoylacetamide or acetylbenzamide be obtained. When acetamide is heated with benzoic chloride, the benzoic chloride acts as a dehydrating agent, and benzoic acid, benzoic anhydride, and acetonitrile, are obtained.

Acetylbenzamide is obtained by boiling benzamide with acetic anhydride for half an hour in a reflux apparatus; benzonitrile and cyanophenin are formed at the same time. The product is made alkaline with potassium carbonate, and the insoluble crystalline mass separated and recrystallised from very dilute alcohol, when the cyanophenin remains undissolved. Acetylbenzamide forms flat, white needles, melts at 120°, and is very easily soluble in alcohol, but only sparingly in water. It is identical with benzimidoacetate, which also melts at 120°, and not at 114°, as formerly stated. Hence, the two isomeric compounds, COPh·NHAc and PhC(NH)·OAc, are not obtained, but one undergoes isomeric change at the moment of formation.

When equivalent quantities of β-naphthamidine hydrochloride and

fused sodium acetate are heated to gentle boiling with 4—5 times the quantity of acetic anhydride for about 15 minutes in a reflux apparatus, the chief product is β-naphthimidine. By prolonging the boiling, less of the imidine is obtained, and naphthamide and naphthoylacetamide are formed. The mixed products are separated as follows:—The cold mixture is diluted with water, and the insoluble portion extracted twice with alcohol, when the imidine remains behind. The alcoholic solution is evaporated, and the residue dissolved in benzene. On cooling the solution, naphthoylacetamide crystallises out, whilst the naphthamide remains in solution.

Naphthimidine, $NH[C(NH)\cdot C_{10}H_7]_2$, crystallises in thick, colourless prisms, melts at 195°, is insoluble in water, very sparingly soluble in hot alcohol and acetic acid, easily in benzene, and is converted into naphthamide by prolonged boiling with acetic acid.

Naphthoylacetamide, $C_{10}H_7\cdot CO\cdot NHAc$, crystallises in large, transparent prisms, melts at 160°, and is sparingly soluble in water, easily in alcohol, very easily in hot benzene, but only sparingly in cold benzene.

Naphthamide crystallises in leaflets, and melts at 191—192°.

E. C. R.

Action of Thiocarbonyl Chloride on Aromatic Thiocarbamides. By M. Freund and H. Wolf (*Ber.*, **25**, 1456—1468).—The products of the action of thiocarbonyl chloride on aromatic thiocarbamides are analogous to those obtained by the action of carbonyl chloride, and investigated by Will (Abstr., 1881, 905).

Thiocarbonylthiocarbanilide, $NPh{:}C<\overset{S}{\underset{NPh}{\rangle}}CS$, is obtained by treating diphenylthiocarbamide, suspended in dry ether, with an ethereal solution of thiocarbonyl chloride. The ether is allowed to evaporate spontaneously, and the residue dried on a porous plate. It crystallises from hot, dilute alcohol, in yellow needles melting at 78—79°. About 15 per cent. of the theoretical yield is obtained. It is very soluble in alcohol, benzene, toluene, and carbon bisulphide, less so in hot acetic acid, chloroform, methyl alcohol, and acetone, and insoluble in water. It dissolves in cold concentrated sulphuric acid, and is precipitated from the solution by water. It becomes slightly brown on exposure to light. When boiled with aniline for an hour, it yields diphenylthiocarbamide. On heating a solution of thiocarbonylthiocarbanilide in absolute alcohol with freshly precipitated mercuric oxide in a reflux apparatus, carbonylthiocarbanilide is obtained. It is not changed when heated with water or dilute hydrochloric acid. On heating with potash (sp. gr. 1·4), it yields aniline, phenylthiocarbimide, hydrogen sulphide, and carbonic anhydride. When heated in a sealed tube with concentrated hydrochloric acid at 100°, no action occurs; at 130°, a little hydrogen sulphide is evolved, and on heating for four hours at 160°, complete decomposition occurs, with formation of hydrogen sulphide and aniline.

When diphenylthiocarbamide, suspended in benzene, is heated on the water-bath with thiocarbonyl chloride, an oil, which readily solidifies, is obtained. The benzene is evaporated, and the mass

extracted with hot absolute alcohol. The residue is sparingly soluble in boiling absolute alcohol, and crystallises from it in needles melting at 156°. It has the composition $C_{14}H_{10}N_2S_3$, and was prepared by Proskauer and Sell (Abstr., 1877, i, 67). The author assigns to it the constitution $\begin{matrix}CS\cdot NPh\\ |\\ NPh\cdot CS\end{matrix}>S$. On treating its alcoholic solution with freshly precipitated mercuric oxide, an oily product was obtained. No reaction occurs on heating with aniline or acetic anhydride. On heating with concentrated potash, phenylthiocarbimide, aniline, hydrogen sulphide, and carbonic anhydride result.

Thiocarbonyldiparatolylthiocarbamide is prepared by the action of an ethereal solution of thiocarbonyl chloride on diparatolylthiocarbamide, suspended in dry ether. The solution is filtered, and the residue washed with ether. By spontaneous evaporation of the ethereal solution, the substance separates in yellow needles melting at 109°. The yield is about 10 per cent. of that required by theory. It is very soluble in hot alcohol, ether, benzene, toluene, carbon bisulphide, and glacial acetic acid, and insoluble in water. When heated with aniline, it probably yields thiocarbanilide and ditolylthiocarbamide. On treatment with mercuric oxide, it gives carbonylditolylthiocarbamide.

Thiocarbonyl-β-dinaphthylthiocarbamide, $C_{22}H_{14}N_2S_2$, is prepared from β-dinaphthylthiocarbamide in a similar manner to the preceding substance. It separates from benzene in yellow, flocculent crystals, and melts at 152° with evolution of gas, leaving a residue which eventually melts at 224°. It is soluble in ether, carbon bisulphide, and hot acetic acid, sparingly so in hot benzene and alcohol.

Carbonylphenylparatolylthiocarbamide, $C_{15}H_{12}N_2SO$, is prepared by the action of carbonyl chloride on phenylparatolylthiocarbamide suspended in toluene. Much hydrogen chloride is evolved, and, on allowing the solvent to evaporate, a crystalline mass is obtained, which separates from dilute alcohol in white needles. It melts at 89° with evolution of carbon oxysulphide, and is soluble in hot alcohol, acetic acid, concentrated sulphuric acid, benzene, carbon bisulphide, and ether. In its preparation, a small proportion of phenylparatolylcarbamide is obtained.

Carbonylphenyl-β-naphthylthiocarbamide, $C_{18}H_{12}N_2SO$, is prepared from phenyl-β-naphthylthiocarbamide in the same manner as the preceding compound. A crystalline mass is obtained, which separates from dilute alcohol in white needles melting at 117°. It is soluble in alcohol, ether, benzene, and acetic acid, and insoluble in water.

Phenyl-β-naphthylthiocarbamide, $NHPh\cdot CS\cdot NH\cdot C_7H_7$, results from the combination of phenylthiocarbimide and β-naphthylamine. It forms white, shining scales, which are soluble in alcohol, ether, carbon bisulphide, and hot acetic acid; it melts at 165°.

W. J. P.

Tertiary Phosphines and Arsines. By O. Holle (*Ber.*, **25**, 1518—1521).—Dimethylphenylphosphine reacts with benzal chloride, yielding a deliquescent substance, the platinochloride of which forms a pale-yellow powder melting at 50°, and has the constitution $(OH\cdot CHPh\cdot PMe_2Ph)_2PtCl_6$. When heated at 100° with benzalde-

hyde and aluminium chloride, it yields the same substance. Diethylphenylphosphine does not react with benzaldehyde.

Dimethylphenylarsine reacts with benzal chloride in the same way as the corresponding phosphine. Diethylphenylarsine does not react with benzal chloride. C. F. B.

Isonitrosoanilacetone. By A. F. Holleman (*Rec. Trav. Chim.*, **10**, 223—227).—Isonitrosoacetone (1 mol.) is dissolved in aniline (1 mol.) diluted with half its volume of alcohol. The reaction takes place with development of heat. The crystalline combination obtained melts with decomposition at 171°. Its formula is $C_9H_{10}N_2O$. It dissolves easily in dilute caustic alkalis with a yellow colour, and is precipitated from the solution by carefully adding mineral acids. Its composition is represented by the formula NPh:CMe·CH:NOH, which accounts for its observed solubility in alkalis. The only other possible formula, COMe·CH:N·NHPh, has been shown by Japp and Klingemann (Trans., 1888, 521) to be that of a substance of very different properties, benzeneazoacetone. Under the name isonitrosoanilacetone, Knorr has described a different substance (Abstr., 1884, 1368), which he has since recognised to be of a nature different from that indicated by the name (*Annalen*, **236**, 82, note).

P. C. Plugge has examined the toxicological properties of this compound. Isonitrosoanilacetone belongs, apparently, to the picrotoxin group of poisons, and acts principally on the spasmodic centres of the brain and medulla oblongata. The convulsions produced differ from those caused by strychnine; reflex tetanus, excited by exterior irritation, does not occur. The poisonous doses for frogs, 0·012—0·015 gram. An injection of 0·008 gram killed a white mouse in three hours. It has no influence on the coagulation of the blood, and does not reduce oxyhæmoglobin or cause the production of methæmoglobin. W. T.

Aromatic Alkyl Ketones and their Oximes. By A. Claus (*J. pr. Chem.* [2], **45**, 377—397; compare Abstr., 1890, 769, 979; 1891, 199, 564, 1222).—In this paper, the author summarises the work on ketones which has lately been done in his laboratory. Most of it has already appeared (*loc. cit.*), and the rules controlling the oxidation of aromatic alkyl ketones have been enunciated (Abstr., 1890, 769). The reduction of these ketones with hydrogen iodide has been the means of isolating a number of hydrocarbons which have as yet only been described in inaugural dissertations, but will be further treated of; they are: *orthethylparisopropyltoluene* (b. p. 204—206°), prepared from paracumyl methyl ketone; *metamethylparethyltoluene* (b. p. 184°), obtained from xylyl methyl ketone; *orthopropylparisopropyltoluene*, *orthobutylparisopropyltoluene*, *orthisobutylparisopropyltoluene*, *orthisoamylparisopropyltoluene*, and *isoamylbenzene*. There are no new compounds definitely described, and the bulk of the paper is occupied by a discussion as to the structure and isomerism of the oximes of these ketones, particularly in reference to Minunni's, Hantzsch's, and Auwers and Meyer's recent dissertations (Abstr., 1891, 1354; this vol., 186, 291, 426, 598). A. G. B.

Oxidation of Cinnamic Acid. By R. Fittig and R. Ruer (*Annalen*, **268**, 27—32; compare this vol., p. 956).—Phenylglyceric acid, $C_9H_{10}O_4$, is formed, together with benzaldehyde, benzoic acid, and oxalic acid, when cinnamic acid is oxidised with potassium permanganate. It crystallises from water in colourless plates, and melts at 141—142° with slight decomposition (compare Lipp, Abstr., 1883, 994), not at about 117° as stated by Anschütz and Kinnicutt (Abstr., 1879, 644); it is not acted on by boiling dilute hydrochloric acid. The barium salt, $(C_9H_9O_4)_2Ba + 2H_2O$, is amorphous, but the calcium salt crystallises in lustrous plates with 4 mols. H_2O, and the silver salt in small needles. F. S. K.

Oxidation of Phenylisocrotonic Acid. By R. Fittig and P. Obermüller (*Annalen*, **268**, 44—50; compare this vol., p. 956).—*Phenylhydroxybutyrolactone*, $O<\begin{matrix}CHPh-\\CO\cdot CH_2\end{matrix}>CH\cdot OH$, prepared by oxidising phenylisocrotonic acid, and boiling the product with dilute hydrochloric acid, crystallises from ether in colourless needles containing $\frac{1}{2}$ mol. H_2O, and loses its water at 100°, or over sulphuric acid; the air-dried lactone melts at 76°. It is readily soluble in hot water, alcohol, and chloroform, but rather sparingly in ether, and almost insoluble in carbon bisulphide; it is not decomposed by boiling water.

Phenyldihydroxybutyric acid, $OH\cdot CHPh\cdot CH(OH)\cdot CH_2\cdot COOH$, is obtained when the lactone is boiled with barium hydroxide and the salt thus formed decomposed with dilute hydrochloric acid; it separates from ether in colourless, monosymmetric crystals, $a : b : c = 1\cdot5369 : 1 : 1\cdot7226$, $\beta = 79° 36'$, melts at 117°, and is readily soluble in alcohol, but rather sparingly in ether, chloroform, carbon bisulphide, light petroleum, and benzene. It dissolves freely in water, and on boiling the solution, especially after adding a few drops of hydrochloric acid, it is converted into phenylhydroxybutyrolactone; the same change takes place when the acid is heated at 100°. The *barium* salt, $(C_{10}H_{11}O_4)_2Ba + H_2O$, crystallises in small, nacreous plates, and is only moderately easily soluble in cold water, and very sparingly in alcohol. The *calcium* salt crystallises in lustrous plates with 1 mol. H_2O. The *silver* salt, $C_{10}H_{11}O_4Ag$, is a colourless, flocculent compound. F. S. K.

Oxidation of Hydrocinnamenylacrylic Acid. By R. Fittig and E. Mayer (*Annalen*, **268**, 50—54; compare this vol., p. 956).—*Phenylhydroxyvalerolactone*, $C_{11}H_{12}O_3$, is produced by the oxidation of hydrocinnamenylacrylic acid. It crystallises from a mixture of chloroform and light petroleum in lustrous, hexagonal plates, melts at 61·5°, and is almost insoluble in light petroleum, very sparingly soluble in cold water, but moderately in hot water, and readily in chloroform and benzene. When the lactone is boiled with bases, it is converted into salts of *phenyldihydroxyvaleric acid*; the acid itself is crystalline, but is very unstable. The *barium* salt, $(C_{11}H_{13}O_4)_2Ba$, crystallises from hot water in lustrous plates, and is rather sparingly soluble in cold water. The *calcium* salt, with 1 mol. H_2O, forms spherical

aggregates, and effloresces in dry air. The *silver* salt, $C_{11}H_{13}O_4Ag$, crystallises from boiling water in small, lustrous needles.

F. S. K.

Decomposition of Phenyldibromobutyric Acid. By R. Fittig, P. Obermüller, and C. Schiffer (*Annalen*, **268**, 71—86; compare this vol., p. 959).—*Phenylbromobutyrolactone*, $\begin{matrix}CO\text{———}O\\ |\\ CH_2{\cdot}CHBr\end{matrix}>CHPh$, is produced when phenyldibromobutyric acid (m. p. 138°) is boiled for a short time with water. It separates from carbon bisulphide in large, monosymmetric crystals, $a : b : c = 0{\cdot}5883 : 1 : 0{\cdot}7897$, $\beta = 64° 44'$, melts at 70°, and is readily soluble in alcohol, ether, benzene, chloroform, and carbon bisulphide, but only sparingly in light petroleum or cold water. When boiled with water for about an hour, it is converted into benzoylpropionic acid (m. p. 116°), identical with the compound described by Fittig and Leoni (Abstr., 1890, 895).

When phenyldibromobutyric acid is treated with a slight excess of sodium carbonate, and the solution kept at the ordinary temperature for some time, there are formed phenylbromobutyrolactone (m. p. 70°), phenylisobromobutyrolactone, and phenylisohydroxybutyrolactone, together with yellow or reddish-brown products which could not be obtained in crystals; the relative quantity of these products depends to a considerable extent on the amount of sodium carbonate used and on the duration of the experiment.

Phenylisobromobutyrolactone, $C_{10}H_9BrO_2$, separates from hot carbon bisulphide in lustrous needles, and from the cold solvent in well-defined, transparent, monosymmetric crystals,

$$a : b : c = 1{\cdot}5587 : 1 : 1{\cdot}8056, \beta = 81° 12',$$

melts at 76°, and is gradually converted into benzoylpropionic acid by boiling water.

Phenylisohydroxybutyrolactone, $C_{10}H_{10}O_3$, separates from ether in monosymmetric crystals, $a : b : c = 2{\cdot}2566 : 1 : 3{\cdot}0965$, $\beta = 66° 34'$, melts at 93—94°, and is readily soluble in alcohol, chloroform, and benzene, but only moderately in ether, and very sparingly in cold water; it dissolves slowly in cold sodium carbonate, and separates again unchanged on the addition of hydrochloric acid. *Barium phenylisodihydroxybutyrate*, $(C_{10}H_{11}O_4)_2Ba$, prepared by boiling the isohydroxylactone with barium hydroxide, is a microcrystalline powder, very sparingly soluble in hot water.

F. S. K.

Decomposition of Phenyldibromovaleric Acid. By R. Fittig and J. Stern (*Annalen*, **268**, 86—92; compare this vol., p. 959).—*Phenylbromovalerolactone*, $C_{11}H_{11}BrO_2$, prepared by treating phenyldibromovaleric acid with a slight excess of sodium carbonate, at the ordinary temperature, crystallises from ether in prisms, melts at 139—140° with decomposition, and is readily soluble in chloroform, but only sparingly in ether, and very sparingly in light petroleum.

Phenylangelicalactone, $C_{11}H_{10}O_2$, is formed, together with phenyllevulinic acid, when the preceding compound is boiled with water for 5—6 hours; it is a yellowish, mobile oil, having a strong, pepper-

mint-like odour, very readily soluble in ether, but only sparingly in water.

Phenyllevulinic acid, $CH_2Ph{\cdot}CO{\cdot}CH_2{\cdot}CH_2{\cdot}COOH$, crystallises from a mixture of chloroform and light petroleum in large, lustrous needles, melts at 55—56°, and is readily soluble in ether, benzene, and carbon bisulphide, but only moderately easily in water and sparingly in light petroleum. The *calcium* salt, $(C_{11}H_{11}O_3)_2Ca$, crystallises from water in small needles containing 6 mols. H_2O, and from alcohol in small plates; it loses the whole of its water at 100°. The *barium* salt, with $1\frac{1}{2}$ H_2O, like the calcium salt, is readily soluble in water, and crystallises in small, spherical aggregates; it loses its water at 120°. The *silver* salt, $C_{11}H_{11}O_3Ag$, separates from hot water in plates, and is very stable in the light. When the acid is treated with sodium amalgam in dilute sulphuric acid solution, and the product then boiled with dilute hydrochloric acid, phenylvalerolactone is formed (compare following abstract). F. S. K.

Hydrocinnamenylacrylic Acid. By R. Fittig and J. Stern (*Annalen*, **268**, 92—96).—*Phenyl-γ-bromovaleric acid*,

$$CH_2Ph{\cdot}CHBr{\cdot}CH_2{\cdot}CH_2{\cdot}COOH,$$

can be obtained by treating hydrocinnamenylacrylic acid with concentrated hydrobromic acid at the ordinary temperature; it separates from a mixture of chloroform and light petroleum in colourless, prismatic crystals, melts at 58—59°, and is readily soluble in carbon bisulphide, benzene, and chloroform, but only very sparingly in cold light petroleum.

Phenylvalerolactone, $\begin{matrix} CO—O \\ | \\ CH_2{\cdot}CH_2 \end{matrix}>CH{\cdot}CH_2Ph$, is formed when the preceding compound is heated with water for a short time, or treated with sodium carbonate at the ordinary temperature; it crystallises from chloroform in thick plates, melts at 33°, and is readily soluble in carbon bisulphide and chloroform, and moderately easily in hot water, but only very sparingly in light petroleum; it has a peppermint-like odour. *Barium phenylhydroxyvalerate*, $(C_{11}H_{13}O_3)_2Ba$, and the corresponding *calcium* salt, obtained by boiling the lactone with barium and calcium hydroxide respectively, are colourless, amorphous powders, soluble in alcohol and water. The *silver* salt separates from hot water in plates.

Phenyl-γ-hydroxyvaleric acid, $C_{11}H_{14}O_3$, is obtained when the calcium salt is decomposed with very dilute hydrochloric acid and the solution immediately extracted with ether; it crystallises from warm water in colourless needles, melts at 101—102° with decomposition, and is readily soluble in carbon bisulphide and chloroform, but only sparingly in light petroleum; when kept for a long time over sulphuric acid, or when warmed with dilute acids, it is converted into the lactone. F. S. K.

New Derivatives of Coumarin. By R. Fittig and R. Claus (*Annalen*, **269**, 1—14; compare this vol., pp. 956, 959).—The authors have attempted, but unsuccessfully, to prepare orthohydroxyphenyl-

propiolic acid in order to compare its properties with those of coumarilic acid, $C_6H_4<^{O-}_{CH}>C\cdot COOH$ (compare Fittig and Ebert, *Annalen*, **216**, 162), with which it is isomeric.

Ethylcoumarinic acid dibromide (orthethoxyphenyldibromopropionic acid), prepared as described by Fittig and Ebert (*loc. cit.*), melts at 156—162° with decomposition, according as it is slowly or quickly heated, and separates from carbon bisulphide in large, colourless, seemingly rhombic crystals.

Orthethoxy-α-bromocinnamene, $OEt\cdot C_6H_4\cdot CH:CHBr$, is formed, together with a small quantity of ethylcoumaric acid and ethoxyphenylacetylene, when ethylcoumarinic acid dibromide is boiled with water for a short time; it is an almost colourless oil of sp. gr. 1·360 at 17°, quickly turns yellow when kept, and boils at 144—147° under a pressure of 15 mm.; it is insoluble in water, but miscible with alcohol, ether, and carbon bisulphide. The *tribromide*, $C_{10}H_{11}OBr_3$, prepared by treating ethoxybromocinnamene with bromine in carbon bisulphide solution, crystallises from alcohol in large, colourless prisms, melts at 51°, and is readily soluble in alcohol, ether, benzene, and carbon bisulphide.

Orthethoxyphenylpropiolic acid, $OEt\cdot C_6H_4\cdot C:C\cdot COOH$, can be obtained by boiling orthethoxyphenyldibromopropionic acid with alcoholic potash. It crystallises from water in slender needles, melts at 112—112·5° with decomposition, and is only sparingly soluble in cold, but moderately easily in boiling, water, the hot solution having an intensely irritating odour; it dissolves freely in ether and alcohol. The *calcium* salt, $(C_{11}H_9O_3)_2Ca + 2H_2O$, crystallises from water in colourless prisms, and is only sparingly soluble in cold water; it does not lose its water at 150°, and at 160° it decomposes and turns brown. The *barium* salt, $(C_{11}H_9O_3)_2Ba + 4H_2O$, is a hygroscopic substance, readily soluble in hot alcohol, from which it crystallises in large, colourless prisms; when dried over sulphuric acid, the crystrals effloresce, and then seem to contain 4 mols. H_2O.

Orthethoxyacetophenone, $OEt\cdot C_6H_4Ac$, is produced, together with orthethoxyphenylchloracrylic acid, when ethoxyphenylpropiolic acid is boiled with moderately concentrated (1 : 1) hydrochloric acid; it crystallises from boiling water in thin, broad prisms, melts at 38·5—39·5°, is volatile with steam, and is readily soluble in alcohol and ether, but only very sparingly in water.

Orthethoxyphenylchloracrylic acid, $OEt\cdot C_6H_4\cdot CCl:CH\cdot COOH$, crystallises from water, in which it is moderately easily soluble, in small, colourless needles melting at 108—109°; it is slowly decomposed by boiling dilute hydrochloric acid, being converted into ethoxyacetophenone, and, on reduction with sodium amalgam, it yields orthethoxyphenylpropionic acid (m. p. 80—81°).

Ethoxyphenylacetylene, $OEt\cdot C_6H_4\cdot C:CH$, is formed when sodium ethoxyphenylchloracrylate is boiled with water, and when ethoxyphenylpropiolic acid is heated with water at 140—150°; it is also produced in small quantities in the preparation of ethoxybromocinnamene in the manner described above. It is a colourless oil, and gives with an alcoholic ammoniacal solution of silver nitrate a colour-

less, crystalline compound of the composition $C_{10}H_9OAg$, which is stable in the light. F. S. K.

Ellagic Acid. By G. Goldschmiedt and R. Jahoda (*Monatsh.*, **13**, 49—57).—Zölffel (Abstr., 1891, 918) and Schiff state that this acid gives a tetracetyl derivative, when digested with acetic anhydride, whilst Barth and Goldschmiedt (*Ber.*, **11**, 846) describe the product as a pentacetyl derivative. In order to determine which of these statements is correct, the authors have prepared the acetyl compound, and submitted it to analysis by three different methods, including those used by the investigators named above; the results, however, obtained by those processes give widely varying numbers. When heated with a large excess of benzoic chloride, ellagic acid gives a well-characterised benzoyl derivative, which forms a yellowish-white, crystalline powder, contains four benzoyl groups, and is unchanged when again heated with benzoic chloride at 295—300°. It follows, therefore, that ellagic acid contains only four hydroxyl groups. G. T. M.

Ethylpseudocumene and the Action of Sulphuric Acid on it. By A. Töhl and D. v. Karchowski (*Ber.*, **25**, 1530—1533).—*Ethylpseudocumene*, $C_6H_2Me_3Et$ [$Me_3 : Et = 1 : 2 : 4 : 5$], was prepared by treating the bromopseudocumene, melting at 72—73° with ethyl bromide and sodium. It boils at 206—208°, and a further proof of its constitution is that, when oxidised with dilute nitric acid, it yields durylic acid, melting at 148°. When treated with excess of bromine in the presence of iodine, it yields *dibromethylpseudocumene*, which crystallises from alcohol, in which it is sparingly soluble, in needles melting at 218°.

When treated with strong sulphuric acid, much remains unaltered, but an *ethyltrimethylbenzenesulphonic acid* is formed, whose *barium salt*, $(C_{11}H_{15}\cdot SO_3)_2Ba$, crystallises with 1 mol. H_2O, and whose *sulphonamide* melts at 153°. This sulphonic acid is probably derived from the original hydrocarbon, for, when its sodium salt is heated at 180° with strong hydrochloric acid, a hydrocarbon is obtained, which boils at 206—209°, and yields a dibromo-derivative melting at 217—218°, showing that it is ethylpseudocumene. When ethylpseudocumene is treated with chlorosulphonic acid, another *ethyltrimethylbenzenesulphonic acid* is formed, whose *potassium*, $C_{11}H_{15}\cdot SO_3K$, and *barium* $(C_{11}H_{15}\cdot SO_3)_2Ba$, *salts* crystallise with 1 and 3 mols. H_2O respectively, and whose *sulphonamide* melts at 86°. It is, therefore, not identical with the above-mentioned isomeric sulphonic acid, but is probably the second sulphonic acid theoretically obtainable from ethylpseudocumene.

Sulphuric acid thus causes no shifting of the side groups of ethylpseudocumene (as it does in the case of durene; compare this vol., p. 968), but only forms an ethylpseudocumenesulphonic acid. C. F. B.

Aromatic Thiosulphonates. By R. Otto and E. Heydecke (*Ber.*, **25**, 1477—1483).—*Ethylene paratoluenethiosulphonate*, $(C_7H_7\cdot SO_2S)_2C_2H_4$,

is prepared by heating ethylene bromide with potassium paratoluenethiosulphonate in molecular proportion, in alcoholic solution, in a reflux apparatus; it is readily soluble in benzene or ether, and crystallises from alcohol in colourless plates which melt at 76—77°, and probably belong to the monosymmetric system; on heating with potash, the compound yields potassium ethylenedisulphinate, potassium toluenesulphinate, and diethylene tetrasulphide, the formation of the latter compound being preceded by that of ethylene mercaptan. On heating the ethereal salt with potassium sulphide, diethylene tetrasulphide, ethylene mercaptan, and potassium toluenethiosulphonate are formed; whilst with zinc and hydrochloric acid in alcoholic solution, ethylene mercaptan, toluenesulphinic acid, and toluene hydrogen sulphide are produced. By the action of zinc dust and alcohol at 150° on the ethereal salt, the zinc compounds of ethylene mercaptan and toluenesulphinic acid are obtained.

Ethylene benzenethiosulphonate crystallises, in all probability, in the monosymmetric system; by the action of bromine in aqueous or alcoholic solution, ethylenedisulphonic acid and benzenesulphonic acid, together with a little sulphuric acid, are formed. J. B. T.

Products from Indigo-blue. By C. O'Neill (*Chem. News*, **65**, 124).—When pure indigo-blue is treated with 20—30 times its weight of glacial acetic acid and gradually with about $\frac{1}{4}$ its weight of permanganate or a corresponding quantity of lead or manganese peroxide, the mass thickens, the blue disappears, and by filtering, washing, and drying in a vacuum, or at 20—25° in the air, a crystalline substance is obtained in quantities amounting to 140 per cent. of the indigo used; this the author terms "*oxyacetoindigotin*." This compound is insoluble in all solvents; is permanent in dry air and, in the cold, in most neutral, acid, and oxidising agents, but is attacked by alkalis and decomposed by heat, yielding, in the presence of moisture, acetic acid, isatin, indigo, and an oxidised product, crystallising from chloroform in silky, golden-yellow crystals, slightly soluble in water, and, unlike isatin, soluble in carbon bisulphide. In dry heat, oxyacetoindigotin loses 31—32 per cent. of its weight, and is resolved into glacial acetic acid, indigo, and a resinous substance soluble in chloroform. With sodium hydroxide in the cold, oxyacetoindigotin yields indigo, sodium acetate, and a salt of an acid, indigotic acid, $C_{32}H_{28}N_4O_{12}$, which separates from alcohol in brilliant crystals; it can also be crystallised from hot water, although 1000 parts of cold water are required for its solution. It decomposes at 240°, yielding, among other products, aniline. It is polybasic, and, of two sodium salts, $C_{32}H_{26}Na_2N_4O_{12}$ and $C_{32}H_{27}NaN_4O_{12}$, the former is very soluble and not crystalline, the latter is less soluble and crystallises well from water. When heated with glacial acetic acid, oxyacetoindigotin is decomposed into acetic acid, indigo, and brilliant, yellow crystals, containing a new substance of the composition C_8H_3NO. D. A. L.

Indigo-green. By V. H. Soxhlet (*Chem. Zeit.*, **15**, 913—914).—The author, some time ago, was engaged in the commercial testing of some indigo-carmines, when, by accident, some indigo solution

got mixed with a considerable quantity of ammonia. Fortunately, this mixture was not thrown away, but corked up and put aside: after the interval of a fortnight, it was noticed that the colour was not, as might have been expected, a dark blue, but had changed to a yellowish-green.

It was evident that the liquid contained several colouring matters, and this was confirmed by the simple, well-known device of dropping some of it on blotting-paper. On consulting the literature on the subject, the author came to the conclusion that the only substance which bears a certain resemblance to the compound is Berzelius' viridinesulphonate; this, although a green colouring matter, is only soluble in absolute alcohol, and has, as yet, found no technical application.

The author now weighed off equal portions of indigocarmine and put them into bottles containing increasing quantities of ammonia, where they were allowed to remain for about 10 days. It now appeared that those portions which contained the largest quantity of ammonia had the purest green tinge, whilst the others had still a good deal of blue shade about them. It was not to be expected that the green colouring matter in its alkaline state would be able to dye wool, and this was confirmed by an experiment on the small scale. A portion of the solution was now faintly acidified with dilute sulphuric acid and then mixed with brine of 1·1 sp. gr. The filtrate was pale green, with a reddish reflex, not at all unlike Berzelius' viridinesulphonic acid. The paste obtained resembles commercial indigocarmine in appearance, without, however, showing the coppery lustre. In warm water it is readily soluble, and woollen threads immersed in the hot solution look as if they have been dyed with methyl-green and show well by artificial light. The dying process proceeds very regularly, in fact better than with the indigo preparations. The goods, moreover, resist the action of alkalis and soap better, although experiments in this direction must still be carried out on the large scale.

In trying to prepare large quantities of indigo-green, the author used the dry commercial indigo extract such as is manufactured and used in England. This is easier to mix with the ammonia than the pasty product, and it also contains less free acid.

The prolonged action of ammonia does not yield a superior product, but rather the reverse. The author thinks that his indigo-green is composed of at least two colouring matters, a yellow and a green dye. L. DE K.

Formation of Closed Chain Compounds by the Elimination of Bromine from the Benzene Nucleus. By W. R. CATHCART, Jun., and V. MEYER (*Ber.*, **25**, 1498—1500).—*Orthobromobenzophenone*, C_6H_4BrBz, prepared by the mutual action of orthobromobenzoic chloride, benzene, and aluminium chloride, melts at 42°; by the action of hydroxylamine hydrochloride, the corresponding hydroxime is formed, but with hydroxylamine in alkaline solution an isoxazole derivative is obtained which readily crystallises, melts at 83—84°, and in small quantities may be distilled without decomposi-

tion; it does not combine with alkalis. The compound has the formula $C_6H_4<\overset{O\cdot N}{\underset{C\,Ph}{\|}}$, and on account of its relation to indene the authors propose to term the complex $C_6H_4<\overset{O}{C}>N$, *indoxazene*.

The hydroximes of the following symmetrical compounds only exist in one form, meta- and para-dibromo-, paradichloro-, paradiiodo-, paradimethyl-, and paradimethoxy-benzophone. J. B. T.

Synthesis of Symmetrical Triphenylbenzene. By M. Delacre (*Bull. Acad. roy. Belg.* [3], **22**, 470—502).—*Dypnopinacone*, $C_{32}H_{28}O_2$, is obtained by heating a mixture of zinc ethyl and dypnone, CMePh:CH·COPh, dissolved in anhydrous ether, but it is most conveniently prepared by gently heating on the water-bath in a reflux apparatus a mixture of zinc ethyl (20 grams), acetophenone (30 grams), and anhydrous ether (200 grams). If the operation is conducted too vigorously, α-dypnopinacolin is obtained. As soon as effervescence commences, the source of heat is removed, and the heating only resumed after some hours. At the end of two or three days, the mixture no longer fumes; the ether is then distilled off, the residue heated at the full temperature of the water-bath for some time, recohobated with ether, and the residue, after distilling off the latter, treated with dilute acid and crystallised from alcohol (500 c.c.); the compound forms white needles, melts at 160·5—161°, and is sparingly soluble in ether and cold alcohol, more readily so in benzene. When the alcohol is distilled from the mother liquor, two isomeric dypnopinacolins and an organo-zinc compound melting at 118°, which is being investigated, may be isolated. The alcoholic character of dypnopinacone is little pronounced, and attempts to prepare an acetyl derivative were unsuccessful; alcoholic potash converts it into an acid and a hydrocarbon of the type of triphenylmethane; when heated with glacial acetic acid, an intensely yellow solution results, from which α-dypnopinacolin separates on cooling; the same compound is obtained by the action of acetic anhydride, acetic chloride, and phosphorus trichloride; in the two last cases, however, "ψ-dypnopinacolin" is also produced; phosphorus pentachloride gives α-dypnopinacolin and dehydrodypnopinacolin; whilst, on fusion or by treatment with zinc ethyl, it yields α-dypnopinacolin, and an isomeride (m. p. 177°). When dypnopinacone is distilled under a pressure of 15 mm., a mixture of acetophenone, dypnone, a crystalline hydrocarbon (m. p. 106—107°), and water pass over below 250°, whilst symmetrical triphenylbenzene remains. Dypnopinacone has probably the constitution

$$\begin{matrix}CH_2\cdot CPh{:}CH\cdot CPh\cdot OH\\ |\qquad\qquad\quad |\\ CH_2\cdot CPh{:}CH\cdot CPh\cdot OH\end{matrix}$$

α-Dypnopinacolin, $C_{32}H_{26}O$, is obtained, as already stated, by treating dypnopinacone with glacial acetic acid, but to avoid the production of a trace of the isomeride (m. p. 177°), it is advisable to heat cautiously. It forms brilliant sulphur-yellow crystals, melts at

133·5—134°, and is readily soluble in hot glacial acetic acid, sparingly so in the cold liquid, alcohol, and ether. When heated on the water-bath with phosphorus trichloride, or in a closed vessel at 100° with dilute hydrochloric acid, or when a current of hydrogen chloride is passed through the fused substance, β-dypnopinacolin (m. p. 140·5—141°) is produced. The same compound is obtained by heating the α-derivative in a sealed tube at 150—180°, as also by boiling it with 10 per cent. alcoholic potash; it does not react with alcoholic hydroxylamine. When equal weights of α-dypnopinacolin, dissolved in benzene, and phosphorus pentachloride are heated together on the water-bath for several hours, dehydrodypnopinacolin (see below) is obtained. The α-modification is instantly converted into the β-derivative when its solutions are heated with mineral acids; whilst by heating them with nitric acid oxidation derivatives of the β-compound are obtained. When α-dypnopinacolin is distilled under diminished pressure, it decomposes into symmetrical triphenylbenzene and acetophenone. The author suggests the following constitution for α-dypnopinacolin, $\begin{matrix}CH_2\cdot CPh{:}CH\\ CH_2\cdot CPh{:}CH\end{matrix}>CPh\cdot COPh$. The argument used in support of the symmetrical constitution of β-benzopinacolin (Abstr., 1891, 456) applies also in the case of α-dypnopinacolin.

α-Dypnopinacolin alcohol, $\begin{matrix}CH_2\cdot CPh{:}CH\cdot CPh\cdot OH\\ CH_2\cdot CPh{:}CH\cdot CHPh\end{matrix}$, is prepared by heating a mixture of dypnopinacolin (4·6 grams) and zinc ethyl (11 grams) on the water-bath for four days; ethylene passes off during the reaction, and the product is treated with dilute acid, and crystallised from alcohol, when it is obtained in large, white crystals, and melts at 138·5—139°. It reacts with acetic chloride forming *dypnopinacolene*, $\begin{matrix}CH_2\cdot CPh{:}CH\cdot CPh\\ CH_2\cdot CPh{:}CH\cdot CPh\end{matrix}$. The latter is obtained when a mixture of dypnone (40 grams) and zinc ethyl (20 grams) is heated on the water-bath for three days; it crystallises from alcohol in white, nacreous scales, melts at 95·5—96°, and, when distilled at the ordinary pressure, decomposes into symmetrical triphenylbenzene and phenylethylene.

β-Dypnopinacolin, $\begin{matrix}CH_2\cdot CPh{:}CH\cdot CPh\\ CH_2\cdot CPh{:}CH\cdot CPh\end{matrix}>O$, is prepared from the α-derivative as above described; it separates from alcohol or acetic acid in well-formed crystals, melts at 140·5—141°, does not react with phenylhydrazine or hydroxylamine, and only reacts with zinc ethyl when heated at 180—200°, giving rise to oily products. When it is distilled under diminished pressure, it decomposes into the same products as the α-derivative, and, on heating it for three hours in a reflux apparatus with alcoholic potash at 180°, it decomposes into benzoic acid and a hydrocarbon, $\begin{matrix}CH_2\cdot CPh{:}CH\\ CH_2\cdot CPh{:}CH\end{matrix}>CHPh$, melting at 95·5°; whilst on heating it in a sealed tube with a large excess of alcoholic potash at 200—210°, a hydrocarbon is produced which crystallises from alcohol in prisms, melts at 145°, and probably has the constitution $CHPh(CH{:}CMePh)_2$.

Dehydrodypnopinacoline, $C_{32}H_{24}O$, is obtained when a few drops of nitric acid are added to a solution of *β*-dypnopinacolin in glacial acetic acid; it crystallises from alcohol in white, satiny tufts, melts at 186·5—187°, distils under diminished pressure at a very high temperature without decomposition, does not react with phenylhydrazine or hydroxylamine, and resists the action of those reagents which attack the dypnopinacolins. It gives dypnopinacolene (see above) when heated with hydriodic acid at 200°, and its constitution is represented by one of the following formulæ, $\begin{matrix}CH\cdot CPh{:}CH\cdot CPh\\ \|\quad\quad\quad\quad|\\ CH\cdot CPh{:}CH\cdot CPh\end{matrix}>O$ or $\begin{matrix}CH_2\cdot CPh{:}C\cdot CPh\\ |\quad\quad\quad\quad|\\ CH_2\cdot CPh{:}C\cdot CPh\end{matrix}>O$. Further experiments are in progress.

A. R. L.

Action of Phenylhydrazine on Unsaturated γ-Diketones. By F. Klingemann (*Annalen*, **269**, 104—130).—The author has studied the action of phenylhydrazine on Zinin's "acicular oxylepidene," a compound which has been shown by Magnanini and Angeli (Abstr., 1889, 729) to be *αβ*-dibenzoylstilbene, CPhBz:CPhBz; the action of phenylhydrazine on *αβ*-dibenzoylcinnamene has been previously investigated by Japp and Huntly (Trans., 1888, 184) and by Japp and the author (Trans., 1890, 671).

Two compounds are formed when dibenzoylstilbene is heated at 100° with an equal weight of phenylhydrazine in alcoholic solution; on boiling the brown, oily product with alcohol, a lemon-yellow powder of the composition $C_{34}H_{26}N_2$ is precipitated, and the filtered solution, on evaporation, yields an orange, crystalline compound of the composition $C_{34}H_{28}N_2O$, which melts at 201° with decomposition, and dissolves in concentrated sulphuric acid with a reddish-brown coloration. The yellow powder is in all probability *anilidotetraphenylpyrroline*, $\begin{matrix}CPh{:}CPh\\ |\quad\quad|\\ CPh{:}CPh\end{matrix}>N\cdot NHPh$; it separates from alcohol in microscopic crystals, melts at 207°, and dissolves in concentrated sulphuric acid with a green coloration; when submitted to dry distillation, it yields three compounds, one of which only was analysed, and found to be a tetraphenylpyrroline (m. p. 206—207°), identical with the compound described by Garrett (Abstr., 1889, 162) and by Fehrlin (Abstr., 1889, 623).

At least two compounds are formed when a glacial acetic acid solution of phenylhydrazine is gradually added to a boiling glacial acetic acid solution of dibenzoylstilbene, and the mixture boiled for 10 minutes; on neutralising the cold diluted acetic acid solution with soda, a precipitate is produced which is partially soluble in boiling alcohol. The insoluble, almost colourless residue does not melt at 340°, and is insoluble in all ordinary solvents except acetic acid, with which it seems to form a salt; its composition may be approximately represented by the formula $C_{12}H_9NO$, but it is possibly a mixture. The reddish-brown alcoholic solution contains a compound of the composition $C_{27}H_{22}N_2$; this substance crystallises from ethyl acetate, in which it is moderately easily soluble, in small four-sided, yellowish-brown plates, melts at 212—213°, and is probably a

dihydrotetraphenylpyrazole. When the acetic acid solution referred to above is neutralised with ammonia instead of with soda, neither of the compounds just described is precipitated, but in their place a yellow substance of the composition $C_{34}H_{28}N_2O$ is obtained; this compound separates from a mixture of ethyl acetate and light petroleum in yellow needles, melts at 196° with decomposition, and gives no coloration with concentrated sulphuric acid.

$\alpha\beta$-Dibenzoylcinnamene and phenylhydrazine interact in boiling acetic acid solution yielding a yellow, amorphous powder of the composition $C_{36}H_{30}N_4O$, melting at 110—120° with decomposition, and a compound of the composition $C_{28}H_{22}N_2$, identical with the substance previously described by Japp and Huntly (*loc. cit.*).

The bidesyls do not react with phenylhydrazine in alcoholic or in glacial acetic acid solution; diphenyldinitrosacyl and its isomeride (compare Hollemann, Abstr., 1888, 275; 1889, 49) are both readily decomposed by phenylhydrazine yielding the hydrazide of benzoic acid. F. S. K.

Amidonaphtholsulphonic Acids. By F. Reverdin and C. de la Harpe (*Ber.*, **25**, 1400—1409).—By warming amidonaphtholsulphonic acid [OH : NH_2 : SO_3H = 1 : 2 : 4], dissolved in sodium carbonate, on the water-bath in the presence of air, a violet dye is obtained which dyes wool black in an acid bath, and is very stable towards soap and light. A dye having the same properties is obtained by sulphonating the oxidation product of amidonaphthol described by Liebermann under the name imidoxynaphthalene. The authors have examined a series of amidonaphtholsulphonic acids, and determined the nature of the dyes formed from each.

Of α-naphthol derivatives, only those which contain the hydroxyl group in the ortho-position to the amido-group give violet-black dyes similar to that obtained from the 1 : 2 : 4-amidonaphtholsulphonic acid. Those sulphonic acids which contain hydroxyl in the para-position to the amido-group yield brown dyes which are of no value.

Of β-naphthol derivatives, those which contain the hydroxyl group in the ortho-position to the amido-group yield dyes which dye wool in an acid bath a reddish-brown shade, and dye cotton mordanted with metallic bases grey to greyish-green. The amidonaphtholsulphonic acid [OH : NH_2 : SO_3H = 2 : 1 : 5] yields a dye which imparts a yellowish-brown shade to wool, and is not fixed by metallic mordants. The disulphonic acid [NH_2 : OH : SO_3H : SO_3H = 1 : 2 : 3 : 3′] yields no dye. The disulphonic acid

$$[NH_2 : OH : SO_3H : SO_3H = 1 : 2 : 1' : 2']$$

yields a small quantity of a dye which dyes wool a dirty reddish-violet shade. E. C. R.

Pinylamine. By O. Wallach and G. Lorentz (*Annalen*, **268**, 197—210; compare Abstr., 1890, 1316; 1891, 1078).—Pinylamine, when freshly prepared, is a thick, colourless oil, but, unless kept in sealed vessels, it soon turns yellow, and decomposes with liberation of ammonia; its sp. gr. is 0·943 at 17°, and it dissolves freely in

alcohol, ether, and chloroform, but is almost insoluble in water. The *hydrochloride*, $C_{10}H_{15}\cdot NH_2,HCl$, crystallises from water in needles, melts at 229—230° with decomposition, and is very readily soluble in water and alcohol, but insoluble in ether. The *platinochloride*, $(C_{10}H_{15}\cdot NH_2)_2,H_2PtCl_6$, forms yellow plates or needles, and decomposes when heated above 200°, but without melting; it dissolves freely in alcohol, but is only sparingly soluble in water. The *nitrate*, $C_{10}H_{15}\cdot NH_2,HNO_3$, crystallises from dilute alcohol in long, colourless needles, and is very sparingly soluble in cold water, but more readily in alcohol. The *sulphate*, $(C_{10}H_{15}\cdot NH_2)_2,H_2SO_4$, forms small needles, and decomposes at a temperature above 200°, but without melting. The *thiocyanate*, $C_{10}H_{15}\cdot NH_2,HCNS$, separates from water in well-defined, colourless prisms, melts at 135—136°, and is readily soluble in alcohol and ether, but more sparingly in water. The *oxalate*, $(C_{10}H_{15}\cdot NH_2)_2,H_2C_2O_4$, melts at 247—248° with decomposition, and is only very sparingly soluble in almost all ordinary solvents. The *picrate* crystallises in small, yellow needles, and dissolves freely in hot water, alcohol, and ether. The *acetyl* derivative, $C_{10}H_{15}\cdot NHAc$, separates from hot light petroleum and from alcohol in colourless crystals which melt at 108—109°, and are insoluble in water. The *benzoyl* derivative, $C_{10}H_{15}\cdot NHBz$, crystallises from hot light petroleum and glacial acetic acid in small, colourless needles melting at 125°.

Pinylcarbamide, $C_{10}H_{15}\cdot NH\cdot CO\cdot NH_2$, prepared by treating pinylamine hydrochloride with potassium cyanate in aqueous solution, crystallises in long, colourless needles, melts at 156°, and is almost insoluble in water and ether, but readily soluble in alcohol.

Benzylidenepinylamine, $C_{10}H_{15}\cdot N{:}CHPh$, the condensation product of the amine and benzaldehyde, separates from alcohol in crystals, melts at 52—53°, and decomposes on keeping.

Furfuropinylamine, $C_{10}H_{15}\cdot N{:}CH\cdot C_4H_3O$, separates from alcohol in crystals melting at 80—81°.

Parahydroxybenzylidenepinylamine, $C_{10}H_{15}\cdot N{:}CH\cdot C_6H_4\cdot OH$, obtained from pinylamine and salicylaldehyde, forms lustrous, yellow crystals, and melts at 108—109°.

When anhydrous pinylamine hydrochloride is submitted to dry distillation, it is decomposed into ammonium chloride, cymene, and a small quantity of a compound boiling at 200—208°, which has the composition $C_{10}H_{16}O$, and from which a crystalline oxime, $C_{10}H_{16}\cdot NOH$, melting at 87—88°, can be obtained. F. S. K.

Constitution of Pinene. By O. Wallach (*Annalen*, **268**, 210—216).—The author replies to the criticisms of Wagner (Abstr., 1891, 1242), and maintains that the formula which Wagner assigns to pinene does not explain the reactions of the compound as well as that previously put forward by the author (Abstr., 1891, 1081); nevertheless, the latter is to be regarded simply as the best representation which can at present be given, and not as a final expression of the truth. F. S. K.

Nitrolamines of Pinene. By O. Wallach and E. Früstück (*Annalen*, **268**, 216—225).—Primary fatty amines interact readily

with pinene nitrosochloride in moderately concentrated warm alcoholic solution, and on pouring the mixture into water, the nitrolamine is precipitated as an oil, which solidifies after some time, and can then be recrystallised from dilute alcohol; the following compounds were prepared in this way:—

Pinenenitrolpropylamine, $NHPr{\cdot}C_{10}H_{16}{\cdot}NO$, separates from dilute alcohol in colourless crystals melting at 96°.

Pinenenitrolamylamine, $C_5H_{11}{\cdot}NH{\cdot}C_{10}H_{16}{\cdot}NO$, crystallises in colourless plates, and melts at 105—106°.

Pinenenitrolallylamine, $C_3H_5{\cdot}NH{\cdot}C_{10}H_{16}{\cdot}NO$, separates from 90 per cent. alcohol in crystals which melt at 94°, and contain 1 mol. C_2H_6O. When treated with a molecular proportion of bromine in sulphuric acid solution, it yields a crystalline compound melting at 138—139°, which has the composition $C_3H_6Br{\cdot}NH{\cdot}C_{10}H_{16}{\cdot}NO$; when hydrogen bromide is passed into a dry, ethereal solution of the nitrolamine, the *hydrobromide* is deposited in colourless needles melting at 147°, and readily soluble in water; on treating the nitrolamine with bromine in well-cooled glacial acetic acid solution, there is formed a colourless, crystalline compound which melts at 163—164°, and has the composition $C_3H_5Br_2{\cdot}NH{\cdot}C_{10}H_{16}{\cdot}NO,HBr$.

When pinenenitrolbenzylamine is heated at 160—180° in a stream of hydrogen, benzylamine distils, and there remains a solid substance, which is almost insoluble in the usual solvents, and which melts only at a temperature above 300°; this solid product has the composition $C_{10}H_{15}NO$, and is probably a polymeride of nitrosopinene, identical with the compound obtained by Tilden (Trans., 1875, 517), by heating nitrosopinene with benzene or oil of turpentine at 180°. Pinenenitrolallylamine undergoes a similar decomposition at 150—160°.

F. S. K.

Preparation of Pinole Glycol and its Derivatives. By O. Wallach and E. Früstück (*Annalen*, **268**, 222—225).—Pinole glycol diacetate (Abstr., 1891, 217) can be easily obtained by heating pinole dibromide with lead acetate in glacial acetic acid solution at 150°; pinole glycol can be prepared directly from the bromide by boiling the latter with freshly precipitated lead hydroxide and water for several hours, and then extracting the filtered solution with chloroform.

Pinole glycol dipropionate, $(C_2H_5{\cdot}COO)_2C_{10}H_{16}O$, prepared by heating a propionic acid solution of the dibromide with silver propionate, or by warming the glycol with propionic anhydride, melts at 106°, and is insoluble in water.

When pinole dibromide is heated at 100° for three hours with formic acid, it is converted into pinene.

F. S. K.

Tetrahydropinene. By O. Wallach and A. Berkenheim (*Annalen*, **268**, 225—228).—*Tetrahydropinene*, $C_{10}H_{20}$, is formed when hydrochloropinene is reduced with hydriodic acid and amorphous phosphorus at 200°; it boils at 162°, has a sp. gr. of 0·795 at 20°, and its refractive energy is $n_D = 1{\cdot}43701$ at 20°. It is not acted on by a mixture of concentrated nitric acid and sulphuric acid in the cold,

but it is readily oxidised by hot nitric acid yielding oily products; when it is kept in contact with bromine, evolution of hydrogen bromide soon sets in. On prolonged shaking with a warm solution of potassium permanganate, the hydrocarbon is oxidised to carbonic anhydride, oxalic acid, and an acid which, from its smell and an analysis of its silver salt, was thought to be valeric acid. Tetrahydropinene is probably hexahydrocymene, and is doubtless identical with the hydrocarbon obtained by Orlow (*Ber.*, **16**, 799) by the reduction of oil of turpentine. F. S. K.

Nitroketone from Camphosulphophenols. By P. Cazeneuve (*Compt. rend.*, **114**, 838—840). — Amethylcamphophenolsulphone, $C_9H_{12}(SO_2)(OH)_2O$, and amethylcamphophenolsulphonic acid,

$$C_9H_{12}(SO_2{\cdot}OH)(OH)O,$$

when treated with nitric acid, both lose the whole of their sulphur in the form of sulphuric acid, and yield a nitroketone of the composition $C_9H_{11}(NO_2)O$. 10 grams of amethylcamphophenolsulphone is dissolved in 300 grams of hot water, mixed gradually with 20 grams of ordinary nitric acid, and allowed to cool. If the liquid is allowed to boil, the product is decomposed. When the operation is successful, no gas is evolved, and the nitroketone gradually separates as a yellowish oil, which afterwards solidifies. It crystallises from alcohol in golden-yellow needles which melt at 47—48°, sublimes without alteration when heated in small quantity, boils at 260—262° with partial decomposition when heated in large masses, and is volatile in steam. It is only slightly soluble in boiling water, from which it separates in brilliant plates, but is soluble in alcohol, ether, benzene, and other hydrocarbons. It is optically inactive.

The energy of the acid function is comparable with that of carbonic acid. The potassium and ammonium salts crystallise from water, the former in red crystals resembling those of potassium platinocyanide. The calcium, barium, and copper salts are insoluble in water, but soluble in alcohol. The lead, silver, and ferric salts are likewise insoluble, and are prepared by double decomposition. Most of the alkaloïds form resinous, yellow precipitates with a solution of one of the alkaline salts.

Acetic anhydride has no action on the ketone; hydroxylamine yields no oxime, but phenylhydrazine forms a liquid azone. Acetic chloride acts violently on the alkaline salts, and seems to form an acetyl derivative; tin and hydrochloric acid yield a base.

The nitroketone dyes silk yellow without a mordant.

C. H. B.

Action of Phenylhydrazine on Cantharidin. By L. Spiegel (*Ber.*, **25**, 1468—1470).—In the preparation of cantharidinphenylhydrazone (Abstr., 1890, 640), a small proportion of a substance of the composition $C_{16}H_{20}N_2O_4$ is obtained. This compound melts at 194—195°, and is very stable towards chemical reagents, long heating with concentrated hydrochloric acid having no effect on it. By heating it at 110°, it gradually loses weight, until its composition

approximates to that of cantharidinphenylhydrazone, $C_{16}H_{18}N_2O_3$; before it attains this composition, however, decomposition sets in.

The author is investigating the constitution of this substance.

W. J. P.

Compounds of Hydrogen Diaminechromium Thiocyanate with Nitrogenous Bases. By O. T. Christensen (*J. pr Chem.* [2], **45**, 356—376; compare this vol., p. 798).—*Methylamine hydrogen diaminechromium thiocyanate*, $NH_2Me,HSCN,Cr(NH_3)_2(SNC)_3 + H_2O$, is precipitated when a saturated aqueous solution of ammonium diaminechromium thiocyanate is added to a concentrated solution of methylamine hydrochloride; it forms slender, microscopic, red needles, and is sparingly soluble in water, but easily in 96 per cent. alcohol; concentrated ammonia dissolves it slowly, the ammonia replacing the methylamine. *Dimethylamine hydrogen diaminechromium thiocyanate*, $NHMe_2,HSCN,Cr(NH_3)_2(SNC)_3$, is similarly prepared from dimethylamine hydrochloride; it crystallises in microscopic, purple prisms, and is less soluble, both in alcohol and water, than the methylamine salt; it dissolves in concentrated ammonia. The *trimethylamine* salt, $NMe_3,HSCN,Cr(NH_3)_2(SCN)_3$, is sufficiently sparingly soluble in cold water to be precipitated when dilute solutions of trimethylamine hydrochloride and the thiocyanate are mixed; it crystallises in microscopic, purple prisms or hexagonal tables, and is very sparingly soluble in cold 96 per cent. alcohol; it is more soluble in concentrated ammonia than in water, and is ultimately converted thereby into ammonium diaminechromium thiocyanate. The *ethylamine* salt, $NH_2Et,HSCN,Cr(NH_3)_2(SCN)_3$, is precipitated when concentrated solutions of ethylamine hydrochloride and the thiocyanate are mixed and excess of hydrochloric acid is added; it crystallises from hot water in slender, purple needles which dissolve sparingly in cold water, freely in cold alcohol, and not at all in absolute ether. The *amylamine* salt,

$$C_5H_{11}\cdot NH_2,HSCN,Cr(NH_3)_2(SCN)_3,$$

separates from a mixture of concentrated solutions of amylamine hydrochloride and the thiocyanate; it crystallises in microscopic needles and tables, and is very easily soluble in alcohol. It is to be noted that the hydrogen diaminechromium thiocyanates of primary amines are readily soluble in cold 96 per cent. alcohol, while those of secondary amines are less soluble, and those of tertiary amines still less soluble in this solvent; the author suggests this as a practical differentiation.

Aniline hydrogen diaminechromium thiocyanate,

$$NH_2Ph,HSCN,Cr(NH_3)_2(SCN)_3,$$

precipitated from dilute solutions of aniline hydrochloride and the thiocyanate, crystallises from hot alcohol in microscopic, red, rhombic tables; it dissolves sparingly in cold water, but freely in hot water, cold alcohol, and ammonia. The *orthotoluidine* salt,

$$C_6H_4Me\cdot NH_2,HSCN,Cr(NH_3)_2(SCN)_3,$$

forms thin, four-sided, red, rectangular laminæ, and dissolves easily

in hot water and cold alcohol. The *paratoluidine* salt crystallises in lustrous, red, rhombic tables; it is more sparingly soluble in cold water than the ortho-salt, and dissolves easily in hot water and cold alcohol. The *phenylhydrazine* salt,

$$NHPh{\cdot}NH_2,HSCN,Cr(NH_3)_2(SCN)_3 + 2H_2O,$$

forms microscopic, purple, tabular crystals, and dissolves very slightly in cold water, but more freely in hot water and cold alcohol. The *pyridine* salt, $C_5NH_5,HSCN,Cr(NH_3)_2(SCN)_3$, forms purple, microscopic, four-sided prisms; it is nearly insoluble in cold water, and only sparingly soluble in hot water and cold alcohol. The *picoline* salt, $C_5NH_4Me.HSCN,Cr(NH_3)_2(SCN)_3$, crystallises in purple laminæ; it is very little soluble in cold water, and only sparingly so in hot water and cold alcohol. The *quinoline* salt,

$$C_9NH_7,HSCN,Cr(NH_3)_2(SCN)_3,$$

forms microscopic, red, rhombic laminæ, practically insoluble in cold water, sparingly soluble in hot water and cold alcohol. The *morphine* salt, $C_{17}H_{19}NO_3,HSCN,Cr(NH_3)_2(SCN)_3$, is a bright-red, crystalline powder, and is nearly insoluble in cold water, but somewhat soluble in cold alcohol. The *quinine* salt,

$$C_{20}H_{24}N_2O_2[HSCN,Cr(NH_3)_2(SCN)_3]_2 + 2H_2O,$$

is a bright-red, crystalline powder; it is less soluble in hot water than the morphine salt, and more so than the strychnine salt; it is also more soluble in alcohol than the morphine salt. The *strychnine* salt, $C_{21}H_{22}N_2O_2,HSCN,Cr(NH_3)_2(SCN)_3$, forms a red, crystalline precipitate, and is very sparingly soluble in cold alcohol and in water. The *pilocarpine* salt, $C_{11}H_{16}N_2O_2,HSCN,Cr(NH_3)_2(SCN)_3$, crystallises from hot alcohol in long, red needles, thus differing considerably in appearance from the salts of the other alkaloïds. The *cocaine* salt,

$$C_{17}H_{21}NO_4,HSCN,Cr(NH_3)_2(SCN)_2,$$

crystallises from hot water and from hot alcohol in red laminæ. The *atropine* and *hyoscyamine* salts were also prepared. The *pentamethylenediamine* salt, $C_5H_{10}(NH_2)_2,[HSCN,Cr(NH_3)_2(SCN)_3]_2 + 2H_2O$, crystallises in lustrous, red laminæ, dissolves very sparingly in cold water and alcohol, but more easily in hot water, by which it is speedily decomposed.

The author remarks that the exactness with which it is possible to determine the chromium in these thiocyanates renders them useful compounds by means of which to determine the character of an alkaloïd.

Luteocobalt diaminechromium thiocyanate,

$$Co(NH_3)_6(SCN)_3,[Cr(NH_3)_2(SCN)_3]_3,$$

is obtained as a bright-red precipitate consisting of microscopic tables when solutions of luteocobalt nitrate and ammonium diaminechromium thiocyanate are mixed together; it is practically insoluble in cold water and cold alcohol. Similar salts were obtained from chloropurpureochromium chloride, chloropurpureocobalt chloride, and chlorochromiumtetramine chloride.

Cadmium diaminechromium thiocyanate,

$$Cd(SCN)_2,[Cr(NH_3)_2(SCN)_3]_2 + H_2O,$$

is a red, crystalline powder, almost insoluble in cold water, and only sparingly soluble in hot water and hot alcohol.

The author makes some general remarks as to the possible structure of these complex thiocyanates, and concludes by pointing out that the above salts seem to show that when the nitrogen in the base is attached to three carbon atoms, or by three valencies to one carbon atom, the thiocyanate is sparingly soluble in cold alcohol, whereas when the nitrogen is only attached to one carbon atom, after the manner of a primary amine, the thiocyanate is easily soluble in cold alcohol. A. G. B.

The Compound $C_{36}H_{28}N_4O_6$ obtained by the Action of Sodium Ethoxide on Ethyl Hippurate. By L. Rügheimer (*Ber.*, **25**, 1568—1572; compare Abstr., 1889, 1210).—The compound $C_{36}H_{28}N_4O_6$, when boiled with an excess of acetic anhydride, yields a colourless diacetyl derivative, $C_{40}H_{32}N_4O_8$, which crystallises from alcohol in delicate needles, and melts at 201—202°; it also forms a dibromo-derivative, $C_{36}H_{24}Br_2N_4O_6$ or $C_{36}H_{26}Br_2N_4O_6$, melting at 240—241°; and the latter, on treatment with zinc-dust and acetic acid, gives a colourless compound melting at 183—184°, resembling in its behaviour dihydroxybenzamidopyrroline (Abstr., 1889, 391); the formation of such a compound as the latter is conceivable if the compound $C_{36}H_{28}N_4O_6$ is disanhydrotetrabenzamidotetrahydroxyoctene, as previously suggested (*loc. cit.*). A. R. L.

Desylacetic Acid. By F. Klingemann (*Annalen*, **269**, 131—142; compare Japp and Klingemann, Trans., 1890, 662).—*Diphenylcrotolactone*, $\begin{matrix}CH_2—CO\\ |\\ CPh{:}CPh\end{matrix}\!\!>O$, is formed, with liberation of water, when the desylacetic acid (*β*-phenyl-*β*-benzoylpropionic acid) described by Meyer and Oelkers (Abstr., 1888, 703) and by Knoevenagel (Abstr., 1888, 706) is distilled under reduced pressure; it crystallises from a mixture of light petroleum and benzene in slender, colourless needles melting at 151·5°.

Two compounds are formed when desylacetic acid is heated with phenylhydrazine; they are separated by treatment with alcohol. The one crystallises from alcohol, in which it is moderately easily soluble, in colourless, rhombic plates, $a : b : c = 0{\cdot}86112 : 1 : 0{\cdot}43096$, melts at 110°, and has the composition $C_{22}H_{18}N_2O$; it is probably an anilidodiphenylpyrrolone of the constitution $\begin{matrix}CH_2—CO\\ |\\ CPh{:}CPh\end{matrix}\!\!>N{\cdot}NHPh$. The second compound is only sparingly soluble in alcohol, crystallises from glacial acetic acid in colourless needles, and melts at 243°; it has the composition $C_{44}H_{34}N_4O_2$.

When the compound just described as anilidodiphenylpyrrolone is treated with bromine in carbon bisulphide solution, it is converted into the colourless substance of the composition $C_{44}H_{34}N_4O_2$; on re-

duction with sodium and amyl alcohol, it yields aniline and *diphenylpyrrolidone*, $\begin{matrix}CH_2\text{——}CO\\ |\\ CHPh\cdot CHPh\end{matrix}>NH$; the last-named compound separates from alcohol in colourless crystals melting at 207°.

Diphenylpyrrolone, $\begin{matrix}CH_2\text{—}CO\\ |\\ CPh{:}CPh\end{matrix}>NH$, is formed when diphenylcrotolactone is heated with excess of alcoholic ammonia at 150°; it crystallises in long, almost colourless needles, and melts and darkens at 188—189°.

Triphenylpyrrolone, $\begin{matrix}CH_2\text{—}CO\\ |\\ CPh{:}CPh\end{matrix}>NPh$, is obtained, together with a colourless, crystalline substance of the composition $C_{44}H_{32}N_2O_2$, when desylacetic acid is heated with aniline; it crystallises from acetic acid in compact, colourless crystals melting at 189—190°.

F. S. K.

Derivatives of α-Phenylquinoline. By E. Murmann (*Monatsh.*, **13**, 58—72).—α-Phenylquinoline is readily sulphonated when it is dissolved in an equal weight of sulphuric acid, and the solution is heated with its own weight of fuming acid, previously added to twice its weight of ordinary acid, until a small quantity withdrawn from the liquid and dissolved in water gives no turbidity with ammonia. The product consists of a mixture of the para- and meta-sulphonic acids, which can be readily separated by the fractional crystallisation of their barium salts, that of the para-compound being relatively very insoluble in water.

Quinoline-α-phenylparasulphonic acid, $C_{15}H_{11}NSO_3 + H_2O$, crystallises from hot water in yellow scales, melts far above 300°, gives a *barium salt* which crystallises in glistening white scales, and an *ammonium salt* which crystallises in anhydrous scales or plates. When the acid is fused with potash, it yields parahydroxy-α-phenylquinoline (m. p. 238; compare Weidel, *Monatsh.*, **8**, 130).

Quinoline-α-phenylmetasulphonic acid, $C_{15}H_{11}NSO_3$, crystallises from hot water in anhydrous, yellow grains, melts far above 300°, and furnishes the salts $(C_{15}H_{10}NSO_3)_2Ba + 1\frac{1}{2}H_2O$, crystallising in needles, $C_{15}H_{10}NSO_3K + H_2O$, crystallising in yellowish plates, and dissolving readily in water, and $C_{15}H_{10}NSO_3Ag + 2\frac{1}{2}H_2O$, which crystallises in drusy masses of slender needles. On fusing this acid with potash, metahydroxy-α-phenylquinoline (m. p. 156°) was obtained (compare Miller and Kinkelin, *Ber.*, **18**, 1908), from which the following derivatives were prepared:—The *hydrochloride*, $C_{15}H_{11}NO,HCl + 1\frac{1}{2}H_2O$, which crystallises in drusy masses of slender needles, is sparingly soluble in water, and melts at 228° (uncorr.); the *acetyl derivative*, $C_{15}H_{10}NOAc$, which crystallises in short, flat, colourless needles, melts at 92° (uncorr.), and is reduced by tin and hydrochloric acid to the *tetrahydride*, $C_{15}H_{15}NO$; the latter melts at 113—115° (uncorr.), and forms a *hydrochloride*, $C_{15}H_{15}NO,HCl$, which crystallises in cubes, melts at 187—188° (uncorr.), and on fusion with potash gives metahydroxybenzoic acid (m. p. 199·5°).

G. T. M.

Nomenclature of Pyrazolones. By L. Lederer (*J. pr. Chem.* [2], **45**, 413—414).—Commenting on Knorr's objection to the terms iso-pyrazolone and hydropyrazolone (this vol., p. 732), the author maintains that no new principle is introduced by their adoption. On the contrary, Knorr's term for reduced pyrazolone, pyrazolidone, is an entirely new departure, and will create the confusion for which he tries to make the author responsible. A. G. B.

Ethyl Malonate Phenylhydrazide and 1-Phenyl-3 : 5-pyrazolidone. By A. Michaelis and R. Burmeister (*Ber.*, **25**, 1502—1513; compare Abstr., 1891, 1068).—The substance obtained by the action of phenylhydrazine on ethyl chloromalonate, $CHCl(COOEt)_2$, is now shown to be *ethyl malonate phenylhydrazide*, $COOEt\cdot CH_2\cdot CO\cdot N_2H_2Ph$, for it is identical with the substance formed when ethyl malonic chloride, $COOEt\cdot CH_2\cdot COCl$, is treated with phenylhydrazine, and when warmed with excess of phenylhydrazine, it yields malonic diphenylhydrazide, $CH_2\cdot(CO\cdot N_2H_2Ph)_2$. It melts at 90°, dissolves sparingly in cold ether, more readily in hot, and readily in benzene, alcohol, and acetic acid; it is insoluble in light petroleum. It dissolves also in hot water, from which it crystallises in large, colourless needles. It dissolves in cold strong sulphuric acid, giving a pale-violet colour, and if a fragment of potassium dichromate is added, reddish or violet streaks are formed (Bülow's reaction for hydrazides); its alcoholic solution stains the skin purple. It reduces Fehling's solution. When heated with strong hydrochloric acid, it is decomposed, phenylhydrazine hydrochloride being formed. With phenyl isocyanate and thiocarbimide, it yields respectively a semicarbazide, $NHPh\cdot CO\cdot N(CO\cdot CH_2\cdot COOEt)\cdot NHPh$, melting at 158°, and a thiosemicarbazide melting at 141°. When the former is dissolved in cold alcoholic potash, and dilute hydrochloric acid added, a substance, $C_{16}H_{13}N_3O_3 + H_2O$, is precipitated, which crystallises from dilute alcohol in white, spherical, crystalline aggregates, melts at 166°, and is probably the semicarbazide of 1-phenyl-3 : 5-pyrazolidone, $\begin{matrix}CO\cdot NPh\\ |\\ CH_2\cdot CO\end{matrix}>N\cdot CO\cdot NHPh$.

On adding sodium nitrite to an acetic acid solution of the phenylhydrazide, *ethyl malonate nitrosophenylhydrazide*,

$$COOEt\cdot CH_2\cdot CO\cdot NH\cdot NHPh\cdot NO,$$

is obtained as yellow needles, which can be crystallised from alcohol. It melts at 85°, decomposes gradually when kept, gives Liebermann's reaction, and reduces Fehling's solution.

1-*Phenyl*-3 : 5-*pyrazolidone*, $\begin{matrix}NPh\cdot CO\\ |\\ NH\cdot CO\end{matrix}>CH_2$, is formed when ethyl malonate phenylhydrazide is dissolved in cold aqueous potash, and dilute hydrochloric acid added. It crystallises from alcohol in lustrous plates melting at 192°, and dissolves sparingly in ether and in cold water and alcohol, more readily in hot water and alcohol, and readily in alkalis. It reduces Fehling's solution, and no longer gives Bülow's reaction. It dissolves in hot strong hydrochloric acid, but when the solution is heated to 170° in a sealed tube, it is decomposed,

carbonic anhydride, aniline, and phenylhydrazine being formed. It probably has the constitution given above, yields metallic salts, and forms condensation products with aldehydes and ketones. The *ammonium salt*, $\begin{matrix}\mathrm{NPh{\cdot}CO}\\ \mathrm{NH\cdot CO}\end{matrix}\!>\!\mathrm{CH{\cdot}NH_4}$, is formed when the pyrazolidone is dissolved in strong ammonia; it crystallises in white plates and melts at 165°. The *potassium* and *sodium salts* are easily obtained, but crystallise badly. The *lead salt*, $(C_9H_7N_2O_2)_2Pb$, is precipitated as a white, amorphous powder when hot solutions of the ammonium salt and of lead acetate are mixed.

1-*Phenyl*-4-*benzylidene*-3 : 5-*pyrazolidone*, $\begin{matrix}\mathrm{NPh{\cdot}CO}\\ \mathrm{NH\cdot CO}\end{matrix}\!>\!\mathrm{C{:}CHPh}$, is formed when the phenylpyrazolidone is heated with benzaldehyde. It forms dark-red plates, dissolves readily in hot acetic acid, sparingly in hot alcohol, not at all in water, ether, and chloroform, and is decomposed by hot aqueous soda. It is also formed, together with benzylidenephenylhydrazone, when malonic diphenylhydrazide is heated with benzaldehyde.

1-*Phenyl*-4-*isopropylene*-3 : 5-*pyrazolidone*, $\begin{matrix}\mathrm{NPh{\cdot}CO}\\ \mathrm{NH\cdot CO}\end{matrix}\!>\!\mathrm{C{:}CMe_2}$, is obtained when the phenylpyrazolidone is boiled with acetone. It forms yellow needles, melts at 164°, dissolves in acetone and hot alcohol and ether, and is insoluble in water.

1-*Phenyl*-3 : 5-*pyrazolidone*-4-*azobenzene*, $\begin{matrix}\mathrm{NPh{\cdot}CO}\\ \mathrm{NH\cdot CO}\end{matrix}\!>\!\mathrm{CH{\cdot}N_2Ph}$, is obtained by adding diazobenzene chloride to a cooled solution of the phenylpyrazolidone in dilute aqueous soda, and acidifying the solution with dilute hydrochloric acid. It crystallises from hot acetic acid in lustrous, golden plates, melts at 232°, dissolves readily in hot acetic acid and dilute soda, sparingly in ether and alcohol, and is insoluble in water.

1-*Phenyl*-4-*isonitroso*-3 : 5-*pyrazolidone*, $\begin{matrix}\mathrm{NPh{\cdot}CO}\\ \mathrm{NH\cdot CO}\end{matrix}\!>\!\mathrm{C{:}NOH} + \mathrm{H_2O}$, is obtained when sodium nitrite is added to a cooled solution of the phenylpyrazolidone, and the mixture poured into cooled dilute sulphuric acid. It crystallises from hot water in dark red needles, melts at 182°, dissolves readily in hot water, acetic acid, and alcohol, and does not give Liebermann's reaction.

1-*Phenyl*-2 : 4-*dibenzoyl*-3 : 5-*pyrazolidone*, $\begin{matrix}\mathrm{NPh{\cdot}CO}\\ \mathrm{NBz\cdot CO}\end{matrix}\!>\!\mathrm{CHBz}$, or $\begin{matrix}\mathrm{NPh{\cdot}CO}\\ \mathrm{NBz\cdot CO}\end{matrix}\!>\!\mathrm{C{:}CPh{\cdot}OH}$, is obtained by boiling the phenylpyrazolidone with excess of benzoic chloride. It melts at 111°, dissolves readily in alcohol and ether, is insoluble in soda and dilute acids, and does not reduce Fehling's solution.

When the phenylpyrazolidone is heated for a few minutes with phenylhydrazine, it unites with 1 mol. of the latter to form a substance, $C_{15}H_{16}N_4O_2$, which crystallises from alcohol in white plates melting at 165°. This is not decomposed by alkalis, dissolves in

hot strong, and in cold dilute acids, reduces Fehling's solution, and gives Bülow's reaction. Its constitution is as yet undetermined.

In conclusion, it is pointed out that 1-phenyl-3 : 5-pyrazolidone stands in the same relation to phenylmethylpyrazolone as ethyl malonate does to ethyl acetoacetate. C. F. B.

Furfuran Compounds. By A. Pinner (*Ber.*, **25**, 1414—1427). —In the course of a research on the conversion of nitriles into imido-ethers, the author has observed differences between the compounds of the aromatic and those of the aliphatic series. He has now examined the imido-ethers and amidines derived from furfuran. He designates the radicle C_4OH_3, "furyl," and the radicle C_4OH_3C, "furfur."

Furyl cyanide is easily prepared by shaking furfuraldehyde with free hydroxylamine in aqueous solution, when furfuraldoxime is precipitated as an oil, which soon crystallises. The mixture is allowed to remain all night, and acidified; the crystalline mass dried, cautiously heated to boiling with twice the weight of acetic anhydride, then diluted with water, made alkaline with sodium hydroxide, and the nitrile extracted with ether. It boils at 145—146°.

Furfurimidoethyl ether hydrochloride, $C_4OH_3{\cdot}C(NH){\cdot}OEt,HCl$, is obtained by passing hydrogen chloride through a solution of the above nitrile in the equivalent quantity of absolute alcohol. It forms colourless, nodular, lustrous crystals, is soluble in alcohol, insoluble in ether, melts at 106° with formation of ethyl chloride and the amide of pyromucic acid, and is decomposed by water into ammonium chloride and ethyl pyromucate (α-furfurancarbonate).

Furfurimidoethyl ether is obtained by treating the hydrochloride with potassium carbonate (33 per cent.) and extracting with ether. It boils at 180—181° without decomposition, has a faint characteristic odour, is insoluble in water, and easily soluble in the other usual solvents.

Furfuramidine hydrochloride, $C_4OH_3{\cdot}C(NH){\cdot}NH_2,HCl$, is obtained by treating the above hydrochloride with alcoholic ammonia. It crystallises in large, transparent, lustrous prisms, which contain 1 mol. H_2O, melts at 72°, is very easily soluble in water and alcohol, and insoluble in ether. Attempts to prepare the free amidine resulted in the formation of the amide of pyromucic acid. When boiled for 10—15 minutes with anhydrous sodium acetate and acetic anhydride, it is converted into a compound which the author believes to be *difurylmethylcyanidine*, $C_4OH_3{<}\begin{matrix}N{:}C(C_4OH_3)\\ N{=}{=}CMe\end{matrix}{>}N$. The latter crystallises from dilute alcohol in silky needles, melts at 138°, is sparingly soluble in water, easily so in alcohol and acetic acid, and has only weak basic properties.

Furylmethylhydroxypyrimidine, $C_4OH_3{\cdot}C{<}\begin{matrix}N{-}CMe\\ N{:}C(OH)\end{matrix}{>}CH$, is obtained by allowing a mixture of furfuramidine hydrochloride, the equivalent quantity of sodium hydroxide, and a slight excess of ethyl acetoacetate to remain for a few days. A thick, crystalline mass is obtained; it is acidified with dilute acetic acid, filtered, and the product crystallised from alcohol. It crystallises in long, silky needles,

melts at 225°, and is easily soluble in alkalis and strong mineral acids.

Furyldimethylhydroxypyrimidine, $C_4OH_3{\cdot}C{\lessdot}^{N\,-\,CMe}_{N{:}C(OH)}{\gtrdot}CMe$, obtained in the same way from ethyl methylacetoacetate, crystallises from alcohol in small, lustrous needles, and melts at 231°.

Furylmethylbenzylhydroxypyrimidine,

$$C_4OH_3{\cdot}C{\lessdot}^{N\,-\,CMe}_{N{:}C(OH)}{\gtrdot}C{\cdot}CH_2Ph,$$

is obtained by mixing equivalent quantities of sodium hydroxide, furfuramidine hydrochloride, and ethyl benzylacetoacetate, then adding alcohol, and allowing the mixture to remain about eight days. It crystallises in slender, white needles, melts at 238°, is almost insoluble in water, sparingly soluble in alcohol and cold acetic acid, more so in hot acetic acid, and easily in alkalis and strong mineral acids.

Furylphenylhydroxypyrimidine, $C_4OH_3{\cdot}C{\lessdot}^{N\,-\,CPh}_{N{:}C(OH)}{\gtrdot}NH$, obtained by the action of ethyl benzoylacetate on furfuramidine hydrochloride, crystallises in slender, white needles, melts at 256°, and is very sparingly soluble in alcohol and cold acetic acid, more so in hot acetic acid.

When furfuramidine hydrochloride dissolved in twice its weight of water is treated with equivalent quantities of 15 per cent. soda and ethyl oxalacetate, heat is evolved, and on allowing the mixture to remain three days, a crystalline precipitate of *ethoxalylacetylfurfuramidine* is obtained. By adding half the volume of 15 per cent. soda to the mother liquor, allowing it to remain, and acidifying with acetic acid the acid, $C_9H_8N_2O_5$, corresponding with the above ethyl salt, is obtained. Ethoxalylacetylfurfuramidine,

$$C_4OH_3{\cdot}C(NH){\cdot}NH{\cdot}CO{\cdot}CH_2{\cdot}CO{\cdot}COOEt,$$

crystallises from acetone in beautiful, transparent prisms, is almost insoluble in water, sparingly soluble in alcohol and cold acetone, easily in hot acetone, begins to blacken at 180°, and melts at 190° with decomposition. The author believes that the acid $C_9H_8N_2O_6$ is *furylhydroxypyrimidinecarboxylic acid*, $C_4OH_3{\cdot}C{\lessdot}^{N{\cdot}C(COOH)}_{N\,=\,C(OH)}{\gtrdot}CH$, H_2O. It is obtained as the sole product if the mixture of furfuramidine hydrochloride and ethyl oxalacetate is boiled with sodium hydroxide, and is also obtained by hydrolysing the above ethyl salt with soda. It crystallises from dilute acetic acid in microscopic prisms, is sparingly soluble in alcohol, cold water, and acetic acid, more so in hot water and acetic acid, melts above 300° with decomposition, and does not lose in weight when heated at 135°. It yields a *silver salt* of the composition $C_9H_4N_2O_4Ag_2$.

The author has examined the action of ethyl oxalacetate on other amidines, and has obtained a pyrimidinecarboxylic acid in every case.

When a mixture of molecular proportions of tolenylamidine (dis-

solved in five times the weight of water), sodium hydroxide (15 per cent.), and ethyl oxalacetate is allowed to remain eight days, a crystalline precipitate is obtained, which is partly soluble in acetone. The soluble portion is *ethoxalylacetyltolenylamidine*,

$$C_6H_4Me\cdot C(NH)\cdot NH\cdot CO\cdot CH_2\cdot CO\cdot COOEt.$$

It crystallises in short, colourless prisms, blackens at 170°, melts at 190° with decomposition, and is easily converted into tolylhydroxypyrimidinecarboxylic acid when treated with sodium hydroxide.

Paratolylhydroxypyrimidinecarboxylic acid,

$$C_6H_4Me\cdot C\begin{matrix}\ll\\ \\ \gg\end{matrix}\begin{matrix}N\cdot C(COOH)\\ N=C(OH)\end{matrix}CH,$$

remains insoluble on extracting the product of the above reaction with acetone. It crystallises from acetic acid in small, nodular crystals, and melts at 252° with decomposition.

Naphthamidine, when treated with ethyl oxalacetate in a similar way, yields *β-naphthylhydroxypyrimidinecarboxylic acid*, which crystallises in small prisms, and melts at 167—168° with decomposition.

Methylhydroxypyrimidinecarboxylic acid, $C_6H_6N_2O_3,H_2O$, is obtained in a similar way from acetamidine. It crystallises in small, white needles, is sparingly soluble in water and acids, loses its water at 100°, decomposes at a high temperature, but is unaltered at 300°.

Ethylhydroxypyrimidinecarboxylic acid, $C_7H_8N_2O_3,1\frac{1}{2}H_2O$, crystallises in slender, silky needles, is easily soluble in hot water, sparingly in alcohol and acetone, melts at 216° with decomposition, and loses its water at 100°.

Benzamidine, when treated with carbonyl chloride, yields dibenzamidylcarbamide, which easily loses ammonia, and yields diphenylhydroxycyanidine (Abstr., 1891, 60). A similar reaction takes place in the case of paratolenylamidine, β-naphthamidine, and furfuramidine. The aliphatic amidines do not, however, yield hydroxycyanidine.

Difurylhydroxycyanidine, $C_4OH_3\cdot C\begin{matrix}\ll\\ \\ \gg\end{matrix}\begin{matrix}N\cdot C(C_4OH_3)\\ N=C(OH)\end{matrix}N$, is obtained by gradually adding a 20 per cent. toluene solution of carbonyl chloride with constant shaking to a concentrated solution of furfuramidine hydrochloride, and 15 per cent. sodium hydroxide (4 mols.), until carbonic anhydride begins to come off. The granular mass which is obtained is crystallised from alcohol: it forms small, white, flat needles, begins to darken at 250°, and, on further heating, slowly decomposes. It is sparingly soluble in alcohol, easily in alkalis.

Ditolylhydroxycyanidine, $C_6H_4Me\cdot C\begin{matrix}\ll\\ \\ \gg\end{matrix}\begin{matrix}N\cdot C(C_6H_4Me)\\ N=C(OH)\end{matrix}N$, obtained in a similar way to the preceding compound, crystallises in slender, satiny needles, is sparingly soluble in alcohol, easily in alkalis, and melts above 300°.

Dinaphthylamidinecarbamide, $CO[NH\cdot C(C_{10}H_7):NH]_2$, is obtained, together with a small quantity of dinaphthylhydroxycyanidine, by treating β-naphthamidine with carbonyl chloride. It crystallises from alcohol in small, nodular aggregates, and does not melt at 300°.

β-Naphthylmethylhydroxypyrimidine, $C_{10}H_7 \cdot C\begin{<}{N\text{—}CMe \\ N{:}C(OH)}\end{>}CH$, is obtained by adding the theoretical quantities of ethyl acetoacetate and sodium hydroxide (15 per cent.) to an aqueous solution of β-naphthamidine, then adding alcohol until a clear solution is obtained, and allowing the mixture to remain eight days. The crystalline precipitate which is formed is collected, and recrystallised from alcohol. It forms long, slender needles, melts at 210°, and is somewhat easily soluble in alcohol.

Naphthyldimethylhydroxypyrimidine obtained in a similar way from ethyl methylacetoacetate, crystallises in lustrous needles or short prisms, is sparingly soluble in alcohol, and melts at 248°.

Naphthylphenylhydroxypyrimidine is obtained in a similar way from ethyl benzoylacetate; it crystallises from acetic acid in short, thin prisms, melts at 265°, and is insoluble in water, very sparingly soluble in alcohol and cold acetic acid, more so in hot acetic acid.

E. C. R.

Tetrazole. By J. A. Bladin (*Ber.*, **25**, 1411—1413).—The author has obtained triazole (this vol., p. 735) by oxidising amidophenyltriazolecarboxylic acid with permanganate in alkaline solution and then eliminating carbonic anhydride from the triazolecarboxylic acid which is first formed. He has now prepared tetrazole in a similar way.

Nitrophenyltetrazolecarboxylic acid, $N\begin{<}{N{\cdot}N{\cdot}C_6H_4{\cdot}NO_2 \\ \| \\ N{:}C{\cdot}COOH}\end{>}$, is prepared by boiling phenyltetrazolecarboxylic acid (10 grams) with fuming nitric acid (100 grams) as long as nitrous fumes are evolved. The product is poured into water, and the precipitate separated and dried. It crystallises from acetic acid in colourless leaflets containing 1 mol. of acetic acid, and in needles containing 1 mol. H_2O, melts at 175° to a yellow oil with evolution of gas, and explodes on ignition.

Amidophenyltetrazolecarboxylic acid is obtained by reducing the above nitro-compound with warm stannous chloride and fuming hydrochloric acid. It is purified by dissolving in ammonia and precipitating with sulphuric acid, and melts at 196° with decomposition.

Tetrazole, $\begin{matrix}NH{\cdot}N \\ \| \\ CH{:}N\end{matrix}\!\!>\!N$ or $\begin{matrix}N{\cdot}NH \\ \| \\ CH{\cdot}N\end{matrix}\!\!>\!N$, is obtained as follows:—

Amidophenyltetrazolecarboxylic acid (7 grams) is dissolved in 50 per cent. soda (56 grams) and the warm solution gradually mixed with concentrated permanganate (35—40 grams). When the permanganate is no longer decolorised, the excess is destroyed with alcohol and the mixture filtered. The filtrate is concentrated, acidified with nitric acid, heated to boiling, and silver nitrate added. A colourless silver salt is precipitated. The latter is warmed with hydrochloric acid, the solution filtered from silver chloride, and evaporated to dryness on the water-bath. Tetrazole is obtained as a yellowish, crystalline mass, and is purified by crystallisation from alcohol. It crystallises from toluene in lustrous leaflets, from alcohol

in hard, aggregated leaflets, sublimes before melting, melts at 155°, and is easily soluble in water, alcohol, acetone, and acetic acid, sparingly so in ether, benzene, and toluene. It reddens blue litmus paper, has no basic properties, and gives precipitates with metallic salts. The silver and copper salts explode violently on heating.

E. C. R.

Nicotine. By A. Pinner and R. Wolffenstein (*Ber.*, **25**, 1428—1433).—The authors have attempted to obtain compounds of known constitution from oxynicotine, $C_{10}H_{12}N_2O$ (obtained by the action of hydrogen peroxide on nicotine), by heating it with hydrochloric acid and with barium hydroxide. With hydrochloric acid, a compound, $C_{10}H_{14}N_2O$, which the authors name pseudonicotine oxide, is obtained. With barium hydroxide, nicotine is obtained, together with a non-volatile resin.

Pseudonicotine oxide is prepared as follows:—Oxynicotine is heated with eight times the quantity of fuming hydrochloric acid for 8—10 hours at 140°, the dark-coloured product is made alkaline with soda, and then distilled with steam as long as the distillate is alkaline. The distillate is acidified with hydrochloric acid and evaporated to crystallisation, when the *hydrochloride*, $C_{10}H_{14}N_2O,2HCl$, is obtained. This crystallises from alcohol in white leaflets, melts at 192°, gives, with mercuric chloride, a double salt melting at 212°, and yields a *platinochloride*, $C_{10}H_{14}N_2O,H_2PtCl_6$, which crystallises in small needles and begins to decompose at 120°. The *free base* is obtained by decomposing the hydrochloride with sodium hydroxide and extracting with ether; on evaporating the ether, an oil is left, which quickly turns red on exposure to air. It is soluble in water in all proportions, and is precipitated as an oil by concentrated sodium hydroxide. Besides pseudonicotine oxide, a basic, brownish-black resin, which is not volatile with steam, is also formed.

Dehydronicotine, $C_{10}H_{12}N_2$, is an oil which comes over between 265° and 275°, when freshly-prepared pseudonicotine oxide is distilled. It does not turn red on exposure to air, and is somewhat sparingly soluble in water. The *picrate* forms very small, prismatic crystals, and melts at 208°. The *platinochloride* is orange-coloured, and does not melt at 260°.

The physiological action of pseudonicotine oxide and dehydronicotine is very similar to that of nicotine. The oxygen-free base, $C_{10}H_{12}N_2$, has as intense an action as nicotine itself. Pseudonicotine oxide is about 20 times weaker.

E. C. R.

Conversion of Cupreïne into Quinine. By O. Hesse (*Annalen*, **269**, 143—144).—A reply to Grimaux and Arnaud (this vol., p. 892).

Halogen Derivatives of the Cinchona Alkaloïds. By W. J. Comstock and W. Koenigs (*Ber.*, **25**, 1539—1551).—It has already been shown (Abstr., 1887, 1123) that two isomeric cinchonine dibromides, giving the same dehydrocinchonine on boiling with alcoholic potash, are formed by brominating cinchonine dissolved in a mixture of alcohol and chloroform. The α-modification, $C_{19}H_{22}N_2O$ +

H_2O, crystallises in rhombic pyramids, exhibiting strong double refraction, the extinction being parallel and perpendicular to the base; whilst the β-modification forms lance-shaped leaflets, frequently combined in stellate groups, exhibiting feeble double refraction, the extinction being parallel and perpendicular to their length. Neither of the dibromides appears to be capable of combining with hydrogen bromide.

In the light of Skraup's experiments, the authors now hold the view that only one quinoline residue is present in the cinchona alkaloïds, and that the so-called second complex ($C_{10}H_{16}NO$), which in cinchonine and cinchonidine is combined with a quinoline residue, and in quinine and quinidine with a paramethoxyquinoline residue, consists of hydrogenised benzene and pyridine nuclei combined in a manner similar to that which Merling has suggested for tropine and ecgonine (this vol., p. 358). In support of this hypothesis, the authors cite the inferior stability of the above-mentioned complex, $(C_{10}H_{16}NO)'$, in comparison with that of a quinoline residue; furthermore, whilst Merling (*loc. cit.*) has shown that tropine and ecgonine give tropinic acid, $C_8H_{13}NO_4$, on oxidation, Skraup (*Monatsh.*, **9**, 783; **10**, 39 and 220) has obtained cincholeuponic acid, $C_5NH_8Me(COOH)_2$, on oxidising the cinchona alkaloïds.

A base, $C_{19}H_{22}Cl_2N_2O$, having the same properties as the "dichlorocinchonine" described by Laurent (*Annalen*, **69**, 9), is obtained by passing chlorine through a cooled solution of cinchonine in hydrochloric acid; it is purified by means of its sparingly soluble nitrate. The free base separates from a mixture of chloroform and alcohol in colourless crystals, and, when the temperature is slowly raised, melts at 202—204° with partial decomposition, whilst, if the temperature is quickly raised, it melts at 220° or even 230°. When boiled with alcoholic potash, hydrogen chloride is slowly eliminated, and a crystalline base, probably dehydrocinchonine, melting at 203—205°, is produced.

Dehydrocinchonine dibromide, $C_{19}H_{20}Br_2N_2O$ (or $C_{19}H_{18}Br_2N_2O$), is obtained by brominating at 0° dehydrocinchonine hydrochloride dissolved in a mixture of chloroform and alcohol; the base crystallises in small, transparent prisms, melts at 172—173°, and is readily soluble in alcohol and chloroform, sparingly so in ether.

"Cinchonine chloride," $C_{19}H_{21}N_2Cl$, is thus prepared:—Dry cinchonine hydrochloride (100 grams) is dissolved in dry chloroform (1200 grams), and, to the cooled solution, finely-pulverised phosphorus pentachloride (134 grams), suspended in chloroform, is added; the mixture is then heated on the water-bath for 1—1½ hours. When boiled with alcoholic potash, cinchen, $C_{19}H_{20}N_2$, is obtained; whilst a secondary base, which was not further investigated, is formed when cinchonine chloride is treated with 2 per cent. sodium amalgam at the ordinary temperature; and octohydrocinchen (see below) seems to be produced by heating it with concentrated hydriodic acid in a sealed tube at 240—250°.

"*Hydrobromocinchonine chloride*," $C_{19}H_{22}BrN_2Cl$, is prepared by dissolving cinchonine chloride in nine times its weight of hydrobromic acid (sp. gr. 1·49), saturating the solution with hydrogen bromide at −17°, and placing the mixture aside for several days; when heated

with hydriodic acid (sp. gr. 1·96; 10 parts) at 240—250° for 9—10 hours, octohydrocinchen is produced. The crude base was converted into the *cadmiochloride*, $C_{19}H_{25}N_2,H_2CdCl_4 + H_2O$, which crystallises in stout, faintly-yellowish crystals, and melts at 140—150°; the *platinochloride* was obtained as an oil, whilst the pure base was not prepared.

Dehydrocinchen forms a *dibromide*, $C_{19}H_{18}Br_2N_2$.

Quinine dibromide, $C_{20}H_{24}Br_2N_2O_2$, is obtained by treating quinine dissolved in a mixture of alcohol and chloroform with bromine at 0°, extracting with water, adding ammonia to the aqueous solution, and purifying by crystallisation of the nitrate. The base is sparingly soluble in cold water, somewhat easily in benzene, and crystallises therefrom with 1 mol. C_6H_6, which it slowly loses on exposure to the air. A. R. L.

Alkyl Derivatives of Cinchona Alkaloïds. By A. Claus (*J. pr. Chem.* [2], **45**, 398—401).—The author is surprised that Freund and Rosenstein, in their recent paper (this vol., p. 892), should have alluded to his work on this subject as having been discontinued. The numerous papers published by the author and his pupils on quinolines and their derivatives are all parts of his work on cinchona alkaloïds, and his most recent paper (*Annalen*, **269**, 232) is concerning these alkaloïds. He therefore insists on his prior claim to the subject. A. G. B.

Strychnine. By J. Tafel (*Annalen*, **268**, 229—255; compare Abstr., 1891, 1262).—*Nitrosoisostrychnic acid*,

$$NO\cdot C_{20}H_{21}NO(COOH):NH + H_2O,$$

is formed when the hydrochloride of isostrychnic acid nitrosamine (*loc. cit.*) is treated with ice-cold alcoholic hydrochloric acid, and the mixture then kept at the ordinary temperature until the yellow solid, which is first precipitated, is redissolved. It is precipitated from its solution in soda, on the addition of hydrochloric acid, in yellowish-green needles, and is only very sparingly soluble in hot water, almost insoluble in boiling alcohol, and insoluble in acetone and chloroform; it dissolves freely in alkalis and in glacial acetic acid, and forms salts with strong mineral acids. When its hydrochloric acid solution is treated with tin, a transient, dark-red, and then a slight yellow, coloration is produced; after precipitating the tin with hydrogen sulphide, the colourless filtrate turns violet on exposure to the air, and after neutralising with soda, it gives, with ferric chloride, an intense violet colour, which changes to green on adding more of the reagent. It yields, with nitrous acid, a nitrosamine, but it does not show Liebermann's reaction, and it does not give any volatile base when boiled with 10 per cent soda.

Methylisostrychnic acid, $COOH\cdot C_{20}H_{22}NO:NMe + 2\frac{1}{2}H_2O$, can be obtained by heating anhydrous isostrychnic acid hydriodide with methyl iodide at 100° for two to three hours. It crystallises in long, colourless prisms, loses the whole of its water over sulphuric acid under reduced pressure, and turns brown when heated above 240°, but without melting completely; its alkaline solutions, unlike those of

isostrychnic acid, do not become coloured on exposure to the air. It gives with concentrated nitric acid, containing a trace of nitrous acid, with ferric chloride, and with a little potassium dichromate, a red coloration, the reaction being in every case more delicate than that given by methyltetrahydroquinoline (kairoline) under similar conditions.

Methylisostrychnic acid behaves in many respects like dimethylstrychnine, and also like the dialkylanilines; when warmed with benzaldehyde and zinc chloride, it yields a colourless leuco-compound, which is converted into a beautiful green dye on oxidation; with diazobenzene chloride, it forms an acid azo-dye similar to helianthin.

Ethyl nitrosomethylisostrychnate, $NO{\cdot}C_{20}H_{21}NO(COOEt){:}NH$, is formed when an alcoholic solution of methylisostrychnic acid is saturated with hydrogen chloride, the hydrochloride obtained in this way treated with amyl nitrite in well-cooled, alcoholic solution, and the product decomposed with dilute soda. It crystallises from benzene in green needles, and dissolves freely in chloroform, warm alcohol, and warm benzene, but is only sparingly soluble in ether. Nitrosomethylisostrychnic acid is stable towards dilute soda, and, even when boiled therewith, it does not yield a volatile base; it does not give Liebermann's reaction.

Deoxystrychnine, $C_{20}H_{26}N\lessdot^{CO}_{N}$ + $3H_2O$, is formed, together with resinous compounds, when strychnine is boiled with concentrated hydriodic acid and amorphous phosphorus for 18 hours, but it is obtained in a state of purity only with great difficulty. It is almost insoluble in water, and only sparingly soluble in ether and benzene, but readily in cold ethyl and methyl alcohol; it melts in its water of crystallisation when quickly heated to about 75°, and loses the whole of its water at 100°, or when kept for a long time over sulphuric acid under reduced pressure; the anhydrous compound melts at 172°, distils without decomposition, and is readily soluble in alcohol, benzene, chloroform, and ethyl acetate, but more sparingly in hot light petroleum. It has the characteristic poisonous properties of strychnine, an even more bitter taste, and its solution in concentrated sulphuric acid gives, with potassium dichromate, a bluish-violet coloration, which soon changes to brown; a solution of its hydrochloride is feebly dextrorotatory. Its salts are, generally speaking, more readily soluble than the corresponding strychnine compounds; like the latter, they contain only one equivalent of the acid, and show, with litmus, an acid, with methyl-orange, a neutral, reaction. The *hydriodide*, $C_{21}H_{26}N_2O,HI$ + H_2O, crystallises in colourless prisms, loses its water at 120°, and is moderately easily soluble in hot water, but more sparingly in cold water and alcohol. The *dichromate*, $(C_{21}H_{26}N_2O)_2,H_2Cr_2O_7$, crystallises in long, yellow needles, and is only very sparingly soluble in hot water, and almost insoluble in boiling alcohol; it begins to decompose at 170°. The *platinochloride*, $(C_{21}H_{26}N_2O)_2,H_2PtCl_6$, forms small, yellow needles, and is very sparingly soluble in boiling water, by which it is slowly decomposed. The *methiodide*, $C_{22}H_{26}N_2O,MeI$, separates in crystals when an alcoholic solution of deoxystrychnine is treated with excess of methyl iodide; it separates from boiling water in colourless crystals, and is only spar-

ingly soluble in hot alcohol, and insoluble in ether. It is not decomposed by hot soda, but when treated with silver oxide in aqueous solution, it is converted into a strongly alkaline ammonium base, which undergoes intramolecular change on evaporating its aqueous solution, yielding a colourless, neutral, crystalline substance, which the author names *methyldeoxystrychnine*.

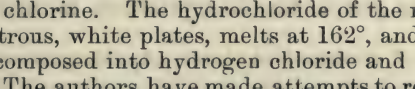
Deoxystrychnic acid, $COOH{\cdot}C_{20}H_{26}N{\cdot}NH + H_2O$, can be obtained by heating deoxystrychnine with an alcoholic solution of sodium methoxide at 180° and decomposing the product with sodium carbonate. It crystallises in colourless, microscopic needles, containing 2 mols. H_2O, one of which is lost over sulphuric acid under reduced pressure; the other molecule of water cannot be expelled, because, when the acid is heated at 100°, it is partially converted into deoxystrychnine. It is only sparingly soluble in hot water, although more readily than strychnic acid, and when treated with alcohol it dissolves almost entirely, crystals quickly separating again from the solution; these crystals are only sparingly soluble even in boiling alcohol, and, on cooling the solution, it deposits colourless prisms which contain alcohol. It dissolves freely in alkalis and in concentrated ammonia, and the solutions do not become coloured on exposure to the air: when treated with acids, it yields salts of deoxystrychnine, and with potassium dichromate and dilute sulphuric acid it gives an intense red coloration. When a well-cooled solution of sodium deoxystrychnate is treated with sodium nitrite and hydrochloric acid, the hydrochloride of the *nitrosamine* is precipitated as a yellowish resin, which separates from hot water in microscopic needles and gives Liebermann's reaction.

The above observations show that strychnine derivatives behave in many respects just like derivatives of tetrahydroquinoline, and probably contain a tetrahydroquinoline nucleus. F. S. K.

Nitroatropine. By A. Einhorn and L. Fischer (*Ber.*, **25**, 1390—1391).—*Nitroatropine* is obtained by gradually adding atropine (10 grams) to a mixture of concentrated nitric acid (20 c.c.) and sulphuric acid (20 c.c.), cooled to 0°. After remaining 1—2 hours, the mixture is poured on to ice, and potassium carbonate added. The nitroatropine separates as an oil and is extracted with ether. The *hydrochloride*, obtained by dissolving it in alcoholic hydrogen chloride, crystallises from absolute alcohol, decomposes at 235°, and is sparingly soluble in absolute and dilute alcohol, methyl alcohol, chloroform, and acetic acid.

When nitroatropine is boiled with hydrochloric acid, it yields an acid which, on oxidation with alkaline permanganate, is converted into paranitrobenzoic acid (m. p. 290°). E. C. R.

Action of Hypochlorous Acid on Tropine. By A. Einhorn and L. Fischer (*Ber.*, **25**, 1391—1394).—If an aqueous solution of tropine (7·5 grams) is added to a solution of hypochlorous acid, prepared by the action of boric acid on sodium hypochlorite, and the mixture allowed to remain 1—2 days in the dark, a white precipitate is obtained. The latter is filtered off, washed with water, and its



ethereal solution shaken with soda. On concentrating the solution, large, prismatic crystals are obtained, which melt at 111°, and sublime unchanged. The compound has the composition $C_7H_6NCl_5O$, and the authors believe it is an ethereal salt of hypochlorous acid, $C_6H_5NCl_4{\cdot}CH{\cdot}OCl$. One chlorine atom is easily displaced, and by boiling with absolute alcohol, a compound of the formula

$$C_6H_5NCl_4{\cdot}CH{\cdot}OH$$

is obtained, which separates in small, white crystals and melts at 108°. When warmed on the water-bath with hydrochloric acid, it dissolves with evolution of chlorine. The hydrochloride of the new compound crystallises in lustrous, white plates, melts at 162°, and when treated with water, is decomposed into hydrogen chloride and the compound melting at 108°. The authors have made attempts to reduce the compound melting at 108°, but at present have obtained no definite results.

E. C. R.

Dihydroxyanhydroecgonine. By A. Einhorn and B. Rassow (*Ber.*, **25**, 1394—1400).—*Dihydroxyanhydroecgonine*,

is obtained as follows:—A solution of anhydroecgonine hydrochloride (10 grams) in 1500 c.c. of water made slightly alkaline with sodium carbonate is gradually added to 778 c.c. of a 1 per cent. solution of potassium permanganate. The temperature must not be allowed to rise above 1°. The mixture is filtered, acidified with hydrochloric acid, and concentrated on the water-bath; the acid oxidation products are precipitated with baryta, and the mixture treated with carbonic anhydride and filtered. The filtrate is evaporated to a syrup and extracted with methyl alcohol. The crude product is converted into hydrochloride, decolorised with animal charcoal, evaporated to a syrup, allowed to crystallise, dried on porous plates, and recrystallised from dilute alcohol. The *hydrochloride* forms small, white crystals, and melts at 251°.

Dihydroxyanhydroecgonine is obtained by boiling the methyl salt with water for 24 hours, and then precipitating by adding alcohol to the aqueous solution. It decomposes at 280°, is easily soluble in water and methyl alcohol, sparingly in methylated spirit, and insoluble in absolute alcohol and ether. With picric acid, it gives a precipitate of slender, yellow needles; it gives no precipitate with ammoniacal copper solution. The *methyl salt* is obtained by passing hydrogen chloride into a solution of the dihydroxy-acid in methyl alcohol; the alcohol is distilled off, the residue poured into water, and the methyl salt precipitated with potassium carbonate and extracted with chloroform. It crystallises from ether in well-formed, prismatic tables, and melts at 138—139°. The *hydrochloride*, *nitrate*, and *sulphate* are very easily soluble in water. The *platinochloride* crystallises in reddish-yellow needles, and melts at 210°.

When the finely-powdered methyl salt is warmed on the water-bath for some hours with 3—4 times the quantity of benzoic chloride, two

alkaloïds are obtained, one yielding a sparingly soluble hydrochloride and nitrate, the other, easily soluble salts. They are separated by means of the nitrates.

Methyl salt of benzoyldihydroxyanhydroecgonine is obtained from the easily soluble nitrate, which crystallises in beautiful, large, lustrous tablets, and melts at 215—216°, by decomposing it with soda and extracting with ether. It forms slender, white needles when precipitated from its aqueous solution by alcohol, and melts at 107—108°. The *hydrochloride* melts at 202—203° with decomposition; the *aurochloride* crystallises in slender, lustrous needles, and melts at 172—173°; the *platinochloride* crystallises in needles, and melts at 207—208°.

Methyl salt of dibenzoyldihydroxyanhydroecgonine is obtained from the sparingly soluble nitrate mentioned above, which crystallises in slender needles and melts at 189—190°, by shaking it, suspended in water, with sodium carbonate and ether until it all dissolves. It is precipitated from alcohol by water in slender needles, and melts at 99—100°. Both the free alkaloïd and its salts are very easily decomposed with evolution of benzoic acid, so that they have not been obtained in a perfectly pure condition. The *hydrochloride* melts at 280°, the *platinochloride* at 205°, and the *aurochloride* at 208°.

Pinnaglobin, a New Globulin. By A. B. Griffiths (*Compt. rend.*, **114**, 840—842).—The blood of *Pinna squamosa* is white, but when exposed to the air becomes brownish. It contains a new globulin, *pinnaglobin*, which is precipitated from the clarified serum by alcohol, dissolved in a dilute aqueous solution of magnesium sulphate, precipitated again by saturating the liquid with magnesium sulphate, washed with strong magnesium sulphate solution, and then treated with water, in which it dissolves, owing to the magnesium sulphate still adhering to it. The solution is heated at 56° in order to coagulate some proteïds, and the pinnaglobin is precipitated from the filtrate by the addition of alcohol, washed with water, and dried, first at 60° and afterwards in a vacuum.

Pinnaglobin has the composition C, 55·07; H, 6·24; N, 16·24; Mn, 0·35; S, 0·81; O, 21·29 = 100, and, like hæmocyanin, exists in two states, oxypinnaglobin and reduced or ordinary pinnaglobin. It combines with methane, forming a greenish product, with acetylene, forming a greyish product, and with ethylene forming a reddish compound, but it does not combine with carbonic oxide or with nitric oxide. 100 grams of pinnaglobin absorb 162 c.c. of oxygen at 0° and 760 mm.; pinnaglobin and oxypinnaglobin give no absorption spectra, but the specific rotatory power of the former is $[\alpha]_D = -61°$.

The ash of the blood of *Pinna squamosa* has the composition—

MnO_2.	CaO.	MgO.	K_2O.	Na_2O.	P_2O_5.	SO_3.	Cl.
0·19	3·70	1·83	4·86	44·02	4·79	2·73	37·88

C. H. B.

Peptone Salts of Glutin. By C. Böttinger (*Ber.*, **25**, 1500—1501; compare C. Paal, this vol., p. 895).—On heating mechanically

purified calf skin with water for six hours at 150°, a hygroscopic, readily soluble compound is formed which is a conversion product of gelatin. On boiling this substance for four hours with very dilute hydrochloric acid (0·2—0·5 per cent. of the dried substance), a colourless compound is formed which has a sweet taste and an odour resembling that of molasses. The insoluble portion of the skin amounts to 7—14 per cent., and consists of mineral matter, fat, and nitrogenous compounds. J. B. T.

Oxygen in Oxyhæmoglobin Crystals. By C. Bohr and S. Torup (*Chem. Centr.*, 1892, i, 321; from *Skand. Arch. Physiol.*, **3**, 69).—Hæmoglobin in solution has been found to absorb 1·5—1·6 c.c. of oxygen per gram, but the quantity seems to depend on the concentration of the solution. The dry crystals do not contain nearly so much free oxygen, 0·40, 0·33, and 0·39 c.c. being obtained in three experiments, whereas the solution of the same specimen of hæmoglobin contained 0·99 and 1·19 c.c. of oxygen. J. W. L.

Formation of Oxyhæmoglobin from Hæmatin and a Proteïd. By H. Bertin Sans and J. Moitessier (*Compt. rend.*, **114**, 923—926).—Defibrinated blood is mixed with ether, and the well-drained coagulum boiled with alcohol of 95° containing 8 to 10 per cent. of tartaric acid. A deep brown liquid is thus obtained containing hæmatin and a proteïd resulting from the decomposition of oxyhæmoglobin, and if excess of ether is added, hæmatin is precipitated, and the proteïd remains in solution. The latter shows no trace of an absorption band.

If an alcoholic solution of the hæmatin is mixed with the aqueous solution of the proteïd and diluted with water, the liquid shows the same spectrum as blood that has been treated with concentrated tartaric acid solution. If a 1 per cent. solution of sodium hydroxide is added very gradually, the spectrum of acid methæmoglobin is seen at the point of neutrality. If the liquid is made very slightly alkaline, the characteristic spectrum of alkaline methæmoglobin is observed. On the addition of a few drops of ammonium sulphide, the band of hæmoglobin appears, and, if air is blown into the liquid, oxyhæmoglobin is formed. Similar formation of hæmoglobin results from the action of hydrogen sulphide on the slightly acid methæmoglobin solution. The hæmoglobin thus formed combines with carbonic oxide, and shows the characteristic spectrum.

The alcoholic solution of hæmatin alone gives no hæmoglobin under the same conditions.

Precisely similar results are obtained with crystallised oxyhæmoglobin. It seems clear that hæmatin unites with the proteïd derived from oxyhæmoglobin, and forms methæmoglobin, which is afterwards readily converted into oxyhæmoglobin. C. H. B.

Physiological Chemistry.

Physiological Oxidation. By O. Nasse (*Chem. Centr.*, 1892, i, 173; from *Naturforsch. Gesell. Rostock*).—Benzaldehyde, when shaken with an aqueous solution of copper sulphate in the presence of the least possible quantity of air, acts as a reducing agent, and copper is precipitated; if sulphur be present, copper sulphide will be formed. On the other hand, if oxidisable substances are shaken with benzaldehyde, water, and air, they are oxidised. Water becomes separated into hydroxyl and hydrogen; the former replaces hydrogen in the oxidisable substance, and the hydrogen unites with any organic sulphur which may be present, or precipitates copper from copper sulphate, or attacks the oxygen molecules of the air, and so makes oxygen atoms available for purposes of oxidation. Similar processes have been observed to take place in protoplasm. J. W. L.

Metabolism in Pigs Fed with Corn Cockle. By C. Kornauth and A. Arche (*Landw. Versuchs-Stat.*, **40**, 177—202).—Whilst the seeds of corn cockle (*Agrostemma githago*) are unanimously held by scientific men to be unsuited, on account of their poisonous nature, for feeding, practical agriculturists do not generally take this view, and many Hungarian farmers fatten pigs almost exclusively with offal consisting largely of this seed. Many experiments have been made to ascertain the effect of feeding with the seeds, but the results have always been uncertain. Pusch thinks it is injurious, under some conditions, but that the poisonous action of the seeds varies, the variation being due to the weather and the nature of the soil; and, further, that the injurious action decreases as the feeding is continued, so that, finally, it will be quite harmless. Taking all the results together, it cannot be considered as proved that, with normal feeding, the seeds are injurious.

In the authors' experiments three pigs were fed for four weeks on offal containing 46 per cent. of corn cockle. Two rabbits, fed at the same time, ate the other constituents, leaving the corn cockle. When the offal was ground, the rabbits ate the whole without injury. Having found that no injurious effect was produced when the whole seeds were consumed, various extracts were prepared and injected subcutaneously. This also was without effect. Systematic experiments were next made in which pigs were fed with a mixture of known amounts of corn cockle, barley and maize. The results of the experiments, which are given in tables showing the increase of live weight, composition of food and fæces, amounts of various constituents digested, &c., point to the following conclusions:—

Feeding with corn cockle has no injurious effect on young pigs. When, for instance, 70 per cent. is employed (an amount which would never occur in practice), the growth of the pigs is diminished, but there was no poisonous action, the depression being due to the lessened appetite caused by the bitter food. The deposition of

albumin was diminished, but the deposition of fat rather increased, owing to the lessened production of carbonic anhydride in respiration. The food was used up to the same extent as other food. The flesh produced with corn cockle feeding was normal. The amount of corn cockle required to produce a given increase in live weight is greater than the weight of food free from corn cockle, but not by any means in the proportion corresponding with the low price of the latter, so that this is to be considered as quite suitable for fattening.

N. H. M.

Action of Oxalic Acid and its Derivatives on the Animal Economy. By P. Krohl (*Chem. Centr.*, 1892, i, 177—178; from *Arb. Pharmakol. Inst. Dorpat*, **7**, 131—156).—Sodium oxalate, sodium malonate, ammonium oxalurate, and oxamide cause glycosuria, accompanied by an interruption of the oxidation processes, and carbonic oxide is formed, either in the free state or in combination, as the group —CO·CO—. Since hydrogen cyanide is oxidised to oxamide by hydrogen peroxide, experiments were made to see if it could be employed as an antidote in the case of hydrogen cyanide poisoning.

These experiments were successful, and hydrogen cyanide, in larger quantity than the fatal dose, was administered to dogs and cats, and its effect stayed by means of hydrogen peroxide. The experiment could be made daily for weeks together without permanently injuring the animal. Moreover, hydrogen cyanide could not be detected in the urine after application of hydrogen peroxide, whereas it is present in ordinary cases of hydrogen cyanide poisoning. J. W. L.

Chemistry of Vegetable Physiology and Agriculture.

Accumulation of Atmospheric Nitrogen in Cultivations of Bacillus radicicola. By M. W. Beyerinck (*Meded. Koninh. Akad. Wetens.* [3], **8**, 460—475).—The results of the author's earlier experiments with cultivations of *B. radicicola* did not show any gain of nitrogen at the expense of the air (Abstr., 1891, 1539). It was shown that peptone, and also, but much less readily, asparagine, ammonium sulphate, and potassium or sodium nitrates, can serve as sources of nitrogen, whilst nitrites, in all states of dilution, seem to act injuriously, and never give rise to growth. It is now found that, with more favourable conditions, especially as regards nutrition and temperature, the bacillus can be made to develop; at the same time, the nutritive solutions in which they grow gain nitrogen. The experiments were carried out as follows:—

Horse beans were allowed to germinate, the stems cut off, and 100 grams (of stems) boiled for a short time with 1 litre of water. 100 c.c. of this liquid was put into each of 12 Kjeldahl's flasks, and 1·5 per cent. of cane sugar added to each. Some of the flasks (Experiments 1—3) had, besides, 0·3—0·1 gram of potassium mono-

phosphate. The contents of the flasks were infected with *B. radicicola*, isolated from the nodules of Windsor beans. The flasks were kept in a box, to which only a little light had access; the temperature was generally between 5° and 12°, but on rare occasions was as low as 2° and as high as 15°. Most of the cultivations showed turbidity in a few days, whilst the check experiments remained clear. The appearances observed during growth are described in detail. At the conclusion the liquids in the flask were evaporated down (in the flasks) at 100° in a current of air. The nitrogen in the residues was then determined by Kjeldahl's method. The results are shown in the following table :—

Expt. No.	1*.	2.	3.	4.	5.	6.
	gram.	gram.	gram.	gram.	gram.	gram.
Infected	0·0058590	0·0061194	0·0069006	0·0082026	0·0075516	0·0079422
Not infected...	0·0049476†	0·0049476	0·0050778	0·0066402	0·0065100	0·0036402
Gain of nitrogen	0·0009114	0·0011718	0·0018228	0·0015614	0·0011416	0·0013020

The gain is, in all cases, only slight, but the experiments lasted for two months only, and the organisms were in full activity when the experiments were stopped.

With the *Robinia* bacilli, which grew more slowly than those of *Vicia faba*, no increase of nitrogen was obtained in eight weeks; but the author expects that his subsequent experiments will give similar results to those described above.

The solutions contained no nitric acid, either at the beginning or at the end of the experiments.

The results show that a gain of nitrogen from the air took place, but the question remains whether it was the free or the combined nitrogen which was utilised. Although the first experiment, in which the air was freed from combined nitrogen before reaching the solution, showed a gain of nitrogen, the author considers a complete proof is wanting, and that it is more probably the combined nitrogen which is taken up by the organisms. Some light may be thrown on the matter by the investigation of other organisms which have the power of depriving the surrounding matter of nitrogen compounds (*loc. cit.*). If it can be shown that with these organisms an accumulation of nitrogen can be effected, it will be more easy to understand why such an important function as the fixation of free nitrogen, being withheld from all higher plants, should not be assigned to lower organisms.

The power which some micro-organisms have of withdrawing nitrogen compounds from solutions so dilute that the roots of higher plants are unable to extract anything is much more intelligible.

* The flasks in this experiment were provided with U-tubes containing dilute sulphuric acid to wash the air before it entered.

† A separate analysis was made in each case. Two solutions were employed, one for Expts. 1—3, the other for the rest.

The fact observed by Hellriegel and Wilfarth, that the plants, and not the soil, gained nitrogen, is, perhaps, due to the absence of a carbohydrate in the ignited soil, although if carbohydrates were present, quicker-growing organisms would have probably developed rather than *B. radicicola*, and thus prevent nitrogen accumulation.

As regards the nitrogenous food of the Papilionaceæ, this must depend entirely on the dying off of the bacteroids in the nodules, as only dead bacteroids seem able to give up as albumin the nitrogen they took up.

The question next arises whether the plant can exercise an influence on the death of the bacteria or on their renewed production. The first question is difficult to answer, whilst, with regard to the second, it is to be expected that a deficit of assimilable nitrogen in the plant will give rise to an excess of carbohydrate, since the formation of albumin must cease, whilst the decomposition of carbonic anhydride goes on. There is every reason to believe that the carbohydrates are beneficial to the bacteria, and enable them to develop more vigorously at the cost of the nitrogen around them. N. H. M.

Fixation of Free Nitrogen by Plants. By T. Schlœsing, jun., and E. Laurent (*Ann. Inst. Pasteur*, **6**, 65—115).—The present paper gives a detailed account of the experiments and of the methods and apparatus employed (compare Abstr., 1891, 353; 1892, 378 and 523). The vessels in which the plants were grown were glass cylinders of about 6—7 litres capacity, closed at the bottom and drawn out to a neck at the upper end. They were filled to about one-third with the sand (2—3 kilos.) or soil (2—2·5 kilos.), the upper space serving to contain the mixed gases supplied and for the development of the plants. The cylinder was connected by means of a mercury joint with the rest of the apparatus, consisting of pump, combustion furnace, tube containing acidified asbestos for the absorption of ammonia, &c., of which sketches are given. As the amount of gas which could be used was very limited, it was of importance that its composition should correspond throughout the experiment with the wants of the plants, and arrangements had to be made so that a portion of the gas could be withdrawn from time to time for analysis (only a small amount of gas was used each time, and the nitrogen residue was returned). The excess of oxygen was got rid of by passing a part of the gas over ignited copper, and the deficiency of carbonic anhydride supplied by heating potassium hydrogen carbonate.

In commencing an experiment, after sowing the seeds or adding the nutritive solutions, or soil extracts, and watering, the whole apparatus was exhausted, carbonic anhydride let in, and again exhausted. The cylinder was then surrounded with water at 30—32°, when a slight amount of gas was given off, which was pumped out. The apparatus was again washed out with carbonic anhydride (still at 30—32°) and exhausted; the gas thus recovered was pure carbonic anhydride. Oxygen, nitrogen, and carbonic anhydride (air was in no case employed) were then introduced, but a pressure from outside was maintained during the whole experiment. At the conclusion of

the experiment, the mixed gases were pumped out, passing through the acidified asbestos to absorb any ammonia, and over heated copper to absorb the oxygen; it was then washed out with carbonic anhydride until the recovered gas was pure carbonic anhydride.

As regards the indirect method, the nitrogen of the seeds was determined by Kjeldahl's method, that of the soil by Dumas' method as modified by Schloesing, sen. (*Compt. rend.*, **107**, 296), 200—250 grams of sand or soil being used for each analysis. At the conclusion of the experiments, the soil from each pot was heated in a flask at 70°, and the vapour given off condensed in a tube surrounded by ice. This water was collected and the ammonia determined. The total nitrogen was then determined in the soil.

In the 1890 experiments in which peas were grown in sand (containing 0·000186 per cent. of nitrogen) with minerals, pots 1 and 2 were microbe-seeded, pot 3 not seeded and left open to the air. The plants of 1 and 2 grew to the height of about 20 cm. and flowered, but did not produce seeds; there was much development of roots, with many nodules. The plants of pot 3 grew to a height of 31 cm., but were slender and without branches; there were pods, but no completely developed seeds. The roots had no nodules. The following table shows the amount of dry produce and the approximate amount of carbonic anhydride assimilated:—

	Dry matter, grams.	CO_2, litre.
Pot 1	2·55	1·4
„ 2	2·10	1·3
„ 3	1·83	—

The nitrogen results are given below, together with those of the subsequent experiments.

In 1891, a poor subsoil containing 0·008722 per cent. of nitrogen was employed (2·5 kilos., pots 1—7; 2·0 kilos., pots 8—13), with the addition of chalk (5 grams), a mixture of several rich soils (5 grams), and a nutritive solution containing, among other things, a little nitrate. The first series comprised the following:—1. Jerusalem artichoke. 2. Oats. 3. Peas. 4. Tobacco. 5, 6, 7. Check experiments. The results were as follows:—1. No flowers, fresh weight about 17 grams, about 2 litres of carbonic anhydride assimilated. 2. Fresh weight (three plants) 25 grams, height 49 cm., 6 litres of CO_2 absorbed. 3. Flowers formed, height 49 cm., many nodules on roots, 4 litres of CO_2 absorbed. 4. 9—10 cm. high, 4 litres of CO_2 assimilated. The surface of the soils in pots 1—5 was covered with lower green vegetation consisting of mosses (*Bryum* and *Leptobryum*) and algæ (*Conferva*, *Oscillaria*, and *Nitzschia*). The soils of pots 6 and 7 were practically free from visible growth of any kind. The nitrogen results given in the table (p. 1023) show that nitrogen fixation took place in pots 1—4, with higher and lower vegetation, and in pot 5, with lower vegetation, but not in pots 6 and 7, where there was no vegetation. Moreover, with regard to pot 5, it was found that only the upper layer of soil (weighing 56·8 grams, and including about 1 gram of dry vegetable matter) had gained nitrogen,

* Including (in 1891 experiments) nitrogen as nitrate added; 37·7 mgm., pot 1; 12·5 mgm., pots 2—5; 14·0 mgm., pots 12 and 13.
† Including (in 1891 experiments) traces of nitrogen as ammonia found in the asbestos tube and in the water distilled from the soil.
‡ Pots 1 and 2, microbe seeded. § Left open to the air and not infected.

the percentage of nitrogen of the rest of the soil remaining practically the same. In connection with this point, Frank (*Landw. Jahrb.*, 1888) already admitted that such a gain could be brought about, but without sufficient evidence. Gautier and Drouin also found that algæ enrich soil in nitrogen, but attributed it to the absorption of combined nitrogen.

In order to avoid the growth of lower vegetation in the next experiments, a layer of dry sand was put over the surface of the soil. The experiments were: Pot 8, check; 9, barley; 10, peas; 11, white mustard; 12, cress; and 13, giant spurrey. The barley grew to a height of 50 cm., and assimilated 2·6 litres of carbonic acid. The peas produced several flowers, grew to a height of 64 cm., decomposed 3·7 litres of carbonic anhydride, and had many nodules on the roots. The mustard grew to 55 cm., and decomposed 2·2 litres of carbonic anhydride. The cress grew to a height of 65 cm., decomposed 3 litres of carbonic anhydride, and produced numerous flowers. The spurrey remained small, 6 cm.

The table, p. 1023, summarises the whole of the results as far as nitrogen is concerned, obtained by two methods, direct and indirect.

The chief points of interest furnished by the authors' experiments are the confirmation, by a direct method, in conjunction with the indirect method, (1) that the *Leguminosæ*, or at least peas, have the power of fixing elementary nitrogen, (2) that some of the lower green plants have the same power, (3) that soils free from visible growth did not fix nitrogen, and (4) that barley, mustard, cress, and spurrey did not fix nitrogen when, under the same conditions, peas did. N. H. M.

Composition and Cultivation of the Jerusalem Artichoke. By G. Lechartier (*Ann. Agron.*, **18**, 68—91).—Experimental plots of this crop have been grown at the agricultural station of Rennes for the six years 1885–90. No nitrogenous manure was used. Plot 1 received no manure; Plot 2, superphosphate equal to 100 kilos. P_2O_5 per hectare; Plot 3, potassium chloride equal to 175 kilos. K_2O per hectare; Plot 4, the same quantities of superphosphate and potassium chloride, mixed. The crop in 1889 was a failure. The yields of the other years are summarised below :—

Tubers. Kilos. per hectare.	1885.	1886.	1887.	1888.	1890.	Mean.
1. No manure	20243	19987	10206	8180	12947	14312
2. Superphosphate only.....	21600	18730	8978	6600	11886	13559
3. Potassium chloride only....	35371	27620	24700	23680	21168	26508
4. Mixture of the two	36606	33385	24008	22890	19000	27978

This soil contained nitrogen, 0·170—0·122; P_2O_5, 0·096; CaO, 0·229—0·193; MgO, 0·405—0·283; and K_2O, 0·309—0·337 per cent.

The extreme dependence of the yield of tubers on the supply of

assimilable potash in the manure, even when the soil is not poor in total potash, is clearly shown in the above figures. The author has followed the variations in the proportions of mineral ingredients in stem, leaf, and tuber, in the different years, on the crops of the differently manured plots, and at different stages of development, by means of very elaborate analyses. The mean composition of the ash of the crop on the best manured plot (Plot 4) was as follows:—

	Per cent. of dry matter in		
	Stems.	Leaves.	Tubers.
Ash	2·860	—	4·193
SiO_2	0·220	4·741	0·299
P_2O_5	0·113	0·326	0·588
CaO	0·920	5 537	0·207
MgO	0·497	1·817	0·139
K_2O	0·330	0·209	2·162
Na_2O	0·052	—	0·100

The figures above represent the distribution of mineral matter at harvest in November or December, the stems being nearly dry, and the leaves black and withered. The maxima and minima of the two principal ingredients were:—

	Tubers.		Leaves.		Stems.	
	Max.	Min.	Max.	Min.	Max.	Min.
P_2O_5	0 740	0·320	0·658	0·200	0·264	0·071
K_2O	2·470	1·640	0·370	0·127	0·584	0·075

The minimum of potash found in the tubers probably corresponds with the smallest quantity necessary to normal development. In wet seasons, the proportion of potash and phosphoric anhydride in the tubers is much higher than in dry seasons. The leaves in wet seasons from the unmanured plots contained less potash than in dry, because they were drained to a greater extent by the greater development of tubers. The influence of the different manures is greatest on the composition of the leaves because the tubers develop normally, so far as they can, at the expense of the leaves. Phosphatic manure applied alone increased neither the phosphoric acid nor the potash assimilated; but potash manure applied alone doubled the quantity of phosphoric acid assimilated, besides trebling or quintupling the amount of potash assimilated. Tubers lifted in September are richer in phosphoric acid and potash than those lifted in November or December, part of the

food at first absorbed being probably used in the growth of the tubers or the development of new ones.

Analysis of the leaves in three stages of development—young and green, yellow and beginning to wither, old and black—from crops on the differently manured plots and in the different years, brings out the following facts:—The green leaves contain twice or even four times as much potash when potash manures are supplied; magnesia is in larger proportion when no potash manure is given; lime is in far less proportion in the young than in the old leaves; phosphoric acid is in much greater proportion in the young leaves on all the plots (17—22 per cent.) than in the yellow leaves (7—14 per cent.) or the blackened leaves (4—12 per cent.). In the yellow leaves, the proportion of potash falls to 1·8—2·4 per cent. on the plots receiving no potash manure; whereas, on those receiving potash manure, it is as high (11—50 per cent.) as in the young leaves.

In the blackened leaves, where no potash was given in manure, the potash fell to 0·6—0·7 per cent.; where it was supplied in manure, there was still 15 per cent. The change from yellow to green of the leaves is not caused by drying, both containing 70—80 per cent. water, but by lack of P_2O_5 or K_2O. These materials being withdrawn from the leaves at first formed for tuber formation later on, eventually fall below certain limits (3·48—4·10 per cent. for P_2O_5 and 3·18—3·36 per cent. for K_2O), and when this is the case, these leaves commenced to turn yellow and afterwards black. On the unmanured plots, many leaves undergo these changes early in the autumn, if the soil is deficient in P_2O_5 or K_2O; when phosphatic and potash manures are supplied, many more leaves remain green until late in the season. Phosphate alone being supplied in the manure, the blackened leaves contained P_2O_5 6·98 and K_2O 1·17 per cent.; potash alone being supplied, they contained P_2O_5 1·07 and K_2O 15·64 per cent.

The author proposes to make comparative estimations of P_2O_5 and K_2O in the old and young leaves taken simultaneously from a growing plant, in order to find out which of these two substances is lacking (in assimilable condition) in the soil; for some crops (? most) a similar proceeding would show the presence or absence of sufficient assimilable nitrogen. The richness of a leaf in mineral matter varies greatly with the season, the soil, the manures supplied, the stage of vegetation, and with its position on the stem; these variations are much greater than are found in tuber or in seed. J. M. H. M.

Kaolin in Arable Soil. By R. Sachsse and A. Becker (*Landw. Versuchs-Stat.*, **40**, 245—255).—Kaolin, when heated in a platinum crucible so as just to give out light, lost 11·04—11·91 and in one case 10·98 per cent. of water; when heated by placing the crucible in melted saltpetre for two hours, the loss was 10·69 per cent. The silicate so produced had the sp. gr. 2·461, and was decomposed by evaporating down with dilute hydrochloric acid. The residue, insoluble in acid and in potash, amounted to 11·30—11·90 in the case of the first mentioned (which lost 11·04—11·91 per cent. of water) and 18·6 and 23·48 per cent. where the loss of water had been respectively 10·98 and 10·69 per cent.

Myelin (containing H_2O, 14·27; SiO_2, 45·41; and Al_2O_3, 40·48 per cent.), when gently ignited, lost 13·0—13·9 per cent. of water, and left a residue, insoluble in acid and alkali, only amounting to 2·4 per cent.

Nacrite (of the composition H_2O = 15·65, SiO_2 = 44·15, and Al_2O_3 = 40·85 per cent.), which is said to be entirely soluble in hydrochloric acid, was found to be soluble only to the extent of about 50 per cent. After ignition, it dissolved, all except 1·43 per cent.

The above results with kaolin agree better with the molecular relation $5Al_2O_3 : 9SiO_2$ than with $Al_2O_3 : SiO_2$.

When the silicate (sp. gr. 2·461) is digested with aqueous sodium silicate (potassium silicate is almost without action) for an hour, a gelatinous substance of the following composition is obtained:—

	SiO_2.	Al_2O_3.	Na_2O.	H_2O.
1	52·72	25·93	12·21	8·88
2	53·01	27·51	11·20	8·66

It has thus taken up water as well as sodium silicate, and become converted into a kind of analcime.

Kaolin was estimated in two muds from arable soil. This was done by extracting the soil, previously dried at 100°, with dilute hydrochloric acid, and estimating the dissolved sesquioxide, and the silica soluble in potash. These determinations were again made in second samples which had been gently ignited, and the *minus* of residue insoluble in acid and potash, or the *plus* of silica and sesquioxide, which was obtained in the second experiment as against the first, calculated as kaolin. The composition of the muds, the one from a heavy clay and the other from a red soil from Paraguay, is given, as well as that of the finest mud of the three loams previously analysed by the authors (compare *Landw. Veruchs-Stat.*, **38**, 411).

Analytical Chemistry.

Improvements in Burettes. By A. F. Reid (*Chem. News*, **65**, 125).—A metal scale constructed to slide on the outside of an ordinary burette, or a graduated tube fixed firmly in an india-rubber ring, which slides up and down, as a piston, inside the burette, is suggested as useful for measuring the delivery of successive small quantities of solution from the same burette. D. A. L.

Use of Iodic and Bromic Acids in Quantitative Analysis. By A. Schwicker (*Chem. Zeit.*, **15**, 845—846).—The author's process agrees in principle with the one described by Feit and Kubierschky (compare this vol., p. 910), but is carried out in a somewhat different manner. The process will prove of good service when the solutions are very dilute, and completely oxidisable by bromic acid in the cold, and it dispenses with the boiling off of the liberated bromine.

Iodic acid is a slow oxidant, and scarcely useful except for the estimation of sulphurous acid; but bromic acid is a useful oxidant, even in a strongly diluted state. The oxidising action of iodic, or bromic, acid may be represented by the equation $2HIO_3 = H_2O + I_2 + O_5$. 2 mols. of iodic, or bromic acid, which, if brought into contact with potassium iodide, would have liberated 6 mols. of iodine according to the equation $2HIO_3 + 10HI = 6H_2O + 6I_2$, give, after reduction, only 1 mol. of iodine. The diminution in iodine corresponds with the oxygen of the iodic or bromic acid which has been taken up by the substance under examination. If now the amount of iodine liberated by potassium iodide is estimated by sodium thiosulphate, before and after the action of the reducing agent, the amount of the latter may be readily calculated.

It is not necessary, of course, to use either bromic or iodic acid in the pure state, but a solution of the readily obtainable potassium iodate or bromate, mixed with sulphuric acid, may be used. The test analyses practised on sulphurous acid and sodium sulphite, also on nitrites of known strength, are very satisfactory. L. DE K.

Separation of Iodine, Bromine, and Chlorine. By C. SCHIERHOLZ (*Monatsh.*, **13**, 1—39; compare Field, this Journal, 1857, 234, and *J. pr. Chem.*, **73**).—When each of the three halogens is present in fair quantity, the author adopts an indirect method, in which two weighings only are necessary. Two equal volumes of the neutral solutions, in which the halogens are to be determined, are measured out, and one of them is accurately titrated with a 1/20 normal silver nitrate solution. The number of c.c. required, *a*, and the weight of the silver precipitate, *b*, are accurately determined. The second portion of the solution is treated with a few grams of potassium bromide, and the same volume of the silver nitrate solution as was required to precipitate the halogens in the first portion, is added. The solution is boiled for some time, diluted with water, and the weight, *c*, of the resulting precipitate, which contains all the iodine, all the silver, and some bromine, is noted. By means of the three values *a*, *b*, and *c*, the quantity of each halogen present can be readily calculated.

If only a small quantity of iodine and bromine is present with relatively much chlorine, the method of estimation depends on the facts that silver iodide is insoluble in moderately concentrated solutions of sodium chloride, and that bromine and chlorine can be separated by distillation with solutions of potassium permanganate and aluminium sulphate (compare White, Abstr., 1888, 1130). For the latter process, the author employs a distillation apparatus, consisting of a retort and condenser, and made of glass in one piece, the last portions of the bromine being expelled by boiling with a little dilute sulphuric acid. The bromine is absorbed in a flask containing dilute ammonia, whereby it is converted into ammonium bromide and probably partly into ammonium hypobromite; the whole of the bromine is, however, precipitated as silver bromide, on adding silver nitrate to the solution. This method of separating the iodine is only available when (say, in a mixture of sodium salts) it is

present in the proportion of not more than 1 part of iodide to 6 or 7 of bromide and 1000 of chloride, under which circumstances, on the addition of a little silver nitrate, only silver iodide is precipitated, since silver bromide and silver chloride are soluble in strong sodium chloride solution. If, however, more bromide, or more iodide and bromide, are present than is indicated by the above-given ratio, it is best to precipitate and estimate the iodide as palladium iodide.

In making the above separations, the author has incidentally investigated the solubility of silver chloride, bromide, and iodide in solutions of the halogen salts of the alkalis, more particularly in sodium chloride. Such solutions dissolve 4—5 times as much of the halogen salts of silver at their boiling point, as at the ordinary temperature. The concentration of the solution of the halogen salts of the alkalis has also a marked effect on the solubility of the silver compounds; a 10 per cent. solution of sodium chloride and 1 per cent. solution of potassium iodide dissolving scarcely any recognisable quantity of the corresponding silver compounds. The very great difference between chlorine and iodine is shown both in the relative solubility of silver chloride and silver iodide, and in the different solvent power of the halogen alkali salts on silver nitrate, silver chloride, &c.; bromine occupying a position between chlorine and iodine. For example, 100 grams of sodium chloride or of potassium chloride in a 20 per cent. solution dissolves hardly a trace of silver iodide, whilst 100 grams of potassium iodide in concentrated solution dissolves about 90 grams of the salt, and a boiling saturated solution dissolves 4—5 times that quantity. Mixtures of the halogen salts of the alkalis, in particular proportions, are unable to dissolve as much of the silver salt as each can before admixture. G. T. M.

Analysis of Sodium Nitrite. By G. Lunge (*Chem. News*, **65**, 134).—According to the author, both the aniline and sulphanilic acid methods (compare this vol., p. 751) were in use 14 years ago, but are tedious, troublesome, and misleading, whereas his own modification of the permanganate method is rapid, simple, and accurate.

D. A. L.

Estimation of Phosphoric Acid in Fertilisers containing Cotton-seed Meal. By F. B. Dancy (*Chem. News*, **65**, 162—163, 170—172).—The author shows that the method of dissolving in nitric acid with a small quantity of hydrochloric acid and precipitating by molybdate is not applicable for determining phosphoric acid in fertilisers containing cotton-seed meal, inasmuch as, although they dissolve readily enough, the solutions do not give up their phosphoric acid to molybdate, and, therefore, low results are obtained. Moreover, solution in hydrochloric acid and potassium chlorate has proved, in some instances, inadequate for the purpose. Fusion with equal parts of sodium carbonate and potassium nitrate gives maximum results, but takes too long, whilst incineration and subsequent solution of the ash in nitric acid sometimes gives low results, owing to the ignited phosphate not being completely soluble in that solvent; this difficulty is apparently overcome by dissolving the ignited residue

in hydrochloric acid, in which it is readily and wholly soluble. This, therefore, furnishes a satisfactory basis for a desirable method.

D. A. L.

Testing Metallic Iron for Arsenic. By O. Sautermeister (*Chem. Zeit.*, **15**, 1021—1022).—The author, applying the official test of the German Pharmacopœia, could get no reaction for arsenic even when 0·1 gram of arsenic trioxide was purposely added. The test consists in dissolving 1 gram of the metal in dilute hydrochloric acid, in a Marsh's apparatus, and allowing the hydrogen flame to play upon a porcelain dish. An examination of the insoluble residue revealed, however, the presence of arsenic, which had been reduced to the metallic state. This fact was, indeed, known to Wöhler in 1839, but has since been overlooked.

The test is, however, more satisfactory when about 2·5 grams of zinc is added to the iron. Although the arsenic does not show at first, it will be gradually evolved when the hydrogen comes off briskly. 0·1 per cent. of arsenic in a sample of iron may be detected in this manner.

L. de K.

Wiborgh's Gasometric Method for the Estimation of Carbon in Iron. By H. v. Jüptner (*Chem. Centr.*, 1892, i, 237; from *Osterrungar. Zeit. Berg. Hütt.*, **39**, 533—537).—The author recommends several slight alterations in the method of using the apparatus.

J. W. L.

Estimation of Gold, Tin, and Cadmium in Alloys. By W. French (*Chem. News*, **65**, 133—134).—The following method is recommended as expeditious and trustworthy. 1 or 2 grams of alloy is heated with just sufficient hydrochloric acid to dissolve the tin and cadmium, and the gold is collected and weighed; the filtrate is then nearly neutralised with potassium hydroxide, 4 to 5 c.c. of hydrogen peroxide (10 vols.) added, the whole diluted to about half a litre, and heated to boiling. In this way the tin is precipitated in a convenient form, and is washed, dried, ignited, and weighed as stannic oxide. The solution is evaporated to about half its bulk, and the cadmium is precipitated at the boiling point by means of potassium carbonate.

D. A. L.

Estimation of Manganese in Iron and Steel. By H. Rubricus (*Chem. Zeit.*, **15**, 882).—The author remarks that he has never had any trouble in determining the end point when titrating manganese with permanganate, and recommends the following process:—

10 grams of the iron or steel is dissolved in 50 c.c. of hydrochloric acid (sp. gr. 1·15), the solution filtered into a 500 c.c. flask, and made up to the mark. 100 c.c. of the liquid (= 2 grams of the sample) is oxidised with nitric acid, cooled, diluted to 600 c.c., and nearly neutralised with sodium carbonate. The iron is now precipitated with a very moderate excess of elutriated zinc oxide; 2 grams of magnesium sulphate is added, and the liquid heated to boiling. On adding the permanganate, the clear, supernatant liquid first becomes brownish, but then gradually clearer until at last the pink colour of the permanganate becomes quite distinct. On account of the great

dilution of the liquid, 0·1 c.c. of permanganate solution must be allowed for. L. DE K.

Analytical Application of Barium and Hydrogen Peroxides. By E. DONATH (*Chem. Zeit.*, **15**, 1085—1086).—The author's process of oxidising chrome-iron ore by means of barium peroxide has been tried by Kinnicut and Patterson, who failed, however, to get satisfactory results. These chemists, therefore, recommend the addition of sodium carbonate. The author again asserts that the ore is completely attacked by barium peroxide alone, provided this is of good quality. The probable reason why Kinnicut and Patterson's results were not satisfactory is that their chrome-iron ores were of exceptional richness and their barium peroxide of poor quality. The author has never insisted on performing the oxidation in a porcelain crucible, but merely remarked that such a crucible may be used.

When sodium carbonate is added, the mass fuses, and is therefore not so easily removed from the crucible; moreover, the use of an alkali causes a portion of the chromium to remain as oxide, which has to be oxidised to chromate by hydrogen peroxide. The usual method of estimating the chromic acid by reduction with a ferrous salt, and estimation of the excess of the latter by permanganate, is, in the author's opinion, inferior to the plan of estimating it by means of potassium iodide and sodium thiosulphate.

As regards hydrogen peroxide, this is an excellent oxidant for ferrous salts, and its excess is very readily removed by boiling. It rapidly oxidises ammonium sulphide without separation of sulphur, and may be successfully used to oxidise an ammoniacal solution of arsenic trisulphide before precipitation with magnesia mixture.

L. DE K.

Estimation of Kaolin in Arable Soils. By R. SACHSSE and A. BECKER (*Landw. Versuchs-Stat.*, **40**, 245—255).—See this vol., p. 1026.

Röse's Process for the Estimation of Alcohol. By L. GRÜNHUT (*Chem. Zeit.*, **15**, 847—848).—A few years ago, Röse proposed a new process for the direct estimation of alcohol. A small quantity of the sample is largely diluted with water, mixed with a large excess of potassium permanganate, and then suddenly mixed with an excess of strong sulphuric acid. After a few minutes, the alcohol is supposed to be completely oxidised to carbonic anhydride and water. The excess of permanganate is destroyed by the addition of a known quantity of potassium tetroxalate, the excess of which is then in turn estimated by permanganate. Röse's preliminary experiments were very satisfactory.

The author has, however, found, as Benedikt did previously, that the reaction does not proceed regularly on these lines, and that a good deal depends on the amount of sulphuric acid, which, if added in insufficient quantity, causes a very incomplete oxidation. If, on the other hand, too much acid is added, an independent decomposition of the permanganate will set in and the result will be untrustworthy.

The process cannot, therefore, be recommended for the estimation of alcohol in technical products. L. DE K.

Action of Alkaline Mercuric Cyanide on Maltose, Dextrose, and Dextrin. By J. A. WILSON (*Chem. News*, **65**, 169).—Alkaline mercuric cyanide has been said to destroy the optical activity of dextroglucose and maltose, but to leave dextrin unchanged. The author has put this to the test:—10 c.c. each of solutions of these carbohydrates (= 1 gram of the dry substance) were boiled severally for two minutes with a slight excess of a solution of alkaline mercuric cyanide, containing 12 grams of mercuric cyanide and 12 grams of sodium hydroxide in 100 c.c. of water. The cooled solutions were acidified with hydrochloric acid, diluted to 50 c.c., clarified by animal charcoal, and polarised in a 200 mm. tube. The results show that the optical activity of dextrose is entirely destroyed by this treatment, that of maltose diminished from +26 to +9, and that of dextrin from +37·2 to +33·5; the dextrin was not quite pure, but not sufficiently impure to account for this loss. D. A. L.

New Reagent for Acetone. By A. SCHWICKER (*Chem. Zeit.*, **15**, 914).—A mixture of acetone and aqueous ammonia dissolves powdered iodine and gets warm. The liquid becomes turbid, and after some time deposits iodoform. At the same time, a substance is formed which is probably an iodine substitution product of acetone, and which is characterised not only by a pungent smell, but also by exciting a flow of tears. There is no apparent evolution of any gas, but a little acetic acid is formed. The process, which is not affected by the presence of alcohol, is carried out as follows:—

The solution, which must be free from aldehyde, is mixed with a few drops of ammonia and a few drops of N/10 iodine solution. Nitrogen iodide is formed at first, but disappears on shaking and warming. If acetone is present in not too small quantity, the iodoform reaction makes its appearance at this point, and is improved by the addition of a little more iodine. The characteristic odour is not greatly obscured by the ammonia. If the nitrogen iodide refuses to disappear, it may be readily removed by the cautious addition of a few drops of a very weak solution of sodium thiosulphate.

If traces only of acetone are present, the reaction will still make its appearance if a little more time be given. The test may be applied to detect acetone in urine. L. DE K.

Estimation of Uric Acid. By H. C. GEELMUYDEN (*Zeit. anal. Chem.*, **31**, 158—180).—An accurate process for estimating uric acid in urine is still a desideratum. Salkowski's method of precipitation with ammoniacal silver and magnesium solution is open to the objection that other nitrogenous substances, especially xanthine and its congeners, are precipitated with the uric acid. The necessity for applying a correction for the solubility of uric acid in the final wash water is a further objection (see also Abstr., 1889, 1250). Ludwig's modification (Abstr., 1886, 102) is no improvement, and introduces fresh sources of error. The author has sought to employ the precipitation of uric acid by barium chloride as a means of estimation, and

has obtained promising results, but is obliged to discontinue the investigation without bringing the method to perfection. Instead of weighing the precipitate, it is preferable to determine the nitrogen in it by Kjeldahl's method. From a solution of sodium hydrogen urate, the uric acid can be almost absolutely precipitated by adding barium chloride, heating for half an hour on the water-bath, allowing the mixture to remain until next day, and filtering off. Solutions containing as little as 9 milligrams in 100 c.c. give very satisfactory results. The presence of ammonium chloride or of disodium hydrogen phosphate or of the two together, is without influence, but free acid or free alkali, and the latter especially in presence of phosphates, prevents complete precipitation. The acidity of normal urine has a similar effect, so that neutralisation is requisite, but this in the presence of phosphates presents peculiar difficulties. If, however, the addition of alkali is stopped, either when precipitation of earthy phosphates commences, or when litmus paper wetted with the liquid just remains blue after drying, precipitation of the uric acid seems to be complete, but other nitrogenous substances appear to be thrown down, since the results calculated from the nitrogen found come out higher than by Salkowski's method. The excess is the greater, the richer the urine is in uric acid, and in one case amounted to 70 per cent. On the other hand, the uric acid obtainable from the barium precipitate (in a case where the barium method showed 0·0059 gram, or 13 per cent. more than Salkowski's) was 0·00365 gram, or 8 per cent. less than Salkowski's; neither could it be ascertained that more than traces was lost. Dilution of the urine leads to lower, but apparently untrustworthy results, since a degree of dilution which would not interfere with a satisfactory estimation if using a pure urate, yet when applied to urine, reduces the amount of nitrogenous substance precipitated to a small fraction of that shown by Salkowski's method. The subject needs and seems to deserve further investigation. M. J. S.

Estimation of Cream of Tartar in Wine Lees. By B. Balli (*Chem. Zeit.*, **15**, 989—991).—The author recommends a process which may at first sight seem rather too complicated for commercial purposes, but which will be found of great use to makers of cream of tartar, as it will enable them to calculate the exact amount of hydrochloric acid to be added in case the wine yeast has been fermenting, and so partly changed into normal potassium tartrate or, as may also happen, into a mixture of potassium hydrogen tartrate and potassium carbonate.

The process may be briefly described as follows:—It consists of two separate analyses. 1. The analysis proper. The cream of tartar is extracted by boiling water and so exposed to the action of the carbonates. The portion acted on by the potassium carbonate is completely changed into normal tartrate, whilst that acted on by calcium carbonate is to the extent of one half changed into normal tartrate. By neutralisation with potash or soda, the remaining, permanent cream of tartar is also made into a soluble normal tartrate, which may then be estimated as potassium hydrogen tartrate by the addition of acetic acid. The result will be, *constant* cream of tartar

+ ½ loss caused by the calcium carbonate + total loss caused by potassium carbonate. 2. The check analysis. The object is the estimation of the amount of pre-existing, or subsequently formed, potassium normal tartrate, also the loss caused by the carbonates. The cream of tartar is dissolved in boiling water, and is, of course, acted on by the carbonates. On cooling, the *constant* cream of tartar practically crystallises out, and the mother liquor retains normal potassium tartrate, which may be precipitated as the acid salt by the addition of acetic acid. The result will show, ½ the loss caused by the calcium carbonate + the loss caused by the potassium carbonate. The difference between the chief and the check analyses gives the constant bitartrate, or, plainly put, the amount of cream of tartar obtained by a single crystallisation. L. DE K.

Detection of Margarin in Butter. By H. RODEWALD (*Landw. Versuchs-Stat.*, **40**, 265—275).—Butter and margarin differ only in their quantitative composition, their qualitative reactions, volatile and insoluble fatty acids, combination with iodine, and refractive property being common to both. The usual process consists in comparing the numbers obtained with the minimum and maximum numbers of natural butter. The method is uncertain when the results fall beyond these numbers, inasmuch as other minimum and maximum numbers may be found for natural butter. More difficult cases occur when the results given by a sample (known to be probably adulterated) fall within the numbers obtained with pure butter. The object of the present paper is to indicate how, in such cases, the probability of adulteration may be established arithmetically from all the results. The numbers obtained by Schrodt and Henzold with pure butter are employed.

In the case of large additions of margarin, the estimation of insoluble fatty acids gives the most certain results. The methods next in value are the estimation of volatile acids and the refractive exponent.

The worst kind of adulteration is, when all the butter is mixed with a little magarin (10—15 per cent.), but butter so adulterated would always be liable to suspicion. N. H. M.

Analysis of Beeswax. By C. MANGOLD (*Chem. Zeit.*, **15**, 799—800).—Owing to the great fluctuation of the acidity, saponification, and iodine numbers of genuine yellow beeswax, adulteration with less than 6 per cent. of paraffin or ceresin is almost beyond detection. A process has been worked out by A. and P. Buisine, which the author thought was well worth trying. It is based on the decomposition of wax soap by hot potash-lime, which does not act on the paraffins, but decomposes the fatty matter with elimination of hydrogen, which serves as a measure of their amount. The paraffins may be extracted from the residue.

The author's investigations practically confirm those of Buisine, but he now recommends the following process:—2 to 10 grams of the wax is saponified by melting it with powdered potash-lime, the reaction being aided by stirring with a glass rod. After complete cooling, the soap is powdered, and intimately mixed with three times its

weight of potash-lime, and the powder transferred to a thick-walled, pear-shaped bulb-tube, which is heated for three hours at 250° in a mercury bath contained in an iron vessel. This is provided with a lid, which screws on air-tight, and is pierced with four apertures through which pass air-tight, respectively, the pear-shaped bulb, a thermometer, a thermostat, and a long tube open at both ends to condense any mercury vapour. A tube connects the pear-shaped bulb with a Hofmann's burette, in which the hydrogen is measured.

The author's process is, however, more particularly directed to the estimation of the paraffins. After three hours, when no more gas will be given off, the residue is powdered, and to prevent any loss the bulb-tube is also broken up, and the whole is extracted with light petroleum in a Soxhlet's apparatus. The petroleum is distilled off, and the residual paraffin dried at 110° and weighed. On applying the process to yellow beeswax of undoubtedly genuine origin, the amount of natural hydrocarbons was found to vary from 11·02 to 14·7 per cent., although in practice the average amount may be put down as 13·5 per cent.

A sample of Transylvanian wax, tested by the author, had an acidity equivalent of 16·66, and a true saponification number of 56·02, which pointed to adulteration with paraffin, or a similar substance. Analysed by the author's method, the percentage of hydrocarbons came, indeed, to 28·12, corresponding with 17 per cent. of adulteration, calculated on the original sample. A sample of wax, which had been purposely adulterated with 8 per cent. of paraffin, showed on analysis 7·4 per cent.

The amount of hydrocarbons in samples of white wax varied from 10·93 to 15·48 per cent., but the purity of some of the samples was rather doubtful. L. DE K.

Estimation of Oil of Mustard. By A. SCHLICHT (*Zeit. anal. Chem.*, **30**, 661—665).—In the course of a study of the decomposition of potassium myronate, a method of estimating allylthiocarbimide in presence of water became necessary. Foerster's method, which consists in converting the compound by ammonia into thiosinamine, and this into sinamine and mercuric sulphide by boiling with mercuric oxide, gives low results. So also does the method of Dircks (Abstr., 1883, 245), which moreover requires much time. The following modification is, however, both simple and trustworthy. The mustard oil is shaken for some time in a corked flask with a mixture of 20 parts of potassium permanganate and 5 parts of potassium hydroxide (both of which must be free from sulphates), and the mixture is finally heated nearly to boiling. The whole of the sulphur is thus oxidised to sulphuric acid. After slight cooling, 5 c.c. of alcohol is added for every gram of permanganate used. This completes the precipitation of the manganese present. The mixture is completely cooled, largely diluted, made up to a known volume, and filtered. A measured portion of the filtrate is slightly acidified with hydrochloric acid, and treated with a solution of iodine in potassium iodide until a feeble yellow colour remains even after warming. This reproduces any sulphuric acid which has been

reduced by the aldehyde, and also removes the aldehyde itself. The sulphuric acid is now determined by barium, and the weight of barium sulphate multiplied by 0·42492 gives the amount of mustard oil. Test analyses gave results varying from 99·74 to 99·95 per cent.

M. J. S.

Picric Acid as a Test for Guanidine. By O. Prelinger (*Monatsh.*, **13**, 97—100).—See this vol., p. 950.

Specific Gravity of Fibres. By De Chardonnet (*Compt. rend.*, **114**, 489).—The values for the specific gravity of fibres as determined by Vignon's method (this vol., pp. 254, 645) are too low, as the air is not completely expelled from their interstices.

A more trustworthy method consists in mixing the silk, cut into pieces not more than 1 mm. long, with a solution of cadmium borotungstate of about the same specific gravity, and exposing the mixture to a vacuum and atmospheric pressure alternately for some hours, to ensure that the fibres are completely permeated with the liquid. Water or concentrated solution of the above salt is then cautiously added until the cloud of fibres remains permanently suspended in the liquid. The specific gravity of the liquid and solid must then be equal, and hence by taking the specific gravity of the filtered liquid, the required figure is obtained.

The values thus obtained for raw and refined silk are 1·66 and 1·43 respectively.

Jn. W.

Specific Gravity of Silk. By L. Vignon (*Compt. rend.*, **114**, 603—605).—A reply to de Chardonnet. The author finds that exposure to reduced pressure under benzene for 10 minutes removes all the gas, and no alteration in sp. gr. is produced by exposure to reduced pressure for three days. The higher results obtained by de Chardonnet are due partly to the mechanical treatment to which the silk was subjected, and partly to the use of strong solutions of metallic salts for the determination of the sp. gr. The author finds by direct experiment that the silk absorbs saline matter from these solutions.

Colour Reactions of the Proteïd Precipitate produced by Potassium Ferrocyanide. By H. Winternitz (*Zeit. physiol., Chem.*, **16**, 439—444; compare Abstr., 1891, 1130).—The precipitate produced in a proteïd solution by the addition of potassium ferrocyanide is a very delicate reaction; it is given by a solution containing only 1 part of the proteïd in 50,000. It is not, however, an absolute proof of the existence of proteïd in such investigations, for instance, as the question of the presence of proteïd in normal urine. It is then necessary to test the precipitate by means of the various colour reactions for proteïds. Of these, that given by Millon's reagent is the most delicate. The precipitate also gives the Adamkiewicz reaction, the xanthoproteïc reaction, Liebermann's reaction, and the reaction of Max Schultze (with concentrated sulphuric acid and a drop of dilute cane-sugar solution). It does not give Fröhde's reaction (blue colour with sulphuric acid containing molybdic acid, *Annalen*, **145**, 376).

General and Physical Chemistry.

Colours and Absorption-spectra of Thin Metallic Films and of Incandescent Vapours of the Metals: Electrical Volatility. By W. L. Dudley (*Amer. Chem. J.*, **14**, 185—190.)—The author describes a number of methods he has employed in the preparation of thin metallic films, and gives a table comparing the colour of metals by transmitted light with that emitted by their incandescent vapours. A thin coherent film of metal usually transmitted light of a colour remarkably similar to that emitted by its incandescent vapour, and if the films were perfect and continuous there would, in all probability, be no exceptions. The colour of the incandescent vapour of a metal is the resultant of the colours of the various rays emitted, and depends on the number and intensities of the rays, and the colour can therefore be fairly predicted on examining a table of wave-lengths and relative intensities of the spectral lines of the metal.

The author further observes that if the order of the electrical volatility of the metals, as given by Crookes, be compared with Lothar Meyer's curve of atomic volumes, it will be found that the volatile metals lie at, or near, the minima of the curves, close together on the ascending sides in the periods IV, V, and VII, alternating from one to the other. Magnesium and aluminium, which are practically non-volatile, lie on the descending side of period III. Aluminium, which is less difficult to volatilise than magnesium, is nearer the minimum of the curve. G. T. M.

Laws of Electrolysis. By A. Chassy (*Compt. rend.*, **114**, 998—1000).—In order to avoid exceptions, the author proposes to substitute the following statement for the statements of Faraday, Becquerel, and Wiedemann:—*When any substance whatever is electrolysed, there is always liberated an equivalent of hydrogen or the corresponding quantity of the electro-positive radicle.* He finds that in the electrolysis of potassium ferricyanide there are liberated K_3 and $FeCy_6$; with sodium nitroprusside, Na_2 and $FeCy_5NO_2$; whilst with basic ferric nitrate $Fe_2O_3,2N_2O_5$, the products are Fe_2 and $2N_2O_5 + O_3$.

C. H. B.

Thermoelectric Phenomena at the Contact of Two Electrolytes. By H. Bagard (*Compt. rend.*, **114**, 980—982).—A thermoelectric couple consisting of two electrolytes, such as dilute sulphuric acid and a solution of zinc sulphate, or dilute sulphuric acid and a solution of cupric sulphate, shows variations with the temperature similar to those observed with a couple formed by an amalgam and an electrolyte. With the zinc sulphate, the E.M.F. at first increases with the temperature, attains a maximum and then decreases; with cupric sulphate the E.M.F. increases, reaches a maximum at about 40°, then at 70° becomes *nil*, and afterwards again increases.

C. H. B.

Separation of Precipitates at the Boundary of Electrolytes. By G. Kümmell (*Ann. Phys. Chem.* [2], **46**, 105—112).—Faraday showed that if in the two limbs of a U-tube layers of pure water are placed above a saturated solution of magnesium sulphate in such a manner that the two liquids do not mix, and a current then passed, a separation of a precipitate of magnesium hydroxide occurs at the boundary of the magnesium sulphate solution, and the water which is below the negative electrode. Herrmann (*Götting. Nach.*, 1887, 342) found that zinc sulphate could be substituted for magnesium sulphate. The author has repeated these experiments, but in place of using solutions of the metallic sulphates in water, has found it convenient to make use of solutions prepared with gelatin, which solidify on cooling. The gelatin does not interfere with the occurrence of the phenomenon, while at the same time the admixture of the salt with the pure water, which otherwise is difficult to prevent, may be avoided. With solutions prepared in this manner it was possible to examine the behaviour of a number of different sulphates, but only with those of magnesium, zinc, cadmium, and aluminium was the occurrence of a precipitate observed. The separation of the hydroxide always takes place first at the negative electrode, the appearance of the precipitate at the boundary of the two liquids being of later occurrence. By suitable modifications in the method of carrying out the experiment it was ascertained that the phenomenon is due to the solid particles being carried mechanically from the negative electrode through the feebly conducting water by the electric current. H. C.

Electrical Conductivity of Substances in Mixed Solvents. By S. Arrhenius (*Zeit. physikal. Chem.*, **9**, 487—511).—When a portion of the water in the aqueous solution of an electrolyte is replaced by a non-electrolyte, such as alcohol, so that the total volume remains unchanged, the electrolytic conductivity of the solution diminishes. If the quantity of non-electrolyte added (x), does not reach more than 10 per cent. the conductivity of the solution may be expressed by the formula $l = l_0\left(1 - \frac{\alpha}{2}x\right)^2$, where l_0 is the conductivity of the pure aqueous solution, and α an empirical coefficient.

The author has investigated 55 different electrolytic solutions with regard to the influence on their conductivity of six non-electrolytes (methyl alcohol, ethyl alcohol, isopropyl alcohol, ether, acetone, and cane sugar), the strengths of the solutions and the quantities of non-electrolyte added being varied. The decrease of the conductivity brought about by the addition of 1 per cent. by volume of the non-electrolyte (α) depends on the nature both of the electrolyte and of the non-electrolyte, varying between 1·5 and 4 per cent. of the conductivity of the pure aqueous solution. As the concentration of the electrolyte increases, α is in general the greater; and the variability of α with the concentration is such that it is smaller, the greater the degree of dissociation of the electrolyte is.

The diminution of the conductivity by the addition of a non-electrolyte is partially due to the increase of the fluid friction of the

solution, which lowers the speed of the ions. In the case of substances that are strongly dissociated (most salts, and strong acids and bases), the diminution is due almost entirely to this cause, and the relation between it and the increase of fluid friction may be expressed by the formula $1000\alpha = C + 1000C'(A - 1)$, where A is the fluid friction (compared to that of water as unity) of a solution with 1 per cent. of the water replaced by the non-electrolyte, and C and C′ are constants, which are the same for various groups of electrolytes. Here the addition of the non-electrolyte does not alter the degree of dissociation. On the other hand, when the dissolved substances are only feebly dissociated, the addition of the non-electrolyte not only diminishes the speed of the ions but also diminishes their number. This diminution of the degree of dissociation is greatest with non-electrolytes that contain no hydroxyl groups, becoming less as the number of hydroxyl groups in the molecule increases.

Temperature has only a slight influence on the proportional diminution of the conductivity, this diminution, however, becoming always smaller as the temperature rises.

The author indicates how to correct the observed conductivity of a solution for fluid friction, so as to reduce the value obtained to that in a liquid whose fluid friction is equal to that of pure water; and, finally, points out the method of applying his results to the determination of the ash in sugar solutions (molasses) by means of observations on the electrolytic conductivity. J. W.

Mechanical Determination of the Boiling Points of Compounds with Complex Terminal Substitution. By G. Hinrichs (*Compt. rend.*, **114**, 1272—1274).—The connection between the boiling points of compounds and the moment of inertia of the molecule round its natural axis of rotation has already been shown by the author in former papers. The application of the general formulæ obtained to the special case of the change of the normal paraffins into alcohols, and of the alcohols into the corresponding acids, is here considered. In a chain of n carbon atoms, the substitution of the mass μ for hydrogen will bring about an alteration of the boiling point $\Delta t = \frac{k}{n}\Sigma\mu\nu^2$, or the rise in the boiling point of a normal paraffin produced by complex terminal substitution is proportional to the sum of the reduced moments introduced, and inversely proportional to the number of carbon atoms in the paraffin. k is not, however, absolutely constant, but its value generally is proportional to the ordinate y_2 of the parabolic curve for the boiling points of the paraffins (*Compt. rend.*, **112**, 1128). H. C.

Mechanical Determination of the Boiling Points of Alcohols and Acids. By G. Hinrichs (*Compt. rend.*, **114**, 1367—1370).—Application of the formula obtained in a former paper (see preceding abstract) for the determination of the boiling points of alcohols and acids from those of the paraffins from which they are derived. The calculated values are found to agree well with those observed, and

the author predicts a boiling point of 212·4° for the normal nonyl alcohol. H. C.

Hydrogenation of Closed Rings: Constitution of Camphoric Acid. By F. Stohmann and C. Kleber (*J. pr. Chem.* [2], **45**, 475—499; compare Abstr., 1891, 376, 1146).—*Methyl dicarboxyglutarate*, $CH_2[CH(COOMe)_2]_2$, is prepared in like manner to the ethyl derivative (Abstr., 1888, 1061); it crystallises in large, brilliant prisms, melts at 48—48·5°, and dissolves easily in the usual organic solvents.

Methyl trimethylenetetracarboxylate (1, 1, 2, 2), $CH_2<\begin{matrix}C(COOMe)_2\\C(COOMe)_2\end{matrix}$, is obtained from methyl dicarboxyglutarate by dissolving it (1 mol.) in a little absolute methyl alcohol, adding sodium methoxide (2 mols.), cooling, and shaking with bromine (1 mol.). The methyl alcohol is then evaporated off and the liquid poured into water, whereby the new salt is separated. It crystallises in large prisms, and melts at 71·5—72°. When heated with fuming hydrochloric acid as long as methyl chloride is evolved, it yields the free acid which melts with evolution of carbonic anhydride at 215° (Abstr., 1890, 879).

Trimethylenedicarboxylic acid (1, 2) melts at 139° (compare Abstr., 1884, 992); the 1, 1 acid melts at 138·5—139° (Abstr., 1884, 832; Trans., 1885, 810). Tetramethylenetetracarboxylic acid (1, 1, 2, 2) melts at 138° (Trans., 1887, 22). Tetramethylenedicarboxylic acid (1, 1) melts at 158° (Trans., 1887, 5). Pentamethylenedicarboxylic acid (1, 2) melts at 161° (Trans., 1887, 244).

The table (p. 1041) shows the results of the author's calorimetric determinations on the above and other ring compounds; a few of the numbers have appeared before (Abstr., 1889, 1097; 1890, 100; 1891, 376), but are here repeated for the sake of coherence.

Each division in the table (excluding camphoric acid) represents successively the di-, tri-, tetra-, penta-, and hexa-methylene rings. It will be noted that the heat of combustion of the first member of each division does not increase over the one preceding it by 156·6 Cal. for the addition of CH_2, as is the case with homologues in the acetic series, even if maleïc acid be taken as the first member instead of fumaric acid. Further, the difference between the observed heat of combustion and that calculated on the basis of 156·6 Cal. increase in the case of the second and third members of the series is positive (+6·9 and +9·2 respectively when fumaric acid is the first member), whilst in the case of the fourth and fifth it is negative (−13·9 and −17·5 respectively), showing that more energy is consumed in closing the tetra-, tri-, and di-methylene rings than in closing the penta- and hexa-methylene rings.

When the numbers are compared for each addition of H_2, it will be noted that this addition, or, in other words, the opening of the ring to this extent, causes the following mean increase in the heat of combustion in Cals.:—In the dimethylene ring, 35·9; in the trimethylene ring, 31·9; in the tetramethylene ring, 29·1; in the pentamethylene ring, 52·9; in the hexamethylene ring, 54·7. The numbers that go to make up the mean for the dimethylene ring are not very concordant

Substance.	Formula.	Molecular weight.	Heat of combustion at constant pressure.	Heat of formation.
			Cal.	Cal.
Fumaric acid	$C_4H_4O_4$	116	320·1	193·9
Dimethyl fumarate	$C_6H_8O_4$	144	664·7	175·3
Maleïc acid	$C_4H_4O_4$	116	326·3	187·7
Succinic acid	$C_4H_6O_4$	118	356·8	226·2
Dimethyl succinate	$C_6H_{10}O_4$	146	703·6	205·4
1, 1-Trimethylenedicarboxylic acid	$C_5H_6O_4$	130	483·2	193·8
1, 2-Trimethylenedicarboxylic acid	$C_5H_6O_4$	130	484·1	192·9
1, 1, 2, 2-Trimethylenetetracarboxylic acid	$C_7H_6O_8$	218	483·0	382·0
1, 1, 2, 2-Tetramethyl trimethylenetetracarboxylate	$C_{11}H_{14}O_8$	274	1170·4	346·6
Glutaric acid	$C_5H_8O_4$	132	515·0	231·0
Methyl dicarboxyglutarate	$C_{11}H_{16}O_8$	276	1202·2	383·8
1, 1-Tetramethylenedicarboxylic acid	$C_6H_8O_4$	144	642·4	197·6
1, 2-Tetramethylenedicarboxylic acid	$C_6H_8O_4$	144	642·5	197·5
Adipic acid	$C_6H_{10}O_4$	146	668·9	240·1
1, 2-Pentamethylenedicarboxylic acid	$C_7H_{10}O_4$	158	776·0	227·0
Pimelic acid	$C_7H_{12}O_4$	160	828·9	243·1
Cis-hexahydroterephthalic acid	$C_8H_{12}O_4$	172	928·6	237·4
Fumaroïd-hexahydroterephthalic acid	$C_8H_{12}O_4$	172	929·5	236·5
Suberic acid	$C_8H_{14}O_4$	174	983·7	251·3
Camphoric acid	$C_{10}H_{16}O_4$	200	1244·3	247·1

among themselves, nor do they agree well with the numbers which the authors have previously obtained for ethylenic linking (Abstr., 1891, 376). On the other hand, those for the hexamethylene ring are fairly constant between 54 and 55. The mean energy lost by the addition of H_2 is, in Cals:—33·1 for the dimethylene ring; 37·1 for the trimethylene ring; 39·9 for the tetramethylene ring; 16·1 for the pentamethylene ring; and 14·3 for the hexamethylene ring.

The structures which have been ascribed to camphoric acid are:—(1) An open chain with one ethylenic linking (Kekulé); (2) a derivative of tetramethylenedicarboxylic acid (Ballo-Brühl); (3) a ketoxycarboxylic acid (Friedel); (4) a hexamethylene derivative of various structure (*a*, Wereden; *b*, Oddo; *c*, Kachler; *d*, Armstrong; *e*, the authors). The authors have calculated the heat of combustion of camphoric acid on the basis of each of the formulæ which have been given (for which see the authors quoted), and find that their

experimental number agrees most closely with the number calculated for Armstrong's formula. The figures are as follows, the bracketed numbers referring to those given above:—Calculated (1) 1255·7; (2) 1268·9; (3) 1257·1; (4) *a*, 1242·2; *b*, 1241·9; *c*, 1244·7; *d*, 1244·1; *e*, 1242·0. Found, 1244·3. A. G. B.

Thermal Function of Phenol. By DE FORCRAND (*Compt. rend.*, **114**, 1010—1012).—Pure sodium and potassium phenoxides were obtained by mixing a solution of sodium or potassium ethoxide in excess of alcohol with an alcoholic solution of phenol, evaporating to dryness in a current of hydrogen, and heating at 135° in order to expel the last traces of alcohol. The sodium compound forms a hard, white crystalline, deliquescent mass, and the potassium compound is similar, but is always slightly coloured.

The thermal results were as follows:—

Heat of dissolution C_6H_5NaO between 13° and 16′	=	+9·35 Cal.
„ „ C_6H_5KO „ „		+7·13 „
C_6H_6O diss. + NaOH diss.	develops	+7·96 „
C_6H_6O „ + KOH „	„	+8·20 „
C_6H_6O sol. + Na sol. = C_6H_5NaO sol. + H gas	develops	+39·10 Cal.
C_6H_6O sol. + NaOH sol. = C_6H_5NaO sol. + H_2O sol.	„	+ 7·23 „
C_6H_6O sol. + K sol. = C_6H_5KO sol. + H gas	„	+46·28 „
C_6H_6O sol. + KOH sol. = C_6H_5KO sol. + H_2O sol.....	„	+12·41 „

The thermal value of the ordinary phenolic function (+39·10 Cal.) is therefore little greater than that of glycol or erythritol, and is lower than that of glycerol. Even taking into account the exaggerations of the value of the first alcoholic function arising from the causes explained in former papers, phenol approaches more nearly to the alcohols, and more especially to the tertiary alcohols, than to the acids. The value for phenol, +39·10 Cal. is, in fact, almost identical with the mean (+39·03 Cal.) of the values of trimethylcarbinol and acetic acid. C. H. B.

The Heat of Dissolution of Gases in Liquids. By S. U. PICKERING (*Phil. Mag.* [5], **34**, 35).—Various substances, of which the heat of vaporisation was known, were dissolved as liquids in water, acetic acid, and benzene separately, and thence their heat of dissolution in the gaseous condition was calculated. The values obtained were in all cases considerable, 5500 to 14000 cal. per gram molecule, showing that there is a considerable loss of potential energy, even when gases dissolve in liquids (to form solutions which are non-electrolytes), and that the dissolved substances cannot be present in a condition analogous to that of a free gas. The heat evolved depends on the nature both of the solvent and of the dissolved substance, and

no numerical relations between the values in the various cases was observed. With water as a solvent the heat evolved is generally greater than with acetic acid or benzene, thus agreeing with the known tendency of water to form molecular compounds. The author then answers *seriatim* the criticisms which J. Walker passed (this vol., p. 264), on his freezing-point determinations and on his arguments against the dissociation theory. S. U. P.

Density of Liquefied Gases and their Saturated Vapours and Critical Constants of Carbonic Anhydride. By E. H. Amagat (*Compt. rend.*, **114**, 1322—1326).—Discussion of the curves given in a former paper (this vol., p. 934) for the densities of liquid carbonic anhydride and its saturated vapour. H. C.

Volume Lag and its Bearing on Molecular Constitution. By C. Barus (*Amer. Chem. J.*, **14**, 191—202).—In studying the relation between melting point and pressure, it was found that the pressure necessary to solidify a substance was decidedly greater than the pressure at which it again passes into the liquid state. At first it seemed that the differences so obtained might be referred to heating effects on compression and to cooling on expansion, but the magnitude of the interval obtained is often too large for this interpretation. If the maximum pressure at which the substance just remains liquid, persistently exceeds the minimum pressure under which it just remains solid, then the observed phenomenon is a true volume lag (hysteresis).

The author assumes, in explanation of the above fact, the existence of cohesive affinities among the atoms, which are of the same nature as those which are active in effecting chemical combination. Change of state of aggregation is brought about by, and is evidence of, a corresponding change of the cohesive valency in one or more of the constituent atoms of the substance. It is shown that this view is in keeping with many physical and chemical properties of substances in addition to that which is noted above. H. C.

Absorption Coefficients of Gases. By F. Henrich (*Zeit. physikal. Chem.*, **9**, 435—443).—The author has recalculated the temperature equations for the absorption coefficients of gases by means of the method of least squares from Bunsen's experiments. His results are as follows :—

Nitrogen in alcohol—

$$C = 0{\cdot}12637 - 0{\cdot}00042813t + 0{\cdot}0000063046t^2$$

Hydrogen in alcohol—

$$C = 0{\cdot}0693 - 0{\cdot}00016654t + 0{\cdot}0000017445t^2$$

Butane in water—

$$C = 0{\cdot}030827 - 0{\cdot}00092585t + 0{\cdot}000020384t^2$$

Carbon monoxide in water—

$$C = 0{\cdot}032784 - 0{\cdot}00080094t + 0{\cdot}000015872t^2$$

Methane in water—

$$C = 0{\cdot}05473 - 0{\cdot}0012265t + 0{\cdot}000011959t^2$$

Methane in alcohol—

$$C = 0{\cdot}522745 - 0{\cdot}00295882t + 0{\cdot}0000177001t^2$$

Ethane in water—

"Methylgas"

$$C = 0{\cdot}085576 - 0{\cdot}0030389t + 0{\cdot}00004979t^2$$

"Aethylwasserstoff"

$$C = 0{\cdot}0939012 - 0{\cdot}0034106t + 0{\cdot}0000547035t^2$$

Ethylene in water—

$$C = 0{\cdot}25487 - 0{\cdot}0088312t + 0{\cdot}00017417t^2$$

Ethylene in alcohol—

$$C = 3{\cdot}5846 - 0{\cdot}056153t + 0{\cdot}00062369t^2$$

Carbonic anhydride in water—

$$C = 1{\cdot}7326 - 0{\cdot}066724t + 0{\cdot}0012394t^2$$

Carbonic anhydride in alcohol—

$$C = 4{\cdot}3294 - 0{\cdot}094261t + 0{\cdot}0012354t^2$$

Nitrous oxide in water—

$$C = 1{\cdot}30263 - 0{\cdot}046254t + 0{\cdot}00072154t^2$$

Nitrous oxide in alcohol—

$$C = 4{\cdot}1902 - 0{\cdot}074389t + 0{\cdot}00078226t^2$$

Nitric oxide in alcohol—

$$C = 0{\cdot}31578 - 0{\cdot}003469t + 0{\cdot}00004827t^2$$

Hydrogen sulphide in water—

$$C = 4{\cdot}4015 - 0{\cdot}089117t + 0{\cdot}00061954t^2.$$

The probable errors of these equations are much less than those of the equations given by Bunsen. J. W.

Viscosity of Aqueous Salt Solutions. By C. Lauenstein (*Zeit. physikal. Chem.*, **9**, 417—434).—The author has determined the viscosity of aqueous solutions of a large number of the sodium salts of organic acids. The temperature chosen was 25°, and the solutions investigated were $\frac{1}{8}$, $\frac{1}{4}$, $\frac{1}{2}$, and $\frac{1}{1}$ normal. The method of measurement was that described by Ostwald (*Lehrbuch*, 2nd ed., **1**, 550). The coefficient η varies in very many cases with the dilution according to the formula of Arrhenius, $\eta = A^n$ (where A is a constant depending on the nature of the dissolved substance, and n is the number of gram equivalents per litre); but in other cases, for example, the salts of the aromatic acids, the formula gives results which agree badly with experiment.

Certain regularities would seem to exist between the value of η for a given dilution of a sodium salt and the composition and constitution of the salt radicle. These regularities, however, are not of

so strict a nature as those observed in the case of the electric conductivity of the acids themselves, and are subject to many exceptions.

J. W.

Theory of Solutions. By J. H. Van't Hoff (*Zeit. physikal. Chem.*, **9**, 477—486).—The author replies in this paper to some objections raised by Lothar Meyer against the osmotic pressure theory of solution. He shows that the osmotic pressure of a given solution is independent of the membrane, provided that this is really semi-permeable; and that the divergence of many of Adie's numbers (Trans., 1891, 344) from those required by the theory, is due to the partial permeability to the dissolved substances of the copper ferrocyanide membrane employed. He expresses complete indifference as to the mechanism of osmotic pressure.

J. W.

The Cryoscopic Behaviour of Weak Solutions. Part II. Sodium Chloride and Copper Sulphate. Part III. Calcium Chloride and Nitrate. Part IV. Alcohol, Cane Sugar, Ether, and Urea. By S. U. Pickering (*Ber.*, **25**, 1314—1324, 1590—1599, 1854–1865).—Part II. Series of results with calcium chloride and copper sulphate were examined in the same way as in the case of the results with sulphuric acid (this vol., p. 678). Values calculated according to the conductivity when compared with the experimental values up to a depression of 1·66°, show a mean difference 374 times greater than the ascertained experimental error in the case of sodium chloride, whilst in the case of copper sulphate the discrepancy is far greater. On the other hand, a four-curve drawing which the author considers represents the results with sodium chloride, attributes an apparent error to the points agreeing exactly with the experimental error, and a similar result is obtained in the case of copper sulphate. The bridging over of any of the "breaks" in these figures increases the apparent error beyond legitimate limits.

Part III. *Calcium chloride and nitrate.*—Owing to the absence of data, the values for the calculated freezing points could not be obtained in these cases, but they could scarcely agree with the observed values in the case of calcium chloride, since the molecular depression with this salt was found to diminish generally with dilution, whereas supposed dissociation, and, consequently, the calculated molecular depression, must increase with dilution. In both cases it is shown that the author's interpretation of the results as curvilinear figures with breaks in them, agrees exactly with the magnitude of the experimental error, though this magnitude is very different in the two cases. The method is described by which the constant error, due to some of the solvents having separated before the freezing point, is observed when the "crystallisation" method is adopted; it consists in comparing the results given by this method with those given by determining the final melting point, as indicated by the rates at which the temperature of a partially crystallised solution rises before and after complete redissolution. The error was found to be 3·44 per cent. of the observed depression.

Part IV. *Alcohol, cane sugar, ether, and urea.*—The results with alcohol (up to a depression of 1·6°) indicated the existence of one

break, those with cane sugar two breaks, those with ether one break, and those with urea, none. The drawings made in accordance with these indications agreed exactly with the ascertained experimental error in each case, though this varied from 0·00050° to 0·00256° in different cases. The omission of any of these breaks, as in other cases, produces figures representing the existence of errors much greater than the known experimental errors, and the insertion of an imaginary break where none exists, does not improve the agreement with the experimental errors to any appreciable extent. A less complete examination of the results with cane sugar has been previously published (this vol., p. 109). The molecular depression with alcohol increases at first and then diminishes as the strength increases, with sugar it increases throughout, with ether it increases and then diminishes, whilst with urea it diminishes throughout. S. U. P.

Partially Miscible Solutions. By H. Pfeiffer (*Zeit. physikal. Chem.*, **9**, 444—476).—When 20 c.c. of amyl alcohol, 20 c.c. of ethyl alcohol, and 32·9 c.c. of water are shaken up together at the ordinary temperature, the mixture separates after a time into two layers. At 39·80° it remains perfectly homogeneous. If, instead of 32·9 c.c. of pure water, an equal volume of a dilute salt solution is added, the temperature at which the mixture no longer separates into layers is changed. Thus, for decinormal solutions, the following results were obtained, T representing the temperature of homogeneity for the solutions, and t that for pure water :—

	T.	t.	T − t.
Na_2CO_3.....	53·20°	39·80°	+13·40°
$BaCl_2$.....	50·00	,,	+10·20
KOH.....	47·85	,,	+ 8·05
NaCl.....	47·60	,,	+ 7·80
HCl.....	39·80	,,	0·00
AmCNS.....	34·10	,,	− 5·70

The author performed many experiments with isobutyl alcohol instead of amyl alcohol, using salt solutions of various strengths. He finds that the difference T − t = Δ increases with the valency of the salt, and that it is approximately proportional to the concentration of the salt solution. Analogous salts have equal differences, and the differences of true double salts are equal to the sum of the differences for their components. The increase of volume of the upper layer, just before complete mixture takes place, or the decrease of volume of the lower layer, is approximately proportional to the salt present. The same is true of the increase in the specific gravity of the layers. The difference Δ is dependent on the amount of salt that enters each layer, and the relation may be expressed by the formula $\Delta = K_2C_2 - K_1C_1$, where C_1 and C_2 are the molecular quantities of salt in 1 litre of each layer, and K_1 and K_2 are constants which are the same for analogous salts. Knowing the constants K_1 and K_2, the difference Δ, and the actual concentration of the two layers, it is possible to calculate the molecular weight of the dissolved substance. The agreement between theory and experiment is fairly good.

The author also made observations on the miscibility of various substances with water at different temperatures. Thus, the quantities of water given in the following table were added to mixtures of amyl and ethyl alcohol (whose composition is indicated by the first and second columns) before any milkiness appeared in the liquid:—

Amyl alcohol.	Ethyl alcohol.	Water at 9·10°.	Water at 19·20°.
3 c.c.	3 c.c.	3·21 c.c.	3·50 c.c.
3 „	6 „	10·35 „	10·80 „
3 „	9 „	18·34 „	19·10 „
3 „	12 „	27·47 „	29·15 „
3 „	15 „	41·25 „	43·15 „

Experiments with ethyl alcohol, water, and various ethereal salts, showed that isomeric ethereal salts have about the same miscibility with water, and that this decreases rapidly with the number of carbon atoms in the molecule. J. W.

Abnormal Dissolution: Saturated Solutions. By F. Parmentier (*Compt. rend.*, **114**, 1000—1003).—The compound of ether and bromine, $3Br_2,2Et_2O$, described by Schützenberger, dissolves readily in ether, but if increasing quantities of ether are added, there arrives a point at which the excess of ether separates from the solution, as already observed in the case of phosphomolybdic and silicomolybdic acids. The quantity of ether required to saturate the solution increases with the temperature, whereas in the case of the two acids referred to, the quantity of ether required decreases with the temperature. The following table shows the weight of ether bromide dissolved by 100 parts of ether at various temperatures:—

−13°.	0°.	12°.	22·5°.	32°.
632	561	462	302	253

The following definition of a saturated solution is framed with a view to meet all cases:—*When substances can, without combination, form a homogeneous liquid, the solution is said to be saturated when one of the bodies, added in excess to the solution, separates from that solution.* C. H. B.

Solubility of Double Compounds. By R. Behrend (*Zeit. physikal. Chem.*, **9**, 405—416).—The isomeric substances, benzylisoparanitrobenzaldoxime (α) and paranitrobenzylisobenzaldoxime (β) unite molecule to molecule to form a double compound ($\alpha\beta$). This double compound is almost entirely dissociated into its components in alcoholic solution, as is shown by observations on the boiling point. The author has made solubility experiments on various mixtures of α and β, in order to determine the influence of the mass of each on the solubility of the double compound in alcohol. Series of determinations were made at temperatures ranging from 9·4° to 14°. A week must elapse before a state of equilibrium is reached in the solutions. The following table exhibits the results obtained. Solutions I and II are solutions of the simple components α and β;

III contains α and β in equivalent proportions; IV is obtained from a mixture containing excess of α, and V from a mixture containing excess of β. The numbers in the columns express parts by weight in 100 parts of solution:—

Solution.	9·4°.		10·4°.		14°.	
	α.	β.	α.	β.	α.	β.
I	1·16	—	1·18	—	1·41	—
II	—	2·16	—	2·19	—	2·60
III	1·25	1·25	1·27	1·27	1·51	1·51
IV	1·23	1·24	1·38	1·26	1·62	1·47
V	0·75	2·23	0·75	2·29	0·93	2·70

These values agree very well with those deduced from the principle laid down by Nernst (Abstr., 1890, 3) for the reciprocal influence of the solubility of salts; it being possible on this basis to calculate the solubility of the mixtures from the solubility of the simple components and of the double compound. Calculation shows that the double compound only exists to the extent of 7—10 per cent. in the alcoholic solution, the remainder being dissociated. J. W.

Isomorphism. Part VI. By J. W. Retgers (*Zeit. physikal. Chem.*, **9**, 385—404).—Lehmann observed that ammonium chloride could form intimate mixtures with chlorides of the heavy metals, with which it is not isomorphous. The author has made experiments with many combinations of corresponding compounds in order to ascertain whether ammonium chloride is singular in this respect, or shares the property with other substances. When a drop of concentrated ammonium chloride solution is spread on a microscope slide, and a few grains of ferric chloride are added, it is observed that the chloride disappears rapidly, and that brown, birefringent crystals of the double salt, $4NH_4Cl,Fe_2Cl_6 + 2H_2O$, appear in its neighbourhood. Further off, cubes of ammonium chloride separate out, showing all shades, from deep reddish-yellow, through pale-yellow, to colourless. These crystals are quite homogeneous, and contain no enclosed particles of ferric chloride. They exhibit striking optical anomalies, being mostly composed of four sectors, which show marked double refraction, as is seen in the polarisation colours and the strong pleochroism from pale-yellow to brown. This behaviour is very different from what is observed in the case of isomorphous mixtures; and the crystalline forms, both of anhydrous ferric chloride and of the above-mentioned double salt, completely exclude the idea of a direct isomorphism.

Ammonium chloride also forms mixed crystals, of the same character as those in which ferric chloride is contained, with the following compounds:—Cobaltous chloride (hydrated), nickel chloride (anhydrous), manganous chloride, ferrous chloride, cadmium chloride,

zinc chloride, cupric chloride (very slight admixture), chromic chloride (in acid solution, violet). Magnesium chloride and aluminium chloride do not mix with ammonium chloride, as is indicated by the perfectly isotropic character of the crystals obtained.

Ammonium bromide does not form mixtures with any of the bromides corresponding with the chlorides mentioned above, nor does ammonium iodide with the corresponding metallic iodides. The nitrate and sulphate behave similarly. Methylammonium chloride does not mix with ferric chloride.

Potassium, rubidium, cæsium, sodium, thallium, and silver chlorides do not form mixed crystals with ferric chloride. On the other hand, lithium chloride can mix with ferric chloride, but not with cupric or cobalt chloride.

The author considers the double refraction observed in the mixed crystals to be due, for the most part, to internal tension, but also, to some extent, to the enclosed birefringent metallic chlorides.

In the second portion of this paper, the author discusses the position of tellurium in the periodic system, and maintains his suggestion (Abstr., 1891, 1152) that this element should be placed in the eighth group with an atomic weight greater than that of iodine. The evidence of its isomorphism with sulphur and selenium is in his opinion inconclusive. J. W.

Inorganic Chemistry.

Alcoholic Solutions of Ammonia. By Delépine (*J. Pharm.* [5], **25**, 496—497).—The following table gives the solubility of ammonia in ethyl alcohol of various strengths and at various tem-

Degree of alcohol.		100°.	96°.	90°.	80°.	70°.	60°.	50°.
Melting ice	weight of gas..	130·5	146·0	173·0	206·5	—	246·0	304·5
	density	0·782	0·783	0·800	0·808	—	0·830	0·835
	sol. coefficient.	209·5	245·0	302·5	390·0	—	504·5	697·7
10°	weight of gas .	108·5	120·0	137·5	167·0	—	198·25	227·0
	density	0·787	0·803	0·794	0·800	—	0·831	0·850
	sol. coefficient.	164·3	186·0	234·4	288·0	—	373·0	438·6
20°	weight of gas..	75·0	97·5	102·0	119·75	137·5	152·5	182·7
	density	0·791	0·788	0·795	0·821	0·829	0·842	0·869
	sol. coefficient.	106·6	147·8	158·3	190·5	223·0	260·8	338·2
30°	weight of gas	51·5	74·0	77·0	81·75	100·3	129·5	152·0
	density	0·798	0·791	0·796	0·826	—	0·846	0·883
	sol. coefficient.	97·0	106·7	114·0	121·6	—	211·6	252·0

peratures. The weight of gas contained in a litre of the solution saturated at 760 mm. is given, also the density of the solution, and the coefficient of solubility calculated from the foregoing data and the density of the solvent.

Methyl alcohol also dissolves enormous quantities of ammonia. A purified commercial alcohol containing less than 3 per cent. of acetone dissolves 40 per cent. of its weight, thus :—

0°	Weight of gas per litre	218·0
	Density.....	0·770
	Coefficient of sol.	425·0

J. T.

Compounds of Carbon and Silicon. By P. Schützenberger (*Compt. rend.*, **114**, 1089—1093).—A covered gas-carbon crucible, containing an intimate mixture of crystalline silicon (1 part) and silica (2 parts), is placed in a larger crucible, and well surrounded by lamp black ; this second crucible is then placed in a third, and also packed with lamp black. After subjecting the whole to a bright red heat for several hours, and subsequently cooling, the friable contents of the first crucible are powdered and boiled with moderately concentrated hydrofluoric acid in order to dissolve the silica and a small quantity of silicon nitride, Si_3N_4, which is formed. No free silicon is present. The insoluble residue, containing nearly one-half of the silicon employed, is extracted with boiling concentrated hydrofluoric acid, and the green powder which remains analysed by fusion with potash, and by heating in a stream of chlorine. This substance is a new *silicon carbide*, SiC, formed, doubtless, by the action of carbon monoxide on the silicon. On treating it with chlorine at a low red heat, silicon chloride is evolved, leaving carbon and part of the carbide unchanged. After burning the carbon in a current of oxygen, a portion of the residue can be acted on by chlorine at a bright red heat, but the residue from this second treatment is not further attacked by chlorine. W. J. P.

Metaphosphates. By G. Tammann (*J. pr. Chem.* [2], **45**, 417—474 ; compare Abstr., 1891, 7).—The author has reinvestigated the metaphosphates, and in this paper details the preparation of the various salts enumerated in the following summary, with which he concludes. A notice of the methods adopted for determining molecular weight has already appeared (Abstr., 1891, 7).

1. The trimetaphosphates of Fleitmann and Henneberg (*Annalen*, 1848, **65**, 304) are now shown to be dimetaphosphates of the general formula $R_2'(PO_3)_2$.

2. Fleitmann's dimetaphosphates (*Ann. Phys. Chem.*, **78**, 233, 338) are trimetaphosphates of the general formula $R_3'(PO_3)_3$.

3. Of tetrametaphosphates, only Fleitmann's salt, $CuNa_2(PO_3)_4$, has been obtained.

4. The following pentametaphosphates are known :—$NH_4K_4(PO_3)_5 + 6H_2O$; $NH_4(NH_4)_4(PO_3)_5$; $NH_4Na_4(PO_3)_5$; $NH_4Li_4(PO_3)_5$.

5. The uncrystallisable hexametaphosphates, $Na_6(PO_3)_6$ and $Ag_6(PO_3)_6$, are obtained from Graham's soluble sodium metaphos-

phate (*Ann. Phys. Chem.*, **32**, 33), which is a mixture of the foregoing sodium salt with several other hexametaphosphates.

6. The soluble potassium, sodium, and lithium hexametaphosphates derived from the acid $H_2Na_4(PO_3)_6$ and the two insoluble salts $Ag_4K_2(PO_3)_6 + H_2O$ and $3Sr_2K_2(PO_3)_6 + 4H_2O$ are prepared from the ordinary insoluble potassium, lead, and lithium metaphosphates.

7. Octametaphosphates of the general formula $R_3''Na_2(PO_3)_8$ are obtained by fusing magnesium, cobalt, nickel, manganese, or zinc sulphate with sodium metaphosphate.

8. Ammonium decametaphosphate is formed when the ammonium dimetaphosphate of Fleitmann (*loc. cit.*) is heated between 200° and 250°, and from this, strontium, manganese, silver, and lead decametaphosphates, and the salt $K_9NH_4(PO_3)_{10} + 10H_2O$ can be prepared.

9. Gregory's tetrakaidecametaphosphate (*Annalen*, **54**, 94), $Mg_6Na_2(PO_3)_{14}$, completes the list of those metaphosphates whose constitutions can be said to be known.

The following salts are still of uncertain formula:—

1. The anhydrous and insoluble copper, manganese, cobalt, and zinc metaphosphates.

2. The anhydrous and insoluble lead, bismuth, barium, cadmium, and silver metaphosphates.

3. Maddrell's insoluble sodium metaphosphate (*Annalen*, **61**, 53).

4. Another insoluble sodium metaphosphate, obtained by keeping sodium metaphosphate in fusion.

5. The soluble crystalline potassium, sodium, and ammonium metaphosphates from glacial metaphosphoric acid.

6. The salts $(NH_4)_2Li(PO_3)_3 + 4H_2O$ and $K_2Li(PO_3)_3 + 2H_2O$, insoluble in cold water.

7. A series of soluble metaphosphates, of which the crystalline potassium salt has the composition $KPO_3 + 3H_2O$.

8. A series of soluble, crystalline metaphosphates, of which the salts $NaPO_3 + H_2O$ and $3KPO_3 + 2H_2O$ are known.

The author describes two metaphosphoric acids. The one, *α-metaphosphoric acid*, is obtained by heating orthophosphoric acid until it retains only as much water as is represented by the formula HPO_3; it is a soft, silky mass. The other, *β-metaphosphoric acid*, is obtained by heating orthophosphoric acid until it sets to a glassy mass on cooling; the potassium salt of this acid is insoluble in potassium hydroxide solution. The β-metaphosphates are more stable in water than the α-metaphosphates; they are all freely soluble in water, and the β-salts can be separated from the α-salts by crystallisation.

A. G. B.

Copper Sulphites. By S. B. Newbury (*Amer. Chem. J.*, **14**, 232—238).—When a slow current of sulphurous anhydride is passed for several hours through a 10 per cent. solution of copper sulphate containing a roll of thin sheet copper, the solution becomes almost colourless, and the metal is found to be covered with red crystals of cuproso-cupric sulphite, $CuSO_3,Cu_2SO_3 + 2H_2O$. This red salt may also be obtained on warming the dark-green solution of cupric sulphite, which is formed by passing sulphurous anhydride through well-cooled water containing pure precipitated cupric hydroxide in

suspension. All attempts to obtain a crystalline salt from the green solution of cupric sulphite were without success, as, in every case, a deposit of the red salt was soon formed. On exposure to the air, or, still better, on passing a current of air through it, the green solution eventually gave a precipitate of a bright, yellow-ochre colour, which, when air-dried, formed a bright-yellow powder. This substance was also formed on adding alcohol to the green solution, and is shown by its properties and analysis to be the *basic cupric sulphite*,

$$3CuO,2SO_2,1\tfrac{1}{2}H_2O.$$

It dissolves in dilute hydrochloric acid to a green solution, giving off sulphurous anhydride without separation of cuprous chloride, and in dilute sulphuric acid without separation of metallic copper. On boiling with water for a few minutes, the compound undergoes complete decomposition, a deep-blue solution of copper sulphate and a brown, insoluble substance being formed, which, by hydrochloric acid, is completely converted into cuprous chloride with liberation of sulphurous anhydride, and dissolves in sulphuric acid with liberation of metallic copper. This substance is in all probability *cuprous sulphite*, for, on continued boiling with water, sulphurous anhydride escapes and bright-red cuprous oxide is formed.

When moist basic cupric sulphite is exposed to the air, it is gradually oxidised, forming cupric sulphate, which may be dissolved out by water, leaving a yellowish-green, insoluble powder, which gives all the reactions of the original substance. It is probably a basic cupric sulphite of simpler constitution than the one described above. G. T. M.

Composition of Glass suitable for Chemical Utensils. By R. Weber and E. Sauer (*Ber.*, **25**, 1814—1819).—The authors give analyses and the numerical results of their experiments on the action of the liquids previously employed (compare this vol., p. 410) on green bottle glass, window glass, and very hard combustion tubing; in all three cases the glass was only slightly acted on by water and by acids, but to a much greater extent by the alkaline liquids.

F. S. K.

Manganese Compounds. By H. Schjerning (*J. pr. Chem.* [2], **45**, 515—530).—Christensen's manganic hydrogen pyrophosphate, $MnHP_2O_7$, is best obtained by adding manganic orthophosphate (Abstr., 1884, 399) to molten orthophosphoric acid in a platinum crucible at 220—230°, so long as it dissolves therein, and continuing the heating for 6—8 hours with frequent stirring until the mass has become semi-solid. While still warm, this product is thrown, in small portions, into cold water, the precipitate washed until free from phosphoric acid, and dried at 97°. It is "pansy-coloured" and of uncertain crystalline form; it undergoes oxidation when moist, and is readily decomposed by alkalis and acids, evolving chlorine with hydrochloric acid and yielding a precipitate of a higher oxide of manganese with sulphuric and nitric acids; when heated, it loses water and oxygen, and is converted into manganous metaphosphate. *Manganic potassium pyrophosphate*, $MnKP_2O_7$, is obtained by adding

the solution of manganic orthophosphate in molten orthophosphoric acid to molten potassium nitrate; after continuing the heating for a minute or two, the melt is poured on to iron or stone, and, when cold, treated with cold water. The new salt is somewhat darker than that just described, and more stable to acids and bases; it is insoluble in water. When heated, it becomes darker and then loses oxygen; when cooled by carbonic anhydride and ether it becomes much paler. The corresponding sodium salt has been prepared by Christensen (Abstr., 1884, 399). Manganic metaphosphate can be prepared by heating the solution of manganic orthophosphate in molten orthophosphoric acid at 350° until it has become pasty, and then treating it with cold water.

Potassium chromic hydrogen pyrophosphate, $Cr_2K_2H_4(P_2O_7)_3$, is prepared by dissolving 10 grams of chromic hydroxide in 65 grams of orthophosphoric acid at 150°, adding 30 grams of potassium carbonate, and heating at 250—260° for some time; the melt is washed with hot water and the insoluble salt dried at 130°. It is bright green and crystalline. At a red heat it gradually loses water. A green salt of doubtful composition was obtained by adding chromic hydroxide and orthophosphoric acid to fused potassium cyanate and subsequently washing the melt with water.

Manganous sodium metaphosphate, $MnNa(PO_3)_3$, is prepared by throwing successive small portions of a mixture of manganic orthophosphate (2 grams), orthophosphoric acid (3 grams), and microcosmic salt (10 grams) into a platinum crucible heated to dull redness, and heating until the mass is colourless. Treatment with water leaves the salt undissolved; it is colourless and crystalline.

The reaction between sodium hydrosulphide and potassium permanganate results in the production of manganese sulphide. That between a solution of sulphur (32 per cent.) in sodium hydroxide solution (30 per cent.) and potassium permanganate yields manganoso-manganic oxide at a high temperature and manganic peroxide at the ordinary temperature. A. G. B.

Iron in Bone-black. By B. Terne (*Chem. News*, **65**, 222—223). —The author finds that bone-black does not yield up its iron to solutions of citric acid, anyway not when a 0·1 or 0·25 per cent. solution of that acid is exposed for 24 hours at nearly 100° to bone-black containing as much as 0·5 per cent. of iron. In fact, he finds that fresh, regular sugar-house-black removed all the iron from citric acid solutions previously rendered dark yellow by the addition of one-tenth per cent. of that metal. A. Behr points out that there are three sources of iron in sugar-house-black:—1. The iron originally contained in the black. 2. The iron in the raw sugar. 3. The iron taken up by the liquors and the bone-black in the sugar refining. He adds that the removal of iron from the sugar only occurs when the black is fresh, and that as the black accumulates iron as it gets old, it even imparts some of that metal to the sugar passing through it; moreover, diluted sugar solution carries away a certain amount of iron, even from very good black. The initial iron in the black should obviously be reduced as low as possible, more especially as being in the

metallic state it can be easily removed by a magnetic separator. In fact, the author employs magnetic separation on a small scale for the rough estimation of iron in the black in the factory. D. A. L.

Mineralogical Chemistry.

Hungarian Minerals. By J. Loczka (*Zeit. Kryst. Min.*, **20**, 317—320).—In 1885 the author was requested by the Hungarian Academy of Sciences to examine 10 Hungarian minerals. The results of his investigation are as follows:—

1. *Antimonite from Felsöbánya.*—Sp. gr. 4·642. The composition is in accordance with the formula Sb_2S_3.

2. *Antimonite from Magurka.*—This mineral is dense, and of a grey colour. Sp. gr. 4·55.

Analysis gave—

Sb.	S.	Pb.	Cu.	Fe.	Quartz.	Total.
69·87	27·60	2·25	0·12	0·11	0·77	100·72

3. *Tetradymite from Zsupkó.*—Soft crystals of a sp. gr. of 7·581 gave, on analysis, results corresponding with the formula $2Bi_2Te_3,Bi_2S_3$.

4. *Hessite from Botes.*—The crystals contain silver, tellurium, gold, and traces of iron. Sp. gr. 8·39. Formula $(AgAu)_2Te$.

5. *Tellurium from Faczebaya.*—Formerly it was impossible to obtain pure material, as it was so intimately associated with quartz and pyrites. An analysis of mineral of this character yielded 80·39 per cent. of tellurium, whilst an analysis of rounded crystals of a sp. gr. 6·084 recently found, yielded 97·92 per cent. of tellurium with gold, iron, copper, quartz, and traces of selenium.

6. *Hæmatite from the Hargita Mountains.*—This mineral has a sp. gr. of 5·289, and gave, on analysis, the following results:—

Fe.	O.	Sn.	Insoluble.	Total.
69·92	28·99	0·52	0·15	99·58

7. *Tetradymite from Rézbánya.*—Sp. gr. 7·022. Analysis gave results corresponding with the formula $2Bi_2Te_3,Bi_2S_3$.

8. *Fauserite from Hodrusbánya.*—This salt has a reddish-violet tinge and a bitter, metallic taste. Sp. gr. 1·67. The author has made six partial analyses, and the mean results are in good accord with the formula $SO_4(Mg,Zn,Co,Fe),7H_2O$.

9. *Rock-salt from Torda.*—Sp. gr. 2·205. The mean of six analyses is appended (Analysis A).

10. *Rock-salt from Vizakna.*—This salt is grey, and mixed with a little earthy matter. Sp. gr. 2·186. The mean of seven analyses is as follows (B):—

	Na.	Cl.	Fe.	Ca.	SO_4.	Mg.	H_2O.	Insol.	Total.
A.	39·362	60·592	0·012	0·008	0·007	0·005	0·015	0·056	100·057
B.	39·356	60·572	0·005	0·013	0·017	0·007	0·024	0·065	100·059

B. H. B.

Martite. By A. Lavenir (*Zeit. Kryst. Min.*, **20**, 271; from *Bull. soc. fran. min.*, **12**, 49).—The examination of some very fine octahedra of martite from Brazil, showed that the substance, which was soluble only in *aqua regia*, yielded, on heating to redness in a current of hydrogen, a quantity of water exactly corresponding with the formula Fe_2O_3. The sp. gr. is 5·194—5·205; whilst it should be, if the substance had been formed from iron pyrites without change of volume, two-thirds of 5. The homogeneity of the material examined appears to be evidence against a pseudomorphous origin. B. H. B.

Brookite, Octahedrite, Quartz, and Ruby. By G. F. Kunz (*Amer. J. Sci.*, **43**, 329—330).—The author records an interesting discovery of minerals at Placerville, Eldorado Co., California, in a decomposed vein of crystallised quartz. Some of the quartz crystals weigh 90 lbs., and are pellucid and free from flaws. Octahedrite and brookite are found implanted on the quartz.

Very large ruby crystals have recently been found in the mines of Burma, some having weighed 300 to 2000 carats. They afford, however, but little fine ruby for cutting. One crystal examined by the author was a perfect, doubly terminated, hexagonal prism, 29 mm. in height. It weighed several ounces, and was valued at £200.

B. H. B.

Fluorine in Natural Phosphates. By A. Carnot (*Compt. rend.*, **114**, 1003—1006).—The author has determined the proportion of fluorine in many varieties of natural phosphates, using the method of estimation previously described (this vol., p. 911).

Direct estimation of the fluorine in apatites verifies the ordinary formula $3Ca_3(PO_4)_2 + Ca(F,Cl)_2$. Fibrous semicrystalline phosphorites have almost exactly the same composition as apatite. Earthy or compact and slightly concretionary phosphorites contain less fluorine. Distinctly concretionary phosphorites contain only from 0·05 to 1·38 per cent. of fluorine. The presence of the smaller proportion of fluorine in the less crystallised varieties is noteworthy in connection with the well-known mineralising effect of fluorine.

In almost all the 12 varieties of sedimentary phosphates examined the ratio of fluorine to phosphoric acid was the same as in apatite. This result agrees with that obtained by H. Lasne. C. H. B.

Cuprodescloizite from Mexico. By F. Pisani (*Zeit. Kryst. Min.*, **20**, 270—271; from *Bull. soc. fran. min.*, **12**, 38).—The author has analysed the mineral from Zacatecas, which occurs in cavities in a vein of galena, and has a greenish-black or brown colour, and a sp. gr. of 6·06. The analytical results were as follows:—

As_2O_5.	V_2O_5.	PbO.	CuO.	ZnO.	H_2O.	Total.
4·78	17·40	53·90	8·80	11·40	3·20	99·48

From a study of previous analyses of similar vanadates, the author concludes that the descloizites examined by Damour and by Rammelsberg are different. Eusynchite and brackebuschite belong to the former, and dechenite is probably identical with eusynchite, as it also contains zinc. B. H. B.

Milarite. By F. P. Treadwell (*Jahrb. f. Min.*, 1892, i, Mem. 167—168).—Hitherto but few analyses have been made of the mineral milarite discovered by Kenngott. A new analysis of 0·6662 gram of absolutely pure material gave the following results:—

SiO_2.	Al_2O_3.	CaO.	K_2O.	Na_2O.	H_2O.	MgO.	Total.
72·79	10·12	11·32	4·32	0·26	1·19	trace	100·00

These results correspond with the formula $R_2O,2CaO,Al_2O_3,12SiO_2$. This formula is also in accord with the results of Ludwig's analysis, but less so with those of Frenzel's and Finkener's analyses. B. H. B.

Gismondine from Westphalia. By F. Rinne (*Zeit. Kryst. Min.*, **20**, 302; from *Sitz. preuss. Akad.*, 1889, 1027).—In the cavities in the melilite-basalt of Hohenberg, in Westphalia, transparent crystals of gismondine occur, apparently in tetragonal pyramids. Optical examination shows, however, that they belong to the monosymmetrical system. The optical characters of the crystals are fully described, but no analysis of the mineral is given by the author. B. H. B.

Cordierite as Contact Mineral. By Y. Kakuchi (*Jahrb. f. Min.*, 1892, i, Ref. 233—235; from *J. Coll. Sci. Imperial Univ. Japan*, **3**, 313—334).—At the Watarasegawa, on the borders of the provinces of Shimotsuke and Kodsuke, Japan, there is a granite mass, 6 miles long and 1 mile wide, surrounded by palæozoic rocks, which are altered at the contact with the granite, and the slate which occurs in immediate vicinity of the granite contains cordierite crystals. On analysis, these crystals gave the following results:—

SiO_2.	Al_2O_3.	FeO.	MnO.	CaO.	MgO.	H_2O.	Total.
48·43	32·36	8·55	1·32	0·46	7·81	1·55	100·48

from which results the author deduces the formula

$$6MgO,4FeO,10Al_2O_3,25SiO_2.$$

The hardness of the mineral is 7, and its sp. gr. 2·642. For this contact cordierite, which differs in several respects from the ordinary variety, the name of *cerasite* is suggested. B. H. B.

Fouquéite, a New Mineral. By A. Lacroix (*Zeit. Kryst, Min.*, **20**, 290; from *Bull soc. fran. min.*, **12**, 83).—From the anorthite-gneiss of Madras, the author has isolated monosymmetrical crystals of a lemon-yellow colour. Analysis yielded:—

SiO_2.	Al_2O_3.	FeO.	CaO.	Loss on ignition.	Total.
38·3	31·9	4·4	23·5	2·7	100·8

The sp. gr. is 3·31. The mineral may be a dimorphous modification of zoisite. B. H. B.

Peridotite in Central New York. By C. H. Smyth (*Amer. J. Sci.*, **43**, 322—327).—In view of the interest attaching to the demonstration by G. H. Williams of the igneous nature of the so-called serpentine of Syracuse, New York, the author regards a further occurrence of similar rocks at Mannheim, New York, as worthy of note. The highly basic character of the Mannheim rock is shown by the following partial analysis:—

Loss on ignition.	SiO_2.	Al_2O_3.	Fe_2O_3.	CaO.	MgO.
15·20	33·80	6·84	12·26	9·50	21·38

The microscopical and chemical evidence brought forward by the author shows that the rock of the Mannheim Dyke is a member of the peridotite group, and probably of the same age as the dykes of Syracuse and Ithaca in New York. B. H. B.

Minerals from the Chrome Iron Ore Deposits of Maryland. By A. C. Gill (*Zeit. Kryst. Min.*, **20**, 285; from *Johns Hopkins Univ. Circ.*, **75**).—In fissures in the chromite of Montgomery Co., there occur chrome-tourmalin (Analysis I) in dark-green needles and fuchsite (Analysis II) in a greenish-white, chlorite-like mineral.

	SiO_2.	B_2O_3.	F.	P_2O_5.	TiO_2.	Al_2O_3.	Cr_2O_3.	Fe_2O_3.	NiO.
I.	36·56	8·90	0·06	0·04	0·09	32·58	4·32	0·79	0·05
II.	42·21	—	—	—	—	34·55	2·03	1·03	—

	CaO.	MgO.	Na_2O.	K_2O.	H_2O.	Total.
I.	0·75	9·47	2·22	0·13	3·74	99·69
II.	0·47	3·13	0·82	9·16	6·77	100·17

B. H. B.

Chromiferous Clay from Brazil. By A. Terreil (*Compt. rend.*, **114**, 983—984).—The clay obtained from the Tocantins, near Cametà, is malachite-green in colour, has a waxy appearance, and is very friable. It melts before the blowpipe and forms a flesh-coloured enamel, the green chromium oxide being converted into the red or ruby oxide. The clay has the composition:—

SiO_2.	Al_2O_3.	Cr_2O_3.	Fe_2O_3.	CaO.	MgO.	H_2O.	Total.
46·20	18·18	1·69	0·92	1·23	3·94	26·64	98·80

C. H. B.

Azure-Blue Pyroxenic Rock from New Mexico. By G. P. Merrill and R. L. Packard (*Amer. J. Sci.*, **43**, 279—280).—On the Gila river, a finely saccharoidal rock of beautiful, light, azure-blue colour occurs in nodular masses in a granular, crystalline, serpentinous limestone, and under the microscope is seen to consist wholly of colourless pyroxene interspersed with calcite. A piece of the blue

rock, free from serpentine, was pulverised, treated with warm hydrochloric acid to remove calcite, and then boiled in an alkaline carbonate. The analysis gave the following results :—

SiO_2.	MgO.	FeO.	CaO.	Total.
54·30	18·33	1·11	25·00	98·74

This reduces to the formula $CaMgSi_2O_6$, which is that of malacolite. The blue colour appears to be due to ferrous oxide. B. H. B.

Melilite-bearing Rock from Canada. By F. D. Adams (*Amer. J. Sci.*, **43**, 269—279).—At Ste. Anne de Bellevue, near Montreal, in 1877, a dyke was discovered during the progress of some blasting operations in the bed of the Ottawa river. The rock was, for the most part, much decomposed, and its true character was not recognised until the discovery by Törnebohm, in 1882, of melilite-basalt on the Island of Alnö, in Sweden. The Swedish and Canadian rocks are so similar that they are classed together by Rosenbusch as *alnoite*. An analysis of the Canadian alnoite gave the following results :—

SiO_2.	TiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	CaO.	MgO.	K_2O.	Na_2O.	CO_2	H_2O.	Total.
35·91	0·23	11·51	2·35	5·38	13·57	17·54	2·87	1·75	9·40		100·51

This rock differs from the original alnoite from Alnö in containing much more olivine, and in being free from plagioclase.

B. H. B.

Serpentine Rock from Borzanasca. By C. Montemartini (*Jahrb. f. Min.*, 1892, i, Ref. 288; from *Atti Accad. Sci. Torino*, **35**, 209—212).—At Borzanasca, in Liguria, there is a green rock with distinct polar magnetism, containing bastite and small crystals of diopside, diallage, and chromite. Numerous white veins of chrysotile traverse the mass. An analysis of the rock (I) and of the mechanically isolated bastite (II) gave the following results :—

	SiO_2.	Al_2O_3.	Fe_2O_3.	FeO.	MgO.	CaO.	Cr_2O_3.	Loss on ignition.	Total.
I.	39·84	3·08	5·82	1·25	36·63	1·14	trace	12·86	100·62
II.	40·21	3·49	—	10·08	30·62	1·90	trace	13·23	99·53

B. H. B.

Rock of the Jiwaara, in Finland. By W. Ramsay and H. Berghell (*Jahrb. f. Min.*, 1892, i, Ref. 307—308; from *Geol. Fören. Förh.*, **13**, 300—312).—The authors have made an exhaustive study of the rock of the Jiwaara mountain, in Northern Finland, and, in the main, confirm the results given by Wiik in 1884. The main constituents are nepheline and pyroxene, with apatite, titanite, and titaniferous garnet (jiwaarite), and with calcite and cancrinite as secondary products. Felspar is absent. The rock belongs to the series of nepheline rocks, and for it the name of ijolite is proposed. Analyses of the rock and of the nepheline are given. B. H. B.

Monchiquite, a Rock of the Elæolite-Syenite Class. By M. Hunter and H. Rosenbusch (*Jahrb. f. Min.*, 1892, i, Ref. 321—322;

from *Min. petr. Mitth.*, **11**, 445—466).—This rock occurs over a large area in the provinces of Rio de Janeiro and Minas Geraës, in Brazil, in the form of narrow veins in gneiss near the contact with elacolite syenite. It is a black, massive rock, with porphyritic crystals of amphibole, pyroxene, mica, and olivine. Under the microscope, colourless, glassy magma, magnetite, and some apatite and plagioclase are seen. The authors give analyses of the glassy magma, the brown hornblende, the reddish-violet augite, and of two varieties of the rock.

B. H. B.

The Prehistoric and Kiowa Co. Pallasites. By O. W. Huntington (*Jahrb. f. Min.*, 1892, i, Ref. 266—267; from *Proc. Amer. Acad.*, **26**, 1—12).—The resemblance between the pallas irons recently found in Kiowa Co., Kansas, and the prehistoric specimens found in Ohio has been noted as being very striking. On further study, however, the author finds that the resemblance is not so remarkable as at first appeared, whilst a comparison with the famous Siberian pallasite and the prehistoric specimens show that they are almost identical. The Kiowa iron shows a far more perfect crystallisation than any other pallasite hitherto described. It also contains large quantities of chromite distributed through it; but no chromite is to be found in the prehistoric nor in the pallas meteorite. B. H. B.

Meteoric Iron from Colfax Township, North Carolina. By G. F. Kunz (*Jahrb. f. Min.*, 1892, i, Ref. 267; from *Trans. New York Acad. Sci.*, **9**, 197—198).—The meteoric iron from Colfax Township, Rutherford Co., is the same as that described by L. G. Eakins from Ellenboro, Rutherford Co. The mean of the following two new analyses is in good accord with that published by Eakins:—

	Fe.	Ni.	Co.	Cu.	P.	S.	Si.	Total.
I.	87·69	11·26	0·62	0·05	0·19	0·10	0·03	99·94
II.	89·22	9·37	0·53	0·04	0·19	0·08	0·01	99·44

B. H. B.

Meteoric Stone from Ferguson, North Carolina. By G. F. Kunz (*Jahrb. f. Min.*, 1892, i, Ref. 267; from *Trans. New York Acad. Sci.*, **9**, 198).—For the meteoric stone formerly mentioned by the author (Abstr., 1891, 279), 6 P.M. is given as the time of falling, and Ferguson, Haywood Co., North Carolina, as the locality.

B. H. B.

Meteorite of Misshof in Kurland, Russia. By B. Doss (*Jahrb. f. Min.*, 1892, i, Mem. 71—113),—On April 10, 1890, at 4 P.M., a meteoric stone was observed to fall on the Misshof estate in Kurland. The fall was accompanied by a loud report. The meteorite is now in the Riga Museum. Its original weight was about 5,800 grams and its sp. gr. is 3·79. It is covered by a dull, black crust $\frac{1}{4}$ to $\frac{1}{2}$ mm. in thickness, and the interior has a somewhat porous texture. It belongs to the chondrite class of meteoric stones. Under the microscope it is seen that fragments of olivine and rhombic pyroxene are associated with particles of iron and of magnetic pyrites, and with the characteristic chondræ forming a porous mass. The metallic portion, which

amounts to 23·77 per cent. of the mass, consists of 5·82 per cent. of magnetic pyrites and 17·95 per cent. of nickeliferous iron, the percentage composition of the latter being as follows:—

Fe.	Ni.	Cu.	Sn.
90·75	7·52	1·06	0·67

A preliminary determination of the composition of the meteorite gave:—

Nickeliferous iron	17·95
Magnetic pyrites	5·82
Silicates soluble in HCl	46·52
Silicates insoluble in HCl	29·26
Chrome iron ore	0·45
Substances soluble in water	0·12
Total	100·12

The memoir is accompanied by two plates and eight woodcuts.

B. H. B.

The Ljungby Meteorite. By O. Nordenskiöld (*Jahrb. f. Min.*, 1892, i, Mem. 138—140).—This meteorite fell in the parish of Ljungby, in Scania, on April 3, 1889, and was subsequently secured for the Stockholm Museum. It is a chondrite, not differing from the most usual type. Its sp. gr. is 3·61, and its composition is as follows:—

Fe.	Ni.	Co.	Cu.	FeO.	Al_2O_3.	NiO.	CaO.	MgO.	K_2O.
14·46	1·91	0·02	0·04	13·18	2·70	0·05	1·40	23·79	0·43

Na_2O.	SiO_2.	Cr_2O_3.	C.	S.	P.	Soluble in water.	Loss on ignition.
1·42	36·97	0·59	0·02	2·38	0·10	0·10	0·40

The composition of the portion soluble in mercuric chloride (nickeliferous iron) was—

Fe.	Ni.	Co.	Cu.	Total.
83·67	16·24	0·17	0·34	100·42

Analysis shows that the portion soluble in hydrochloric acid consists of fairly pure olivine, and that insoluble in acid consists of bronzite.

The various constituents are present in the meteorite in the following proportions:—

Nickeliferous iron	11·76
Olivine	40·98
Bronzite	38·86
Troilite	6·55
Iron phosphide	0·55
Chrome iron	0·87
Carbon and soluble salts	0·52
Total	100·09

Manganese and tin are not present. The high proportion of nickel in the nickeliferous iron is noteworthy. B. H. B.

Water and Basins of the Lakes of Aiguebelette, Paladru, Nantua, and Sylans. By L. Duparc and A. Delebecque (*Compt. rend.*, **114**, 984—987).

Per litre.	Aiguebelette. Aug. 26, 1891.	Paladra. Aug. 5, 1891.	Nantua. Feb. 25, 1892.	Sylans. Mar. 13, 1892.
Total residue..	0·1549	0·1682	0·1810	0·1750
SiO_2	0·0055	0·0042	0·0032	0·0015
CaO	0·0708	0·0845	0·0875	0·0710
MgO.....	0·0061	0·002	0·0071	0·0052
SO_3	traces	none	0·0042	0·0021
Cl	traces	traces	0·0001	traces

The calcium and magnesium are present chiefly as carbonates. The total solid matter in the affluents is, as a rule, not greatly different from the total solid matter in the lakes.

The basins of the lakes consist chiefly of silica, silicates, and calcium carbonate, with iron, aluminium, and magnesium. The proportion of silica and silicates is 7·15 to 27·15 per cent. in the case of Paladru, 6·90 to 33·80 at Nantua, 8·35 to 24·20 at Sylans, and 31·30 to 76·95 at Aiguebelette. C. H. B.

Organic Chemistry.

1 : 3-Dinitropropane. By F. Keppler and V. Meyer (*Ber.*, **25**, 1709—1714).—1 : 3-Dinitropropane may be obtained by the action of silver nitrite on trimethylene iodide. Dry powdered silver nitrite (3 mols.) is slowly added to the cooled iodide (1 mol.); a little ether is then added, and the mixture very gently warmed for some time. The silver salt is precipitated by ether, the solution filtered and evaporated; the residue is then again treated with silver nitrite (3 mols.). After precipitating the silver salt with ether, filtering and evaporating the ethereal solution, the residual oil is allowed to remain for some days at a low temperature, in order that all the silver iodide may separate. The oil is now dissolved in absolute alcohol, and on adding alcoholic sodium ethoxide, *sodiodinitropropane*, $C_3H_5(NO_2)_2Na$, separates as a white powder, and is repeatedly washed with alcohol and ether. It explodes violently on heating. Its aqueous solution gives a yellowish precipitate, which rapidly blackens with silver nitrate. Copper nitrate and lead acetate give yellowish precipitates, and mercuric chloride a white precipitate. Disodiodinitropropane could not be prepared. Dilute sulphuric acid liberates free *dinitropropane*, $CH_2(CH_2{\cdot}NO_2)_2$, from the aqueous solution of its sodium derivative; the solution is extracted with ether, the ethereal

solution dried by anhydrous sodium sulphate, and evaporated. The nitro-compound is then obtained as a yellow oil, which totally decomposes on distillation in a vacuum. After some days it becomes converted into a brown, viscid oil. The two other isomeric dinitropropanes can be distilled without decomposition, and have but few properties in common with 1 : 3-dinitropropane.

Trimethylene iodide is conveniently prepared by dissolving trimethylene bromide (1 vol.) in absolute alcohol (2—2·5 vols.), and digesting for two days with dry powdered potassium iodide (3 mols.) in a reflux apparatus on the water-bath. The solution is precipitated by ether, filtered, evaporated, and the residue again dissolved in alcohol and digested with potassium iodide (3 mols.), precipitated with ether, filtered, and the filtrate evaporated. The residual oil is freed from dissolved iodine by potash, and contains 92·3 per cent. of the iodide.

Trimethylene bromide reacts very violently with silver nitrite, giving a poor yield of dinitropropane.

Dinitropropanedisazobenzene, $CH_2[CH(NO_2)\cdot N_2Ph]_2$, is obtained by slowly adding an aqueous solution (10 c.c.) of diazobenzene sulphate (1·5 grams) to sodiodinitropropane (0·5 gram) and sodium acetate (0·5 gram) dissolved in water (10 grams). It separates as a gummy mass, which soon hardens, and is extracted by boiling alcohol; the residue separates from acetic acid in reddish-yellow needles, melts at 173°, and gives a cherry-red solution with concentrated sulphuric acid. It is soluble in hot acetic acid, chloroform, and ether, sparingly so in alcohol.

Dinitropropaneparadisazotoluene crystallises from acetic acid in beautiful yellow needles melting at 199°, and gives a yellow solution with concentrated sulphuric acid.

Dinitropropaneparadisazoanisoïl forms small, yellow needles melting at 181°, and gives a cherry-red solution with concentrated sulphuric acid.

Tetrabromo-1 : 3-*dinitropropane*, $CH_2(CBr_2\cdot NO_2)_2$, is obtained by slowly adding an aqueous solution (200 c.c.) of sodiodinitropropane (3·5 grams) to a saturated aqueous solution of bromine (8 grams); the liquid is subsequently made slightly alkaline with very dilute soda. More bromine is now shaken with the solution, and a flocculent precipitate separates; after again making alkaline, the precipitate is collected, washed with water, and crystallised from dilute alcohol. It forms silky needles, which melt at 98—99°, and, on strongly heating, decomposes with evolution of brown vapours.

Dinitropropane behaves in many respects like nitroethyl alcohol, and only partially as a nitro-compound. On reduction with zinc dust and acetic acid it yields ammonia. It gives the nitrolic acid reaction, and on heating with hydrochloric acid yields hydroxylamine, and, probably, malonic acid. W. J. P.

Nitropropylene. By P. Askenasy and V. Meyer (*Ber.*, **25**, 1701—1708).—*Sodionitropropylene* (*sodionitroallyl*), $C_3H_4Na\cdot NO_2$, is prepared by heating a mixture of perfectly dry silver nitrite and sand in a reflux apparatus at 40° with a solution of allyl iodide or bromide (1 vol.) in

ether (2—3 vols.) for 35—45 minutes. The colourless solution is filtered and allowed to remain for 12 hours, in order that the dissolved silver salt may separate. After the addition of absolute alcohol (2 vols.) to the filtered solution (1 vol.) the sodium compound is precipitated on addition of a solution of sodium ethoxide in absolute alcohol. The precipitate is collected, washed frequently with absolute alcohol and ether, and dried on a porous plate. The product obtained in this manner turns red on drying, owing to the retention of a little allyl iodide; if, however, the ethereal solution be distilled in a current of ether vapour before precipitation with sodium ethoxide, a little nitropropylene comes over, and on adding absolute alcohol and sodium ethoxide the sodium compound separates and retains its dazzling white colour on keeping. On treatment with concentrated sulphuric or hydrochloric acid, it carbonises with emission of light, and when slowly heated in a glass tube it explodes violently at 190—200°.

Nitropropylene is obtained by treating the aqueous solution of the sodium compound with the calculated quantity of dilute sulphuric acid and extracting with ether. The ethereal solution is washed with water and dried by anhydrous sodium sulphate; the ether is then distilled off, and the residual oil dried in a vacuum. The pure substance may also be obtained by distilling the ethereal solution in a current of ether vapour, and evaporating the distillate. It is a thick, brownish oil, which combines with bromine and polymerises to a black, tarry mass on remaining for some days. It explodes on heating, and cannot be distilled, without decomposition, under 20 mm. pressure.

Allylnitrolic acid, $CH_2{:}CH{\cdot}C(NO_2){:}NOH$, is prepared by slowly mixing ice-cold aqueous solutions (5 c.c. of each) of sodium nitrite (0·7 gram) and sodionitropropylene (1 gram); to the mixture is now slowly added concentrated sulphuric acid (1 gram) dissolved in water (5 c.c.). Dilute soda is added until the appearance of a permanent red colour, which is then destroyed by dilute sulphuric acid. The solution is now treated with excess of barium carbonate, filtered, acidified, and repeatedly extracted with ether. On evaporation of the ethereal solution, allylnitrolic acid separates in long needles, and may be crystallised from water. It melts at 68° in a capillary tube, but at 82—83° when in large quantities. It explodes violently with carbonisation at about 95°, and has a very pungent taste.

Nitropropyleneazobenzene, $NO_2{\cdot}C_3H_4{\cdot}N_2Ph$, is obtained by adding a concentrated aqueous solution of sodium acetate (0·5 gram) and diazobenzene sulphate (1 gram) to sodionitropropylene (0·5 gram), dissolved in a little water. It separates as an orange precipitate, which coagulates and turns deep red on standing. It crystallises from alcohol in red needles, and melts at 95—96° with decomposition. On heating with aqueous alcohol and cooling, it separates, mixed with a substance which crystallises in thin red scales.

Nitropropyleneparazotoluene, $NO_2{\cdot}C_3H_4{\cdot}N_2{\cdot}C_6H_4Me$, is prepared in a similar manner to the preceding compound, and crystallises from alcohol in brownish-red needles which melt at 95°.

Nitropropyleneorthazotoluene forms red needles melting at 85·5°.

With concentrated sulphuric acid it gives first, a brownish-yellow, and ultimately a dirty brown solution.

Nitropropyleneparazoanisoïl, $NO_2 \cdot C_3H_4 \cdot N_2 \cdot C_6H_4 \cdot OMe$, is very soluble in alcohol, and separates from the solution in brownish-red needles melting at 80°.

Nitropropyleneparazophenetoïl crystallises from alcohol in long, brownish-red needles, which melt at 94—95°. It gives a dark brown solution with concentrated sulphuric acid.

Nitropropylenemetazobenzoic acid, $NO_2 \cdot C_3H_4 \cdot N_2 \cdot C_6H_4 \cdot COOH$, is obtained in brick-red, nodular crusts, and is sparingly soluble in alcohol, ether, and chloroform. It decomposes at 145—150° without melting, and gives a reddish-yellow solution with concentrated sulphuric acid.

Nitropropyleneazometabromobenzene separates from absolute alcohol in light brown crystals, which melt at 93—94°. The corresponding *chloro*-derivative forms reddish-brown needles; it is very soluble in alcohol, and melts at 105·5°.

Nitropropyleneazopseudocumene crystallises in needles resembling alizarin. It is readily soluble in alcohol, melts at 104°, and gives an orange-brown solution with concentrated sulphuric acid.

On reduction with zinc dust and acetic acid, nitropropylene yields allylamine; with stronger reducing agents, ammonia is evolved. When heated with hydrochloric acid, nitropropylene gives acrylic acid and hydroxylamine.

Nitrobromopropylene, $CH_2{:}CH \cdot CHBr \cdot NO_2$, is prepared by the addition of bromine water to the aqueous solution of sodionitropropylene and subsequent extraction with ether. On evaporating the ethereal solution the bromide is obtained as a yellowish oil, which decomposes on heating.

Nitrotribromopropane, $CH_2Br \cdot CHBr \cdot CHBr \cdot NO_2$, obtained by the action of bromine on the monobromide, is a heavy, yellowish oil, which decomposes on heating, and evolves hydrogen bromide on keeping.

W. J. P.

Action of Organic Acids on Acetylenic Hydrocarbons. By A. Béhal and A. Desgrez (*Compt. rend.*, **114**, 1074—1077).—*Normal amylacetylene*, prepared by the successive action of phosphoric chloride and dry potash on œnanthaldehyde, boils at 101—102° under 750 mm. pressure; on heating it (1 part) with glacial acetic acid (4 parts) in a sealed tube at 280° for 24 hours, and subsequently fractionally distilling the product under reduced pressure, a mixture of the unchanged substance with a ketone is obtained. The fraction boiling above 120° is distilled with steam and treated with sodium hydrogen sulphite. On boiling the product with water, amyl methyl ketone is obtained as a liquid boiling at 149—150° under 755 mm. pressure.

Normal hexylacetylene is prepared by the successive action of phosphoric chloride and dry potash on hexyl methyl ketone, and boils at 126—126·5° under 753 mm. pressure; on heating with acetic acid as above described, it yields hexyl methyl ketone.

Butylmethylacetylene is obtained by the action of alcoholic potash on amylacetylene. It boils at 111—113° under 755 mm. pressure,

and does not combine with cuprous or silver salts. When heated with acetic acid it gives normal amyl methyl ketone.

Amylmethylacetylene, prepared by the action of dry potash on caprylene bromide, boils at 133—134° under 760 mm. pressure, and yields hexyl methyl ketone, boiling at 171°, when heated with acetic acid as above described.

On heating chloramylethylene, $C_5H_{11}\cdot CH{:}CHCl$, with silver acetate at 250°, amyl methyl ketone results; if the mixture be heated at 180°, however, it yields œnanthaldehyde.

The authors consider that these experiments show that an unstable acetate, $R\cdot CH{:}CH_2\cdot OAc$, is first formed on heating the hydrocarbon, $R\cdot C{:}CH$, with acetic acid, and that this undergoes hydrolysis with formation of an alcohol, $R\cdot C(OH){:}CH_2$, which then changes into the ketone, $R\cdot CO\cdot CH_3$. W. J. P.

Hydrocarbon derived from Perseïtol. By L. Maquenne (*Compt. rend.*, **114**, 1066—1069).—The author considers that heptine, C_7H_{12}, obtained by the action of hydriodic acid on perseïtol, is a cycloid hydrocarbon containing only one double bond. This view is supported by the fact of its ready conversion into toluene (Abstr., 1887, 565), its resemblance to the terpenes, and its colour reactions. The hydrocarbon of the composition C_7H_{14}, obtained by the reduction of heptine (*Compt. rend.*, **114**, 918), is a saturated hydrocarbon, and is not attacked by bromine, sulphuric acid, and cold nitric acid. Its molecular refraction, MR = 32·25 (Lorenz's formula) also shows it to be saturated. On treatment with chlorine, either in presence or absence of iodine, it yields hydrogen chloride and an oil which is carbonised by cold alcoholic potash and turned green by nascent hydrogen. Bromine and aluminium chloride convert the hydrocarbon into a resin with evolution of hydrogen bromide. It is most probably hexahydrotoluene, as its physical properties agree completely with those of that substance. W. J. P.

Action of Potassium Cyanide on Ammoniacal Cupric Chloride. By E. Fleurent (*Compt. rend.*, **114**, 1060—1061; compare this vol., p. 420).—On heating an ammoniacal solution (350 c.c.) of cupric chloride (21 grams), ammonium chloride (3 grams), and potassium cyanide (27 grams) in a sealed tube at 140—145° for four or five hours, an unstable double salt, $2Cu(CN)_2,NH_4CN,2NH_3 + 3H_2O$, is deposited in long, blue needles grouped in tufts. The crystals rapidly lose ammonia. On exposing the mother liquor to the air, ammonia is lost, and a very stable salt,

$$2Cu(CN)_2,Cu_2(CN)_2,2NH_3 + 3H_2O,$$

is deposited in large, rectangular, green scales. This compound is insoluble in water and decomposes at 100°. It is deposited unchanged from its ammoniacal solution, and, on treatment with dilute acids, yields cuprous cyanide with evolution of hydrogen cyanide. The mother liquor, after separation of this double salt, is colourless, and ultimately deposits two crystalline substances, which are now under examination.

The author estimates the cyanogen in these compounds by heating them in a sealed tube for two hours at 50—60° with concentrated nitric acid (1 vol.), silver nitrate, and water (2 vols.). This method is very rapid and gives good results. W. J. P.

Sodiotrimethylcarbinol: Value of the Tertiary Alcoholic Function. By De Forcrand (*Compt. rend.*, **114**, 1062—1064).—Trimethylcarbinol melts at 25·5° and has the sp. gr. 0·771 at 35·5°. The heat of solution of the crystalline compound in water (74 grams in 2 litres) is +3·50 Cal. at 5—8° and +3·23 Cal. at 13—15°. These values are comparatively high, and point to the existence of a hydrate like $C_4H_{10}O,H_2O$. On the addition of aqueous soda (1 equivalent in 2 litres) to the solution and allowing for the heat of dilution of the soda, −0·02 Cal. is liberated at 6—7°, and −0·06 Cal. at 14—16°; these numbers represent the calorific reaction between the alcohol and soda alone, and are of the same order as those obtained with the primary alcohols.

Sodiotrimethylcarbinol, C_4H_9ONa, is prepared as a white, pulverulent mass by heating finely-divided sodium with a large excess of the carbinol at 110° for 5—6 hours. The unchanged alcohol is eliminated by continued heating at 110° in a current of hydrogen. The heat of solution of the sodio-derivative in water (96 grams in 4 litres) is +18·30 Cal. at 15°.

From the above numbers the value of the function of solid trimethylcarbinol may be deduced as +27·89 Cal.; this is probably the value of the tertiary alcoholic function measured in the solid state. It differs by about 2 Cal. from the corresponding value for secondary alcohols (+29·75 Cal.) and by about 4 Cal. from that of primary alcohols (+32·00 Cal.). W. J. P.

Carbohydrates. By F. Ullik (*Chem. Centr.*, 1892, i, 432—433; from *Zeit. Brauwesen, München*, **15**, 15—17, 28—31, 39—41).—The carbohydrates, exclusive of the sugars, are grouped by the author as follows:—I, the amylums; II, cellulose; III, soluble starch; IV, dextrins; V, gums; VI, dextrin acids; VII, gum acids; VIII, pectins; IX, pectin acids.

The author considers that the last-named, the pectins and the "acid" bodies derived from them, belong strictly to the group of carbohydrates, because, on the one hand, glucoses may readily be obtained from them, whilst, on the other, substances corresponding with the pectins may be obtained from starch.

The addition of alkali, whether in excess or not, to the pectin acids, does not alter the rotatory power, and the same property belongs to some dextrins which have been obtained by the action of acids, and also to maltose. Pectin acids do not diffuse through a membrane, but their salts do so readily. The author separated a pectin acid from beetroot, the coefficient of rotation for which was $[\alpha]_D = 300$, and from which, by oxidation, 70—80 per cent. of mucic acid was obtained.

Soluble starch, cellulose, dextrose, and maltose all show the same rotatory power when dissolved in concentrated sulphuric acid.

Soluble starch appears to exist in different modifications, which are distinguished from one another in outward appearance, degree of solubility, and iodine reaction, but they all have the same rotatory power, namely, $[\alpha]_D = 199\ 6—200{\cdot}8$. J. W. L.

First Product of the Reduction of Nitro-compounds with Stannous Chloride. By A. Kirpal (*Ber.*, **25**, 1714—1718).—The author shows that the methylhydroxylamine obtained by Hoffmann and Meyer (this vol., p. 291) by the reduction of nitromethane with stannous chloride is, as they supposed, identical with the β-methylhydroxylamine prepared by Dittrich (Abstr., 1891, 317) from β-benziledioxime methyl ether. The substance (1 mol.) obtained by both methods reduces Fehling's solution with production of equal quantities (2 mols.) of cuprous oxide. The hydrochloride melts at 85—90° and is very hygroscopic. On oxidation with Fehling's solution, methylamine and ammonia are obtained. No methyl alcohol is produced.

Nitroethane, nitropropane, nitropentane, and nitropropylene, on reduction with stannous chloride, yield bases which readily reduce Fehling's solution. Chloropicrin and bromonitroethane also give basic substances which contain halogen and are readily oxidised by Fehling's solution.

Negative results were obtained on attempting to reduce aromatic nitro-compounds with production of bases analogous to the foregoing. W. J. P.

Special Case of Isomerism. By R. Schiff (*Ber.*, **25**, 1690—1691).—When butylchloral hydrate reacts with an amide, two isomeric additive compounds are always formed. The mixture obtained on melting butylchloral hydrate with acetamide may be separated into an α-butylchloralacetamide, $C_6H_{10}Cl_3NO_2$, which is very sparingly soluble in boiling alcohol, and an isomeric β-butylchloralacetamide which is readily soluble in dilute alcohol. Corresponding isomeric additive products, whose melting points are given below, are obtained with other amides.

	Melting points.	
	α.	β.
Butylchloralacetamide	158°	170°
Butylchloralbenzamide.....	132	146
Butylchloralformamide	125	132

On distilling the α- and β-butylchloralacetamides with dilute sulphuric acid, two isomeric butylchloral hydrates, which both melt at 78°, are obtained. On treatment with nitric acid, they both yield trichlorobutyric acid, which gives ethyl salts boiling at 230—232°. The oximes derived from the α- and β-hydrates both melt at 65—66° and behave similarly towards acetic anhydride and alkalis. On melting the two hydrates with acetamide, however, they are found to yield the corresponding additive compounds having different melting points.

Two butylchlorals therefore exist, and can only be distinguished

by their behaviour towards amides, their melting points and other properties being identical. W. J. P.

Citronellic Aldehyde. By E. Kremers (*Amer. Chem. J.*, **14**, 203—212; compare Dodge, Abstr., 1890, 231; 1891, 285; and Semmler, Abstr., 1891, 539).—The substance employed by the author in his investigations was the so-called *citronellon*, from the oil of *Eucalyptus maculata*, var. *citriodora*, and was supplied by Schimmel of Leipzig. The oil was distilled under a reduced pressure of 15 mm., and the larger portion, which came over between 195° and 220°, was collected apart. It had a specific gravity of 0·875 at 21° and showed a rotatory power of $[\alpha]_D = +6·81°$. On analysis, numbers were obtained corresponding with the formula $C_{10}H_{18}O$, which is also in harmony with the general behaviour of the substance.

Citronellic aldehyde is an unsaturated compound and readily absorbs bromine in the ratio $C_{10}H_{18}O : Br_2$, but the additive product is so unstable that it can not be obtained in a crystalline condition. With sodium hydrogen sulphite, the crystalline solid, $C_{10}H_{18}O,NaHSO_3$, was formed, and from it the aldehyde was again liberated on treatment with sodium carbonate.

Citronellic aldehyde appears to form an oxime with hydroxylamine hydrochloride, but the compound was not isolated in a crystalline form. No satistactory condensation product was obtained with phenylhydrazine. On oxidation with ammoniacal silver oxide (compare Semmler, *loc. cit.*), the aldehyde gives an acid which forms a by no means characteristic silver salt, $C_{10}H_{17}O_2Ag$; whilst, with permanganate, it gives, in addition to oxalic and formic acids, two acids, the salts of which were not obtained in a sufficiently pure state to enable their composition to be determined. G. T. M.

Acetic Fluoride. By M. Meslans (*Compt. rend.*, **114**, 1020—1023).—Acetic fluoride can be obtained (1) by the action of acetic chloride vapour on silver fluoride heated at 300°; (2) by the action of acetic chloride on arsenic fluoride, the removal of the last traces of chlorine and arsenic being somewhat difficult; (3) by the action of acetic chloride on antimony fluoride in the cold, the product being kept in a closed glass vessel in contact with fragments of antimony fluoride; (4) by the action of acetic chloride on anhydrous zinc fluoride.

The last method is the best and most rapid. Zinc fluoride dried in a vacuum at 250° is added gradually to well-cooled acetic chloride. The vessel is then closed, and heated at 40° with agitation. The product is distilled, and collected in a well-cooled receiver, containing fragments of zinc fluoride. From this receiver it is distilled a second time, and is kept in perfectly dry glass vessels, hermetically sealed. Great care must be taken to avoid the presence of any moisture.

Above 19·5°, under atmospheric pressure, acetic fluoride is a colourless gas, does not fume in the air, and burns with a blue flame, producing water, carbonic anhydride, and hydrogen fluoride. Its odour recalls that of carbonyl chloride, and when inhaled its action is

not immediate, but in a short time it produces intense bronchial irritation.

Below 19·5° it is a very mobile, colourless liquid, miscible with alcohol, ether, and chloroform. It dissolves in all proportions in benzene, amyl alcohol, terebenthene, and glacial acetic acid. It does not mix with water or carbon bisulphide, but is slightly soluble in both of them. It dissolves very little iodine and no sulphur, but is dissolved in large quantity by bromine. At −23° its vapour tension is still 118 mm., and it does not solidify even at −55°; its vapour tension at the latter point is about 10 mm. Its vapour density is 2·163 (calc. 2·146). C. H. B.

Acetic Fluoride. By M. Meslans (*Compt. rend.*, **114**, 1069—1072; compare preceding abstract).—Acetic fluoride boils at 19·5°, and its vapour does not fume in the air. It is much more stable than acetic chloride. Water acts on it with production of hydrogen fluoride and acetic acid; the action is, however, much less vigorous than in the case of the chloride. Aqueous potash and soda have a similar action. Quicklime reacts with production of acetic anhydride. Ammonia acts on acetic fluoride with formation of pure, odourless acetamide. Aniline has a vigorous action on the fluoride, acetanilide and hydrogen fluoride being obtained. Acetic fluoride is soluble in all proportions in alcohol; no immediate action occurs, but after several hours ethyl acetate and hydrogen fluoride are formed. Amyl alcohol under similar conditions yields amyl acetate. Small quantities of acetic anhydride and sodium fluoride are obtained on heating acetic fluoride and sodium acetate in a sealed tube for four hours at 100°. Sodium and sodium amalgam have no appreciable action on the substance at ordinary temperatures, but at a low red heat, sodium decomposes it with incandescence, sodium fluoride, carbon, and a small quantity of liquid being formed. W. J. P.

Configuration of the Aldoximeacetic Acids or β-Oximidopropionic Acids. By A. Hantzsch (*Ber.*, **25**, 1904—1907).—The only representative of the aldoximeacetic or β-oximidopropionic acids has been prepared by Pechmann (Abstr., 1891, 1458), and all attempts to obtain an isomeride have been without success; the known compound must have the "anti-" configuration,

$$\begin{matrix} H\cdot C\cdot CH_2\cdot COOH \\ \| \\ HO\cdot N \end{matrix},$$

for unlike the only known modification of the oxime of acetoacetic acid (methylsynketoximeacetic acid), it does not under any circumstances yield an anhydride, and gives only a yellow coloration with ferric chloride, in place of the violet given by the acetoacetic derivative. Further, it very readily loses carbonic anhydride on boiling with water.

Although only one isomeride of the acid itself could be prepared, the acetyl compound appears to exist in two modifications; thus by the action of acetic chloride on the acid Pechmann obtained an acetyl compound melting at 145°, which is not acted on by a solution of

sodium carbonate, but is decomposed by soda, re-forming the original acid; this derivative gives a wine-red coloration with ferric chloride. If acetic chloride be replaced by acetic anhydride, an oily acetyl compound is formed, which is hydrolysed by sodium carbonate solution, and gives the same coloration with ferric chloride as the acid itself; if allowed to remain, it is slowly converted into the crystalline modification. Hence it appears that the acetyl derivative exists in two stereometric forms, the oily compound having the same configuration ("anti-") as the acid itself, and the second the syn-configuration.

$$\begin{array}{l} H\cdot C{:}CH_2\cdot COOH \\ \quad\quad\| \\ AcO\cdot N \end{array} \qquad \begin{array}{l} H\cdot C\cdot CH_2\cdot COOH \\ \quad\quad\| \\ \quad\quad N\cdot OAc \end{array}.$$

H. G. C.

Action of Ethyl Chlorocarbonate on Ethyl Sodacetoacetate. By L. Claisen (*Ber.*, **25**, 1760—1776).—The author and Zedel have previously shown (*Inaug. Diss.*, *Munich*, 1889) that the interaction of sodacetylacetone and ethyl chlorocarbonate leads to the formation of two substances, namely, ethyl diacetoacetate,

$$CHAc_2\cdot COOEt,$$

and an isomeride which has probably the constitution

$$CHAc{:}CMe\cdot O\cdot COOEt;$$

the former has an acid character, forms a copper derivative, and gives an intense red coloration with ferric chloride in alcoholic solution, whereas the latter is a neutral substance, and gives neither of the reactions just mentioned.

The behaviour of ethyl sodacetoacetate with ethyl chlorocarbonate was found to be analogous to that of sodacetylacetone, the one product being ethyl acetomalonate, the other a compound, insoluble in alkalis, which has probably the constitution

$$COOEt\cdot CH{:}CMe\cdot O\cdot COOEt.$$

The latter reaction has also been recently studied by Michael (*J. pr. Chem.*, **37**, 473) and by Nef (this vol., p. 140). Michael isolated only the neutral compound to which he assigned the constitution given above, or the alternative formula

$$OEt\cdot C(CHAc)\cdot O\cdot COOEt,$$

which the author regards as highly improbable. Nef came to the conclusion that the neutral compound produced in the reaction is ethyl acetylcarbintricarboxylate, $CAc(COOEt)_3$, and assumed that the neutral compound described and analysed by the author was a mixture.

In the present paper the author proves conclusively that the neutral compound in question is not ethyl acetylcarbintricarboxylate but ethyl carboxethylacetoacetate.

Ethyl carboxyethylacetoacetate, $COOEt\cdot CH{:}CMe\cdot O\cdot COOEt$, is formed together with ethyl acetomalonate when solid, alcohol-free ethyl sodacetoacetate is gradually added to a well-cooled ethereal solution of excess of ethyl chlorocarbonate, and, after keeping for half an hour, the mixture warmed on the water-bath; it is a colour-

less oil, boiling at 130—131° under a pressure of 14 mm. Analyses of the carefully purified substance, vapour density determinations by Hofmann's method, and molecular weight determinations by Raoult's method in glacial acetic acid solution, all gave results agreeing well with those required by a compound of the molecular formula $C_9H_{14}O_5$; the compound is, moreover, identical in properties with the substance erroneously supposed by Nef to be ethyl acetylcarbintricarboxylate. Further proof that the compound obtained by the author is not ethyl acetylcarbintricarboxylate is afforded by the fact that even when the conditions are chosen so as to favour the formation of the last-named compound the principal product is, as before, ethyl carboxyethylacetoacetate.

Methyl carboxymethylacetoacetate, COOMe·CH:CMe·O·COOMe, is formed when methyl chlorocarbonate is treated with methyl sodacetoacetate in ethereal solution; it melts at 37—38°, and boils at 124—126° under a pressure of 19 mm., and at 224—226° with slight decomposition under the ordinary atmospheric pressure; it is insoluble in alkalis, and gives no colour reaction with ferric chloride. Molecular weight determinations in glacial acetic acid and in benzene solutions gave results agreeing with those required by a compound of the molecular formula $C_7H_{10}O_5$.

The ethereal salt of the composition $C_{10}H_{16}O_5$, obtained by treating ethyl sodiomethylacetoacetate with ethyl chlorocarbonate, is a colourless liquid of sp. gr. 1·085 at 15°, insoluble in alkalis; it boils at 136—139° under a pressure of 15 mm., that is to say, a few degrees higher than the compound obtained in like manner from ethyl acetoacetate; if the latter had the constitution assigned to it by Nef, the difference in boiling point would have been about 50° or 60° the other way.

A careful investigation of the interaction of ethyl chlorocarbonate and ethyl sodiomalonate has completely confirmed the statements of Conrad and Guthzeit on this subject; the sole product is ethyl methanetricarboxylate (m. p. 28°), the vapour density and molecular weight of which were determined by the usual methods; this ethereal salt has a distinctly acid character, and dissolves freely in dilute alkalis. F. S. K.

Action of Ethyl Cyanacetate on Organic Bases. By I. Guareschi (*Chem. Centr.*, 1892, i, 382—383; from *Atti. R. Accad. Sci. Torino*, **27**).—Ethyl cyanacetate reacts with ethylenediamine with development of heat, *dicyanacetylethylenediamine*,

$$C_2H_4(NH·CO·CH_2·CN)_2,$$

and ethyl alcohol being formed. The mixture solidifies on cooling to a white, crystalline mass. Dicyanacetylethylenediamine is sparingly soluble in cold water, readily soluble in hot water and in alcohol, insoluble in ether. When strongly heated, it decomposes into ammonia, hydrogen cyanide, and an odour of coniine is emitted.

With pentamethylenediamine, ethyl cyanacetate forms the corresponding *dicyanacetylpentamethylenediamine*,

$$CH_2(CH_2·CH_2·NH·CO·CH_2·CN)_2.$$

It forms colourless needles melting at 135—136°. With benzylamine, *cyanacetylbenzylamine*, $CH_2Ph{\cdot}NH{\cdot}CO{\cdot}CH_2{\cdot}CN$, is formed. It crystallises in beautiful, long, lustrous needles, melts at 124—124·5°, and boils at 339—340° with partial decomposition. It is soluble in hot water and alcohol, sparingly soluble in ether. This reaction of benzylamine with ethyl cyanacetate forms a means of separating it from aniline (see following abstract). A mixture of both bases is warmed gently with the cyanacetate for a few minutes, after which the mixture is distilled with steam, when the aniline passes over unchanged, whilst the residue contains the cyanacetylbenzylamine. The latter may then be boiled with potash, when benzylamine passes over. With piperidine, ethyl cyanacetate forms *cyanacetylpiperidine*, $C_5NH_{10}{\cdot}CO{\cdot}CH_2{\cdot}CN$, crystallising in large prisms, which melt at 88—89°. J. W. L.

Action of Ethyl Cyanacetate on Aniline. By E. Quenda (*Chem. Centr.*, 1892, i, 383; from *Atti R. Accad. Sci. Torino*, **27**).—Aniline reacts with ethyl cyanacetate only when heated. *Cyanacetylaniline* is first formed and then *malondianilide*, $CH_2(CO{\cdot}NHPh)_2$. The former, $NHPh{\cdot}CO{\cdot}CH_2{\cdot}CN$, is sparingly soluble in cold water, readily soluble in hot water and in alcohol, insoluble in ether; it melts at 198·5—200°, and volatilises at a higher temperature unchanged. It does not form salts with acids, and, when boiled with alkalis, it is decomposed into ammonia and aniline. J. W. L.

Constitution of Ethyl Acetoacetate and of the so-called Formyl Derivatives of Ethereal Salts and of Ketones. By L. Claisen (*Ber.*, **25**, 1776—1787).—Since it has been proved that ethyl acetoacetate yields two classes of derivatives, one of which must be regarded as derived from the ketonic ethereal salt $CH_2Ac{\cdot}COOEt$, whilst the other must be supposed to be derived from ethyl hydroxycrotonate, $OH{\cdot}CMe{:}CH{\cdot}COOEt$ (compare Nef, this vol., p. 140), there remain at the present time only two ways in which the constitution of ethyl acetoacetate can be determined, namely, by studying its physical properties and by comparing its chemical behaviour with that of compounds of known constitution.

Brühl (this vol., p. 583), from a determination of the molecular refraction of ethyl acetoacetate, concludes that at the ordinary temperature the compound must be represented by the ketone formula; this view is confirmed by the observations of Perkin (Proc., 1892, 100) on the molecular magnetic rotation of ethyl acetoacetate. Assuming that ethyl acetoacetate is a hydroxy-compound, the fact that it does not yield an acetyl derivative when heated with acetic anhydride or acetic chloride is remarkable. Further, if ethyl acetoacetate is ethyl hydroxycrotonate, it would probably show, to a certain extent, the same behaviour as ethyl salicylate, since both compounds contain the atomic complex $OH{\cdot}C{:}C{\cdot}COOEt$, but, as a matter of fact, the properties of the two compounds are quite different; as, however, the fact that in ethyl salicylate the atomic complex in question forms part of a closed chain, makes the analogy somewhat doubtful, the question can only be decided with certainty

by comparing the behaviour of ethyl acetoacetate with fatty compounds, such as the hydroxymethylene derivatives, which contain the atomic complex $OH\cdot\overset{|}{C}:\overset{|}{C}\cdot CO$—.

This comparison has shown that the behaviour of ethyl acetoacetate is so different from that of hydroxymethylenecamphor (Abstr., 1891, 574) and from that of the hydroxymethylene derivatives of ethyl phenylacetate, ethyl phenyl ketone, and deoxybenzoïn, that the constitution of the first named cannot be analogous to that of the hydroxy-compounds. The latter are converted by acetic chloride and by benzoic chloride into neutral acetates and benzoates just as readily as are the phenols; the benzoates are also formed when the sodium derivatives are suspended in ether and treated with benzoic chloride, and when the hydroxy-compounds are treated by Schotten-Baumann's method. When the sodium derivatives of the hydroxymethylene compounds are heated with ethyl iodide, alkyl derivatives of the constitution $OEt\cdot\overset{|}{C}:\overset{|}{C}\cdot CO$— are formed, with separation of sodium iodide; the same alkyl derivatives are obtained when the hydroxy-compounds are treated with phosphorus trichloride, and the chlorides obtained in this way decomposed with sodium ethoxide. These alkyl derivatives are hydrolysed by alcoholic potash and behave in this respect like the ethereal salts. On oxidation, the hydroxymethylene derivatives are decomposed in such a way that the $:CH\cdot OH$ group is replaced by an atom of oxygen.

A full account of these experiments will be published.

Since in many respects the hydroxymethylene derivatives are analogous to the isonitroso-compounds, it is possible that the former, like the latter, may exist in stereoisomeric forms; in the case of hydroxymethyleneacetone, for example, the two configurations would be represented by the formulæ $\begin{matrix}Ac\cdot\overset{||}{C}\cdot H\\OH\cdot\underset{|}{C}\cdot H\end{matrix}$ and $\begin{matrix}Ac\cdot\overset{||}{C}\cdot H\\H\cdot\underset{|}{C}\cdot OH\end{matrix}$. As a matter of fact, the benzoyl derivative of hydroxymethylenecamphor exists in two modifications, one of which can be converted into the other.

When the sodium derivative of hydroxymethyleneacetone is treated with benzoic chloride, there are formed two crystalline compounds, melting at 93° and 117° respectively; analyses of these two substances gave, in both cases, results agreeing with those required by a benzoyl derivative of the composition $CHAc{:}CH\cdot OBz$; nevertheless, they are not isomeric. The compound of higher melting point can be obtained by heating the compound melting at 93° with excess of benzoic acid; it has, probably, the constitution $CH_2Ac\cdot CH(OBz)_2$, is insoluble in alkalis, and gives no coloration with ferric chloride.

When hydroxymethyleneacetone is treated with hydroxylamine, two isomeric isoxazoles are formed; they are both colourless liquids, having an intense pyridine-like smell. The one is *γ-methylisoxazole*, and boils at 118°. The isomeride boils at 122° and is *α-methylisoxazole*; this compound is converted into sodiocyanoacetone by sodium ethoxide. Cyanoacetone (compare Holtzwart, *J. pr. Chem.*, **39**, 237) is a colourless, unstable liquid, which readily undergoes polymerisation.

F. S. K.

Action of Nitrous Acid on Ethyl Acetosuccinate and Diacetosuccinate. By R. Thal (*Ber.*, **25**, 1718—1727).—*Isonitrosolevulinic acid*, $COOH{\cdot}CH_2{\cdot}C(NOH){\cdot}COMe$, is obtained when a solution of ethyl acetosuccinate and potassium hydroxide (5 grams of each) in water (100 grams), after remaining at a moderately low temperature for 12 hours, is mixed with one of sodium nitrite (2 grams) in water (50 grams), the mixture being then cooled by ice, acidified with sulphuric acid, and quickly extracted with ether. The acid crystallises from ether in bunches of white needles, is readily soluble in alcohol, ether, and water, melts at 119° with the evolution of carbonic anhydride, whilst isonitrosomethylacetone distils over at 184—185°. It reduces Fehling's solution on warming, and, when kept, becomes black, being then insoluble in ether. The salts crystallise badly, the best being the *barium* salt, $(C_5H_6NO_4)_2Ba + 3H_2O$, which decomposes at 80°; the *phenylhydrazone* forms slender, silky needles, and melts at 152°. When an aqueous solution of the acid is mixed with hydroxylamine hydrochloride, and allowed to remain for some weeks, a brown, amorphous substance separates, whilst ether extracts a compound from the solution which crystallises from chloroform in leaflets, melts at 85°, and has one of the following constitutions, $NOH{:}CMe{\cdot}C\begin{matrix}N-O\\ |\\ CH_2{\cdot}CO\end{matrix}$ or $NOH{:}C\begin{matrix}CO-NMe\\ |\\ CH_2{\cdot}C\end{matrix}$. When isonitrosolevulinic acid is reduced with stannous chloride and hydrochloric acid, after adding an excess of concentrated potash, ether extracts tetramethylaldine; whilst, when the acid is allowed to remain in the cold with 20 times its weight of 15 per cent. sulphuric acid, an explosive compound, soluble in alkalis, is produced.

When ethyl diacetosuccinate is treated with nitrous acid in a similar manner to ethyl acetosuccinate, it gives two compounds, $C_2(NOH)_2(COMe)_2$ and $NOH{:}C(COMe){\cdot}CH_2{\cdot}COMe$; the former melts at 152·5° with decomposition, and the latter melts at 75° and boils at 185—188°. Ethyl β-methylacetosuccinate, on analogous treatment, yields a compound insoluble in all solvents with the exception of alkalis, which dissolve it with a yellow colour; it melts at 129—130° with the evolution of gas, and is probably methylisonitrosolevulinic anhydride, $COMe{\cdot}C\begin{matrix}N-O\\ |\\ CHMe{\cdot}C\end{matrix}$. A. R. L.

Hydrogenation of Closed Rings. By F. Stohmann and C. Kleber (*J. pr. Chem.* [2], **45**, 475—499).—See this vol., p. 1040.

Synthesis of Dihydrobenzene. By A. Baeyer (*Ber.*, **25**, 1840—1841).—The author has obtained dihydrobenzene by heating with quinoline the dibromohexamethylene obtained from quinitol (this vol., p. 833).

Dihydrobenzene is a liquid resembling benzene, has a characteristic penetrating odour, and boils at 81·5° (impure). The vapour at once turns paper moistened with permanganate brown. It combines with hydrogen bromide under the same conditions as dipentene, and forms a saturated *hydrobromide*. With bromine, it yields a beautifully

crystalline *tetrabromide*, which is reconverted into dihydrobenzene when treated with zinc-dust and acetic acid. With alcoholic sulphuric acid, it gives an intense blue coloration, and is converted into an oily condensation product. It dissolves in concentrated sulphuric acid with a red coloration. E. C. R.

Lignite Tar. By F. Heusler (*Ber.*, **25**, 1665—1678).—A quantity of the lighter portions of the distillate from lignite tar was fractionated after treatment with dilute acids and alkalis. On distillation at ordinary pressures, decomposition sets in at about 180°. The oil is readily attacked in the cold by potassium permanganate in dilute sulphuric acid solution. A quantity (1950 c.c.) of the oil boiling at 148—162° was treated with potassium permanganate (167 grams) in the cold until the action was over. On steam distillation, an oil (1208 grams) boiling at 130—165° was obtained; the largest fraction (328 grams) of this distilled at 145—150°. The lower boiling parts of the crude tar oil are acted on with explosive violence by nitric acid. After treatment with potassium permanganate, however, nitration proceeds quietly; the greater portion of the oil dissolves with evolution of gas, and on pouring the acid solution into water, a heavy oil separates which is partially soluble in soda. A considerable proportion, however, remains undissolved, and consists of nitro-derivatives of aromatic hydrocarbons.

On fractional bromination in the cold of the oil dissolved in ether, a product is obtained which may be separated by steam distillation into a light and a heavy oil. The lighter portion consists of bromo-derivatives of aromatic hydrocarbons.

Lignite tar oil is readily acted on by concentrated sulphuric acid with evolution of sulphurous anhydride. The oil (15 parts), if agitated first with a mixture of water (1 part) and concentrated sulphuric acid (2 parts) and then with a mixture ($4\frac{1}{2}$ parts) of water (1 part) and concentrated sulphuric acid (3 parts), yields an oil which, on steam distillation and subsequent fractionation, is found to be similar to that obtained by oxidation with permanganate and to have a strongly aromatic odour. The fraction of this oil, boiling at 80—93° was found, by nitration, to contain about 34 per cent. of benzene. The fraction boiling at 100—110° of the oil obtained by the treatment with permanganate, described above, was found by nitration to contain about 45 per cent. of toluene. Derivatives of metaxylene and mesitylene were also recognised among the products of nitration. The fraction boiling at 135—140° of the oil obtained by treatment with permanganate contained about 30 per cent. of aromatic hydrocarbons.

On nitration of the oil, a certain quantity was always unattacked; this consists of naphthenes, and the proportion increases as the boiling point of the oil rises, and varies from 14·5 per cent. in the fraction boiling at 90—100° to 33·3 per cent. in the part boiling at 300°.

No evidence of the presence of terpenes in the oil could be obtained on treating the oil by Wallach's methods. Indene and cumarone, also, could not be detected. The fraction boiling at

180—240° was found by treatment with picric acid to contain 4—5 per cent. of naphthalene. W. J. P.

Action of Iodoform on the Additive Product obtained from Sulphurous Anhydride and Sodium Phenoxide. By C. Schall and J. Uhl (*Ber.*, **25**, 1875—1901).—It has already been shown by Schall and Kopp (this vol., p. 970) that sulphurous anhydride and sodium phenoxide unite in molecular proportions forming the additive compound $NaSO_2 \cdot OPh$, which reacts with alkyl iodides forming the phenyl salts of alkylsulphonic acids. Benzyl chloride and carbonyl chloride act in a different manner, causing the evolution of sulphurous anhydride and forming benzyl phenyl ether and phenyl carbonate respectively. The authors then examined the action of iodoform in the hope of obtaining derivatives of the sulphonic acid, but the reaction proceeds in an entirely different manner to those mentioned above, yielding a substance of high molecular weight, which has the properties of a colouring matter.

The mixture of iodoform (1 mol.) and phenyl sodium sulphite (3 mols.) is heated in a sealed tube at 180°; the product contains, besides the above-mentioned colouring matter, considerable quantities of free iodine, sodium sulphate, sodium iodide, small quantities of water, carbon, methyl iodide, and phenyl methylsulphonate, sulphurous anhydride, and carbon monoxide being also evolved. To isolate the colouring matter, the product is treated with sodium thiosulphate to remove free iodine, the residue distilled in a current of steam, extracted with benzene, and, finally, recrystallised from alcohol with addition of water. It then forms odourless, microscopic plates, having a red to blackish-brown colour, or reddish-brown when in the form of powder; the authors, therefore, propose to term it *rubbadin* (from *ruber*, red, and *badius*, chestnut-brown) until its constitution shall be more exactly determined.

The analysis of the substance and the determination of its molecular weight by the boiling-point method lead to the formula $C_{44}H_{32}S_4O_8$; it sinters at 145°, commences to swell up and, apparently, to decompose at 160°, dissolves readily in alcohol, ethyl acetate, and phenol, sparingly in acetic acid, and is insoluble in other neutral solvents. Dilute soda and ammonia also dissolve it forming an intense Bordeaux-red solution, but the compound is reprecipitated unaltered by acids, or even by water from ammoniacal solution. In alcoholic or ammoniacal solutions it colours silk and wool a pale Bordeaux-red, and cotton a peculiar, pale yellowish-violet tint.

Diacetylrubbadin, $C_{44}H_{30}S_4O_8Ac_2$, is prepared by the action of an excess of acetic anhydride on rubbadin at 100°, and crystallises from chloroform on addition of light petroleum, and cooling strongly; it forms a greyish-yellow, crystalline powder which sinters at 155° and decomposes at a higher temperature without melting. On boiling in alcoholic solution, it undergoes decomposition, being resolved apparently into two acetyl derivatives, $C_{24}H_{16}S_2O_6Ac_2$ and $C_{20}H_{16}S_2O_2Ac_2$. With bromine it yields *hexabromodiacetylrubbadin*, $C_{44}H_{24}Br_6S_4O_8Ac_2$, which separates from ethyl acetate on addition of light petroleum as a fine, red, crystalline powder, and decomposes without melting above

300°. *Dimethylrubbadin*, $C_{44}H_{30}S_4O_8Me_2$, is obtained by boiling a solution of the colouring matter in alcoholic potash with a slight excess of methyl iodide; it is a dark, reddish-brown powder, and may be recrystallised from chloroform on addition of light petroleum, after which it sinters at 147° and decomposes at 210°.

When the solution of rubbadin in soda or acetic acid is treated with zinc-dust, 1 atom of sulphur is displaced by 2 atoms of hydrogen; the product separates in pale-red flakes, and can be crystallised from a mixture of ethyl acetate and light petroleum.

Concentrated nitric acid, freed from lower oxides by addition of carbamide, acts on an acetic acid solution of rubbadin, forming a *hexanitro*-compound $C_{44}H_{26}(NO_2)_6S_3O_8$, which contains 1 atom less sulphur than rubbadin, forms a red, crystalline powder, decomposing at 203°, and colours silk and wool pale yellow. When treated with reducing agents, it yields products which are insoluble in all solvents with the exception of phenol, and appear to consist of nitramido-derivatives.

Sulphuric acid acts on rubbadin with evolution of sulphurous anhydride and formation of other products which could not be isolated, whilst nitric acid at 100° yields picric acid and considerable quantities of sulphuric acid; on distillation with zinc-dust, it yields impure phenol. Dilute hydrochloric acid decomposes it at 200° with evolution of hydrogen sulphide and formation of phenol, and a new compound having the formula $C_{32}H_{20}S_2O_8$; the latter is a dark-red, crystalline powder, which decomposes above 300° without melting, dissolves readily in alcohol, ethyl acetate, and acetone, sparingly in acetic acid and ether; it also dissolves in concentrated soda, but scarcely in ammonia. When the alkaline solution is treated with methyl iodide, the *dimethyl* derivative, $C_{32}H_{18}S_2O_8Me_2$, is formed, which separates out in reddish-brown, lustrous plates, sinters at 200°, and decomposes on further heating. The *diacetyl* derivative

$$C_{32}H_{18}S_2O_8Ac_2,$$

is a yellowish-brown, crystalline powder, which sinters at 198°, and also decomposes on further heating; it combines with bromine to form the *tetrabromodiacetyl* derivative, $C_{32}H_{14}Br_4S_2O_8Ac_2$, which is a pale-red, crystalline powder.

When fused with soda and a little water, rubbadin yields phenol, a little salicylic acid, and *dihydroxydiphenyl sulphoxide*, $SO(C_6H_4{\cdot}OH)_2$. The latter forms a sandy, greyish-yellow powder which melts at 95°, is insoluble in benzene and light petroleum, readily soluble in ethyl alcohol, ether, and soda. Its *acetyl* derivative, $SO(C_6H_4{\cdot}OAc)_2$, is also a greyish-yellow powder, and melts at 108—109°. The same acetyl derivative is obtained from dihydroxydiphenyl sulphide by acetylation and oxidation with potassium permanganate, thus showing that the above constitution is correct. When dihydroxydiphenyl sulphoxide is heated with dilute hydrochloric acid at 200°, it is converted into a polymeride $(C_{12}H_{10}SO_3)_2$, which forms a reddish-brown, microcrystalline powder, and begins to melt at 188°.

The above results are insufficient to establish the exact constitution

of rubbadin, but the authors propose, provisionally, the following constitutional formula:—

$$HO\cdot C_6H_4\cdot CH{:}S<\begin{matrix}O\cdot O\cdot C_6H_4\\ O\text{—}C_6H_4\end{matrix}>S{:}S<\begin{matrix}C_6H_4\cdot O\\ C_6H_4\cdot O\end{matrix}>S<\begin{matrix}O\cdot C_6H_4\\ |\\ CH\cdot C_6H_4\cdot OH\end{matrix}$$

Thymol. By F. Kehrmann (*Ber.*, **25**, 1662).—A polemical paper.

Orthophenylene Hydrogen Antimonite. By H. Causse (*Compt. rend.*, **114**, 1072—1074).—*Orthophenylene hydrogen antimonite*,

$$C_6H_4<\begin{matrix}O\\ O\end{matrix}>Sb\cdot OH,$$

is prepared by saturating an aqueous solution (200 c.c.) of catechol (20 grams) with sodium chloride at 50°; a neutral solution (100 c.c.) of antimonious chloride prepared by the author's method (see this vol., p. 413) is then added. On cooling, the antimonite crystallises out, and is separated after 24 hours, washed, and dried in the air. The substance does not melt; it is insoluble in most neutral solvents, but dissolves in alkalis and alkali carbonates, and in hydrochloric and sulphuric acids. Its solution in nitric acid soon decomposes with separation of antimonious oxide. It is decomposed by boiling with water or by treatment with hydrogen sulphide. On heating the salt (3 grams) with acetic anhydride (30 grams) in a closed vessel for four hours at 130°, diacetylcatechol is formed. Dibenzoylcatechol is obtained in a similar manner. W. J. P.

Paramidoalkylorthotoluidines. By A. Weinberg (*Ber.*, **25**, 1610—1614).—*Paramidoethylorthotoluidine* is prepared by the reduction of the corresponding nitroso-compound, and boils at 272° (corr.). The *sulphate*, $C_6H_2EtMe(NH_2)_2,H_2SO_4$, is deposited in large crystals on the addition of dilute sulphuric acid to the base dissolved in alcohol. By the action of nitrous acid on the base, a diazo-compound is formed. The *acetyl derivative* is obtained by heating the base with glacial acetic acid, and is amorphous; the salts are readily soluble. By the action of nitrous acid, a *nitrosamine* is formed as a yellow, viscid liquid.

On heating the acetyl derivative with ethyl bromide and alcohol in a sealed tube for 12 hours, *paracetamidodiethylorthotoluidine* is formed; it is a viscid liquid, and is purified by treatment with nitrous acid and ether; on heating with potash, *paramidodiethylorthotoluidine* is formed; this is a colourless liquid which does not undergo change on exposure to air, and boils at 260—261°. The *sulphate* crystallises in colourless prisms; the *hydrochloride* in small, lustrous plates. The *diazo-derivative* is pale yellow, and readily soluble. Paramidodiethylorthotoluidine does not yield thionine or indamine derivatives, neither could a thiosulphonic acid be obtained; this apparently points to an inner linkage between the amido- and alkyl-groups. That such is the case with paramidoethylorthotoluidine is shown by its yielding an indamine, a thionine, and a *thiosulphonic acid* which crystallises in lustrous prisms, and is almost insoluble in water. A comparison of the boiling points of aniline, ortho-, para-, and meta-toluidine, and of

the ethyl and diethyl substitution products shows that the boiling point rises with increasing molecular weight, except in the case of diethylorthotoluidine, which boils 9° lower than ethylorthotoluidine. The dialkylorthotoluidines do not condense with aldehydes, but the monoalkyl compounds readily combine to form methane derivatives.

J. B. T.

Oxalylorthamidophenyl Mercaptan, and Oxalylorthamido-α-naphthyl Mercaptan. By W. Lang (*Ber.*, **25**, 1902—1903).—When a mixture of aniline, glycerol, and sulphur is heated to the boiling point, hydrogen sulphide is evolved in quantity, the evolution continuing for 50—60 hours. If the product be then distilled, a yellow oil passes over far above 300° which quickly solidifies, and after recrystallisation from xylene forms pale-yellow needles, melts at 304°, and is identical with the oxalylorthamidophenyl mercaptan obtained by Hofmann from sulphur and acetanilide (Abstr., 1880, 885). If the aniline be replaced by α-naphthylamine, the oxalylorthamido-α-naphthyl mercaptan also described by Hofmann is formed, but the yield in both cases is much smaller than that obtained by the older method. The phenyl derivative may also be prepared by heating sulphur and ethylaniline at 200—300°.

H. G. C.

Dinitrosoazobenzene. By C. Wllgerodt (*J. pr. Chem.*, [2], **45**, 554—555).—The author complains that Kehrmann and Messinger (this vol., p. 889) have taken up an investigation which he had reserved. Even if it be granted that their experimental work is correct they are wrong in drawing the conclusion that "dinitrosoazobenzene" is nitrophenylazimidobenzene.

A. G. B.

Action of Diazo-compounds on Oximes. By J. Mai (*Ber.*, **25**, 1685—1689).—The author continues his study of the action of diazo-compounds on oximes (see this vol., p. 163).

Paratoluidine (2·5 grams) is diazotised in hydrochloric acid solution and slowly added to an ice-cold aqueous solution of ethylaldoxime (3 grams) and potash (2 grams). The reaction is somewhat uncertain, an oily mass sometimes being formed; the normal product is a solid which is extracted with ether. On evaporation of the ethereal solution, a viscid mass is obtained which ultimately solidifies, and on crystallisation from light petroleum yields colourless leaves which melt at 86°, and decompose with evolution of gas at above 120°. This substance may have the constitution $C_6H_4Me{\cdot}NH{\cdot}N(O{\cdot}N{:}CHMe)_2$. It is sparingly soluble in ether, more so in alcohol, and separates unchanged from its solution in acetic acid.

The interaction of ethylaldoxime and diazobenzene chloride results in the formation of a substance which separates from light petroleum as an oil which ultimately solidifies and is deposited from ether as a solid which melts at 86° and decomposes with evolution of gas at 120°. Its constitution may be $NHPh{\cdot}N(ON{:}CHMe)_2$.

Paratoluidine (2 grams) and acetoxime (3 grams), when treated as described above, give a quantitative yield of a substance having

the composition $C_{13}H_{20}N_4O_2$, which crystallises from a mixture of alcohol and ether in scales melting with evolution of gas at 140—145°.

Similarly, diazobenzene chloride and acetoxime yield a compound of the composition $C_{12}H_{18}N_4O_2$, which crystallises from a mixture of alcohol and ether.

The two benzaldoximes react with diazobenzene chloride giving crystalline compounds of the composition $C_{20}H_{18}N_4O_2$, which melt with decomposition at 125°, and agree completely in their properties.

W. J. P.

Oximes. By A. Claus (*J. pr. Chem.*, [2], **45**, 556—560).—A reply to the recent paper by V. Meyer and Cathcart (this vol., p. 992; compare this vol., pp. 598, 985). A. G. B.

Parethoxyphenylhydrazine and Dimethylparethoxyphenylpyrazolone. By F. Stolz (*Ber.*, **25**, 1663—1665).—*Parethoxyphenylhydrazine*, $OEt{\cdot}C_6H_4{\cdot}N_2H_3$, is prepared by cautiously diazotising parethoxyaniline dissolved in concentrated hydrochloric acid, and subsequently reducing the cooled solution with stannous chloride and hydrochloric acid. It crystallises from benzene in lustrous leaflets, reduces Fehling's solution, melts at 74°, and is sparingly soluble in ether; the free base deliquesces and becomes dark on exposure to the air.

Parethoxyphenylmethylpyrazolone, $N<\begin{matrix}CMe-CH_2\\ N(C_6H_4{\cdot}OEt)\end{matrix}>CO$, separates as a crystalline mass when molecular proportions of the last described compound and ethyl acetoacetate are dissolved in toluene and the solution heated on the water-bath; it melts at 147°, and resembles pyrazolone in its behaviour. When heated at 100—120° with methyl iodide and wood spirit, *dimethylparethoxyphenylpyrazolone* (*parethoxyantipyrine*) $NMe<\begin{matrix}CMe=CH\\ N(C_6H_4{\cdot}OEt)\end{matrix}>CO$, is produced; this crystallises in lustrous leaflets, melts at 90—91°, and resembles antipyrine in its general behaviour. A. R. L.

Paralkyloxy-derivatives of Phenylhydrazine, Hydracetine, and Antipyrine. By J. Altschul (*Ber.*, **25**, 1842—1854).—The author has been working on the same compounds as Stolz (preceding abstract) and claims priority. The preparation of parethoxyphenylhydrazine by V. Meyer's method, namely, by the action of stannous chloride and hydrochloric acid on the diazo-salt of parethoxyamidobenzene gives very bad results; the author has obtained good results by a modification of E. Fischer's method.

Sodium parethoxydiazobenzenesulphonate, $OEt{\cdot}C_6H_4{\cdot}N_2{\cdot}SO_3Na$, is obtained by treating a mixture of parethoxyamidobenzene (100 grams), water (750 grams), and hydrochloric acid (sp. gr. = 1·19; 200 grams) with sodium nitrite (54 grams), dissolved in water (400 grams); when the diazotisation is complete, the mixture is poured into a mixture of sodium sulphite (400 grams), water (1600 grams), ice (500 grams), and sodium hydroxide (40° B., 120 grams). The diazosulphonate is thus obtained as a crystalline, yellow precipitate. That remaining in

the mother liquor is precipitated with salt. It crystallises from water in beautiful, yellow leaflets and thick, brownish-yellow prisms.

Sodium parethoxyphenylhydrazinesulphonate is obtained by gradually adding zinc dust (200 grams) to a solution of the above salt (400 grams) in water (2000 grams), and acetic acid (200 grams). On concentrating the filtrate, the greater part of the hydrazine sulphonate crystallises out; the rest is precipitated with salt. It crystallises in small, colourless prisms, is easily soluble in warm water, when damp quickly turns yellow, but remains unaltered when dry, and reduces Fehling's solution in the cold.

The corresponding methoxy-salts are obtained in a similar way. *Sodium paramethoxydiazobenzenesulphonate* forms yellow leaflets very similar to the ethoxy-salt. *Sodium paramethoxyphenylhydrazinesulphonate* crystallises in white needles.

When the above sodium hydrazinesulphonates are treated with concentrated hydrochloric acid with the object of converting them to the hydrazine hydrochlorides, decomposition takes place, and the properties characteristic of the hydrazine group are lost. The hydrazine hydrochlorides are easily obtained by treating them with alcoholic hydrogen chloride.

Parethoxyphenylhydrazine hydrochloride is obtained as follows:—A mixture of dry sodium paraethoxyphenylhydrazinesulphonate (100 grams), and 90 per cent. alcohol (600 grams) is heated to boiling in a reflux apparatus and mixed with hydrochloric acid (sp. gr. 1·19; 20 grams); after a short time the mixture is filtered hot; the filtrate cooled to 10° and mixed with a further quantity (350 grams) of hydrochloric acid. The semi-solid, crystalline mass so obtained is filtered and washed with alcohol. It crystallises from water or alcohol in colourless needles, is very easily soluble in water, less so in alcohol, decomposes when in a damp state, but is stable when dry. On adding ammonium oxalate to the aqueous solution, the *hydrazine oxalate* is precipitated in beautiful, colourless prisms.

Parethoxyphenylhydrazine is obtained by heating the hydrochloride with concentrated sodium hydroxide on the water-bath. It forms a bright-yellow, crystalline powder, melts at 74°, is distinctly soluble in cold water, easily in alcohol, sparingly so in ether, is very unstable, and soon decomposes into a brownish-red resin. It can be distilled in a vacuum, when it partially decomposes and the colourless distillate is a mixture of crystals (m. p. 74°) and a yellowish oil. When heated with aqueous mineral acids or with organic acids, it is quickly decomposed with formation of ammonia. On examining the alcoholic mother liquors obtained from crystallisation of the hydrochloride, the author separated parethoxyazobenzene, $N_2(C_6H_4{\cdot}OEt)_2$. When treated with glacial acetic acid at 100°, the mono- and di-acetyl compounds are obtained. *Monacetylparaethoxyphenylhydrazine* crystallises from water in colourless leaflets, from alcohol in lustrous prisms, melts at 141·5°, is soluble in 20 parts of boiling water and in 1 part of hot alcohol, and is sparingly soluble in cold water. It is distinguished from hydracetine by a characteristic colour reaction. The latter yields a colourless solution with sulphuric acid which goes

red on the addition of nitric acid. Monacetylparaethoxyphenylhydrazine dissolves in sulphuric acid with a blood-red coloration which changes to a beautiful yellowish-green on adding nitric acid. The *diacetyl compound* is obtained from the mother liquors of the monacetyl compound. It melts at 112—116° and forms colourless crystals similar to the monacetyl compound. Both compounds reduce Fehling's solution in the cold.

The corresponding methoxy-compounds are obtained in a similar way. *Paramethoxyphenylhydrazine* melts at 65°, and is more sparingly soluble in water and more easily so in ether than the ethoxy-compound. The *monacetyl compound* crystallises from water in colourless leaflets, melts at 133·5°, and gives the same colour reactions as the ethoxy-compound.

The decomposition of salts of hydrazinesulphonic acids by means of alcoholic hydrogen chloride may be used with advantage in other cases. The author has obtained phenylhydrazine by this method in a very pure state and from potassium parahydroxyphenylhydrazinesulphonate he obtained a compound which he believes to be parahydroxyphenylhydrazine.

Parethoxyphenylhydrazinesulphonic acid is obtained as follows:—The sodium salt (50 grams) is dissolved in warm water (200 grams), cooled to 40°, and mixed with 7 per cent. hydrochloric acid (100 grams). The liquid turns deep yellow, and after a short time solidifies to a crystalline magma. It is purified by washing with water. It leaves no ash on combustion, is easily soluble in alcohol, sparingly so in water, and is entirely decomposed on heating at 100°, and also by boiling with water and aqueous acids; the aqueous solution blues Congo-paper. On remaining, it quickly changes into *paradiethoxysulphophenylhydrazide*, $(OEt{\cdot}C_6H_4{\cdot}N_2H_2)_2SO_2$. The latter is undecomposed by heating at 100°, turns brown at a higher temperature, and decomposes at 130—140°. It is sparingly soluble in water, crystallises in white needles, is neutral, has strong reducing properties, and yields paraethoxyphenylhydrazine when treated with alcoholic hydrogen chloride, and subsequently with sodium hydroxide.

Ethyl acetoacetate reacts with parethoxyphenylhydrazine as described by Stolz (preceding abstract), and the author obtained parethoxyphenylmethylpyrazolone (m. p. 147°) and parethoxyphenyldimethylpyrazolone (m. p. 91°). The latter crystallises in colourless prisms about a centimetre long.

Parethoxyantipyrine salicylate is obtained by melting parethoxyantipyrine with the equivalent quantity of salicylic acid and a little alcohol. It crystallises from alcohol in beautiful, colourless prisms, and melts at 131°.

Paramethoxyphenyldimethylpyrazolone is very similar to the ethoxy-compound, and melts at 82°.

The author has prepared nitrophenylmethylpyrazolone from paranitrophenylhydrazine by the action of ethyl acetoacetate, and finds that it is identical with the nitro-compound obtained by nitrating phenylmethylpyrazolone. E. C. R.

Isomeric Oximes and Hydrazones. By A. Hantzsch (*Ber.*, **25**, 1692—1700).—This paper is purely polemical, being a reply to Claus (this vol., pp. 50, 598), who opposes stereochemical hypotheses.

W. J. P.

Derivatives of Dibenzylcarbamic, Paraditolylcarbamic, and Benzylparatolylcarbamic Acids. By H. Hammerich (*Ber.*, **25**, 1819—1825).—*Dibenzylcarbamic chloride*, $N(CH_2Ph)_2 \cdot COCl$, is formed when carbonyl chloride is treated with dibenzylamine (2 mols.) in toluene solution; it is a yellow oil and decomposes on keeping.

Phenyldibenzylcarbamide, $C_{21}H_{20}N_2O$, prepared by treating the preceding compound with aniline in alcoholic solution, crystallises in small, lustrous needles, melts at 126—128°, and is soluble in hot alcohol, ether, benzene, and glacial acetic acid, but insoluble in water and light petroleum.

Paratolyldibenzylcarbamide, $C_{22}H_{22}N_2O$, crystallises in small, prismatic needles, melts at 168—169°, and is soluble in hot alcohol, benzene, and glacial acetic acid, but insoluble in ether, light petroleum, and water.

Tribenzylcarbamide, $C_{22}H_{22}N_2O$, crystallises in prisms, melts at 119—120°, and is soluble in benzene, ether, alcohol, and glacial acetic acid.

Tetrabenzylcarbamide, $C_{29}H_{28}N_2O$, crystallises in hexagonal prisms, dissolves freely in ether, benzene, alcohol, and glacial acetic acid, and melts at 85°.

Isobutyldibenzylcarbamide, $C_{19}H_{24}N_2O$, crystallises in small, prismatic needles, melts at 108—109°, and is readily soluble in ether, benzene, glacial acetic acid, and warm alcohol.

Paraditolylcarbamic chloride, $N(C_6H_4Me)_2 \cdot COCl$, crystallises in prismatic needles, melts at 102—103·5°, and is very readily soluble in ether and benzene, but more sparingly in glacial acetic acid, alcohol, and light petroleum.

Phenylparaditolylcarbamide, $C_{21}H_{20}N_2O$, melts at 135—136°, crystallises in prismatic needles, and is soluble in alcohol, benzene, ether, and glacial acetic acid.

Triparatolylcarbamide, $C_{22}H_{22}N_2O$, crystallises in prismatic needles, melts at 189°, and is insoluble in ether, light petroleum, and water, but soluble in warm benzene, glacial acetic acid, and alcohol.

Benzylparaditolylcarbamide, $C_{22}H_{22}N_2O$, melts at 136—137°; *tetraparatolylcarbamide*, $C_{29}H_{28}N_2O$, at 78—80·5°; and *isobutylparaditolylcarbamide*, $C_{19}H_{24}N_2O$, at 118—119°; they are all crystalline compounds soluble in alcohol, ether, benzene, and glacial acetic acid.

Benzylparatolylcarbamic chloride, $CH_2Ph \cdot N(C_6H_4Me) \cdot COCl$, is a dark brown oil.

Phenylbenzylparatolylcarbamide, $C_{21}H_{20}N_2O$, melts at 111—113°, *paraditolylbenzylcarbamide*, $C_{22}H_{22}N_2O$, at 115°, and *dibenzylparatolylcarbamide*, $C_{22}H_{22}N_2O$, at 83—85°; they are all crystalline compounds soluble in ether, alcohol, benzene, and glacial acetic acid.

Dibenzylditolylcarbamide, $C_{29}H_{28}N_2O$, separates from light petroleum in crystals, melts at 91—93°, and is soluble in alcohol, benzene, glacial acetic acid, and ether.

Isobutylbenzylparatolylcarbamide, $C_{19}H_{24}N_2O$, separates from light petroleum in crystals melting at 41°.

Ethyl dibenzylcarbamate, $C_{17}H_{19}NO_2$, is formed when dibenzylcarbamic chloride is heated with an alcoholic solution of sodium ethoxide; it is a yellowish liquid and cannot be distilled.

Ethyl paraditolylcarbamate crystallises from alcohol in well-defined, rhombic plates, melts at 60—62°, and dissolves freely in alcohol, benzene, ether, glacial acetic acid, and boiling light petroleum.

F. S. K.

Tetrabenzyloxamide and Tetraparatolyloxamide. By H. Hammerich (*Ber.*, **25**, 1825—1826).—*Tetrabenzyloxamide*,

$$N(CH_2Ph)_2{\cdot}CO{\cdot}CO{\cdot}N(CH_2Ph)_2,$$

prepared by treating dibenzylcarbamic chloride (compare preceding abstract) with sodium in ethereal solution, crystallises from alcohol in prismatic needles, melts at 127—128°, and is soluble in ether, benzene, and glacial acetic acid.

Tetraparatolyloxamide, $C_{30}H_{28}N_2O_2$, crystallises in small, lustrous plates, melts at 100—101·5°, and is soluble in benzene, alcohol, ether, glacial acetic acid, and light petroleum, but insoluble in water.

F. S. K.

Action of Silver Cyanide on Dibenzylchlorocarbamide and Paraditolylchlorocarbamide. By H. Hammerich (*Ber.*, **25**, 1827—1829).—*Dibenzylcyanocarbamide argentocyanide*,

$$N(CH_2Ph)_2{\cdot}CO{\cdot}CN,AgCN,$$

is obtained by heating dibenzylchlorocarbamide dissolved in alcohol with excess of silver cyanide in a reflux apparatus for 4 to 8 hours. The precipitate of silver chloride is filtered off and the filtrate evaporated to crystallisation. It crystallises in small, prismatic needles, melts at 165—167°, is soluble in alcohol, insoluble in ether, benzene, acetic acid, and light petroleum, and blackens on exposure to light.

Paraditolylcyanocarbamide diargentocyanide,

$$N(C_6H_4Me)_2{\cdot}CO{\cdot}CN,2AgCN,$$

is obtained in a similar way to the preceding compound. It crystallises in small, prismatic needles, begins to melt at 103°, gradually decomposes at higher temperatures, and blackens on exposure to light.

The author was unable to obtain an analogous compound from benzylparatolylchlorocarbamide.

E. C. R.

Aromatic Phosphino-compounds, RPO_2. By A. Michaelis and F. Rothe (*Ber.*, **25**, 1747—1752).—*Phosphinobenzene*, $Ph{\cdot}PO_2$, is obtained when dry phenylphosphinic acid (m. p. 158°; 7 grams) is heated in a reflux apparatus with the chloride of the same acid, $Ph{\cdot}POCl_2$ (12 grams), until the evolution of hydrogen chloride ceases. The product is washed with dry cold benzene, dissolved in hot benzene, and the concentrated solution cooled to its solidifying point. On now cautiously thawing the benzene and decanting it, the com-

pound remains, and is dried first in a current of carbonic anhydride at 70°, and subsequently in a desiccator. It is a white, crystalline powder, melts at 100°, is readily soluble in benzene, and when exposed to moist air is converted into phenylphosphinic acid, thus behaving as an anhydride of the latter.

Paraphosphinotoluene, $C_6H_4Me{\cdot}PO_2$, is prepared from paratolylphosphinic acid (m. p. 189°) and its chloride in the same manner as the benzene derivative, which it resembles; it melts at 101°.

Phosphino-ψ-cumene, $C_6H_2Me_3{\cdot}PO_2$, is obtained from *ψ-cumylphosphinic acid* (m. p. 212°), which will be described in a subsequent paper, and its chloride. It separates from benzene in small, well-formed, rhombic leaflets, melts at 216°, and is sparingly soluble in cold benzene, very easily in chloroform, and insoluble in light petroleum. It does not absorb water so readily as do the two first-mentioned analogues.

The phosphino-compounds are also obtained when the substituted phosphorous acids are heated with phosphoric chloride; this method does not, however, give such good results as the alternative one. The remainder of the paper is devoted to a comparison of the phosphorus and arsenic analogues of nitrobenzene, azobenzene, and aniline. A. R. L.

Ethylnitroketone and Acetylnitroketone from Camphosulphophenols. By P. Cazeneuve (*Compt. rend.*, **114**, 1012—1014). —The nitroketone derived from the camphosulphophenols (this vol., 999) seems to be a nitroketone of a propylbenzene dihydride ($NO_2 : H_2 : O : Pr = 1 : 2 : 3 : 4$), the methyl of the paracymene nucleus of camphor having disappeared on the formation of a methyl camphophenolsulphone and its isomeride.

The potassium salt of the nitroketone, when heated with excess of ethyl iodide at 130° for an hour, yields an ethyl derivative, $NO_2{\cdot}C_9H_{10}OEt$. It is a yellow, syrupy liquid, insoluble in water, but miscible with alcohol or ether, and it explodes if heated rapidly above 200°. When treated with a cold alcoholic solution of sodium ethoxide, it yields immediately an alkaline salt, $NO_2{\cdot}C_9H_{10}ONa$, with liberation of ether.

The carefully-dried potassium salt reacts rapidly with acetic chloride. The latter is added gradually until the red colour changes to yellow, showing that the reaction is complete, and the product is washed, first with water, then with water containing alkali, and is finally crystallised from alcohol, from which it separates in large, greenish-yellow, tabular hexagons. This product is the acetyl derivative, $NO_2{\cdot}C_9H_{10}OAc$; it melts at 65°, remains in superfusion even at the ordinary temperature, and explodes if heated above 250°. When treated with an alcoholic solution of sodium ethoxide, it yields ethyl acetate and the sodium derivative of the nitroketone.

Although the ethyl and acetyl derivatives are somewhat unstable, it still seems necessary to assume the existence of the grouping $NO_2 : H_2 : O = 1 : 2 : 3$. The difference between the acidic function of the CH_2 group in this nitroketone and in acetylacetone is probably due to the fact that in the latter the CH_2 group is connected with

two carbonyl groups, and not with one nitro-group and one carbonyl group. C. H. B.

Phenylanthranilic Acid and Acridone. By C. Graebe and K. Lagodzinski (*Ber.*, **25**, 1733—1736).—Phenylanthranilic acid, $COOH{\cdot}C_6H_4{\cdot}NHPh$ [1 : 2], is prepared by reducing Schöpff's meta-nitrorthanilidobenzoic acid (Abstr., 1891, 304) with tin and hydrochloric acid and eliminating the amido-group by the diazo-reaction. It forms a compound with concentrated hydrochloric acid, which is decomposed on addition of water, and, when nitric acid is added to its solution in a little concentrated hydrochloric acid, an intense, violet coloration is produced; it melts at 181° (corr.), which value is not in agreement with that of Claus and Nicolaysen (Abstr., 1886, 68); Claus is, however, resuming its study.

When phenylanthranilic acid is heated at 100° with concentrated sulphuric acid for 1—2 hours, acridone, $C_6H_4{<}\overset{CO}{NH}{>}C_6H_4$, which is perhaps identical with the compound obtained by Graebe and Caro by oxidising acridine (Abstr., 1880, 399), is formed; it crystallises in stout, yellow needles, melts at 350°, volatilising at a higher temperature without decomposition, and dissolves somewhat readily in hot alcohol or glacial acetic acid, its solution having a yellow colour and a bluish fluorescence; it also dissolves in concentrated hydrochloric acid on warming, but is insoluble in aqueous alkalis. It gives Decker's methylacridone (this vol., p. 881) on methylation, and, when heated with zinc-dust, it is quantitatively converted into acridine.

A. R. L.

Condensation of Ethyl Cyanacetate and Benzaldehyde: Ethyl α-Cyanocinnamate. By J. T. Carrick (*J. pr. Chem.* [2], **45**, 500—515).—The author has already shown that this condensation takes place at the ordinary temperature in the presence of sodium ethoxide (Abstr., 1890, 1270), the product of the reaction being *ethyl α-cyanocinnamate*. The best yield is 80 per cent. of the calculated quantity, the conditions being those already given (*loc. cit.*). The same product was obtained in very small quantity when benzaldehyde (5 grams), acetic anhydride (20 grams), and ethyl cyanacetate (5 grams) were heated together in a sealed tube at 150—160°.

Ethyl α-cyanocinnamate melts at 50°, and boils with decomposition about 360°; it dissolves very easily in hot alcohol, in 8—9 parts at the ordinary temperature, and very slightly below 0°; water does not dissolve it at all, but ether, chloroform, benzene, and glacial acetic acid do so easily; it is very volatile with alcohol vapour and with steam. Dilute aqueous alkalis readily decompose it into benzaldehyde and ethyl cyanacetate, which further yields malonic acid, ammonia, and, finally, acetic acid and carbonic anhydride; but with hot water and cold, even concentrated, acids, it is very stable. When heated with concentrated hydrochloric acid in a sealed tube, it is converted into carbonic anhydride, benzaldehyde, and malonic acid. It is unattacked by hot glacial acetic acid, and only decomposed to a slight extent by a mixture of glacial acetic acid and acetic anhydride

in a sealed tube at 150—160°. It is not attacked by bromine, or by hydrogen, either from zinc-dust or sodium amalgam, in glacial acetic acid. Its molecular weight, as determined by Raoult and Beckmann's method, corresponds with the formula $C_{12}H_{11}NO_2$.

α-Cyanocinnamic acid, $C_{10}H_7NO_2$, melts at 178°, and is prepared from the ethyl salt by saponifying it with alcoholic potash, dissolving the *potassium* salt in warm water, cooling, and adding acetic acid; the white precipitate thus thrown down is the hydrogen potassium salt, and yields the acid when dissolved in warm water and decomposed by hydrochloric acid. The molecular weight of the acid was determined. The *hydrogen potassium* salt, $KC_{20}H_{13}N_2O_4$, crystallises in long needles, melts at 240° with decomposition, and is soluble in water, but not in ether; when silver nitrate is added to its alcoholic solution, the *silver potassium* salt, $KAgC_{20}H_{12}N_2O_4$, is precipitated in long, silky needles, contrasting with the *normal silver* salt, which is amorphous. The *normal ammonium* salt, $NH_4{\cdot}C_{10}H_6NO_2$, is obtained when alcoholic ammonia is added to an ethereal solution of the acid, and the *hydrogen ammonium* salt when this is dissolved in water, cooled to 0°, and decomposed with dilute acetic acid; the latter salt melts with decomposition at 210°. The *normal barium* salt,

$$(C_{10}H_6NO_2)_2Ba + H_2O,$$

the *normal copper* salt, the *normal lead* salt (with 4 mols. H_2O), and an *aniline* salt, $C_{10}H_7NO_2{\cdot}NH_2Ph$, were also prepared. By heating the potassium salt with ethyl bromide at 140—150°, it was reconverted into the ethyl salt (m. p. 50°).

When the ethyl salt is dissolved in alcoholic ammonia, there separates, after a time, a crystalline compound which melts at 168°, and is converted into an oil, having the odour of benzaldehyde, when evaporated with ammonia. This crystalline compound appears to be *ethyl cyanocinnamamate*, $CHPh{:}C(CN){\cdot}COOEt,CHPh{:}C(CN){\cdot}CONH_2$; it is insoluble in water and requires 270 parts of ether and 50—60 parts of hot alcohol to dissolve it; chloroform dissolves it easily, while benzene, glacial acetic acid, and strong sulphuric acid separate benzaldehyde from it; alkalis decompose it immediately. When methylamine is substituted for ammonia, the resulting substance has the formula $CHPh{:}C(CN){\cdot}COOEt,CHPh{:}C(CN){\cdot}CO{\cdot}NHMe$, but appears to be a mixture of two isomerides, one of which dissolves in glacial acetic acid and melts about 180° with decomposition, whilst the other is insoluble in this solvent and melts about 157° with decomposition. Attempts to obtain normal cyanocinnamamide failed.

When the ethyl salt is kept in concentrated aqueous ammonia for 24 hours, it becomes converted into a yellow oil which gradually dissolves in the liquid yielding an insoluble precipitate; this precipitate behaves as a very feeble base, and is easily soluble only in chloroform and concentrated mineral acids; it melts at 194°. Another new compound is precipitated by acidifying the ammoniacal solution; it dissolves in chloroform, and melts with decomposition between 175° and 200°.

The oil obtained as a bye-product in the preparation of ethyl

cyanocinnamate (Abstr., 1890, 1270) solidifies gradually, and then has the same melting point as the ethyl salt; it also contains the same percentage of nitrogen and behaves similarly to reagents. The author, therefore, concludes that it is a geometrical isomeride of the ethyl salt (compare Fiquet, *Bull. Soc. Chim.* [3], **7**, 11).

A. G. B.

Mandelic Acid and its Nitrile. By H. A. Michaël and J. Jeanprêtre (*Ber.*, **25**, 1678—1684).—Attempts were made, with negative results, to prepare a sodium derivative of phenylhydroxyacetonitrile corresponding with that yielded by phenylacetonitrile (V. Meyer, Abstr., 1889, 596), in order that by its interaction with ethyl iodide, phenylethoxyacetonitrile might be obtained.

Phenylchloracetonitrile is prepared by slowly adding phenylhydroxyacetonitrile to a strongly cooled solution of phosphorus pentachloride (1 part) in benzene (3 parts). The solution is finally heated on the water-bath, cooled, and poured on to ice. On evaporation of the benzene solution, the nitrile remains as an oil which, after fractional distillation under reduced pressure, boils at 131—133° at ordinary pressures. It is a colourless, strongly refractive liquid, and its vapour has a very irritating effect on the eyes and lungs. On hydrolysis with concentrated hydrochloric acid in a sealed tube at 100°, it readily yields phenylchloracetic acid and phenylchloracetamide. On treating the nitrile with alcoholic sodium ethoxide, sodium chloride is precipitated, and dicyanostilbene remains in solution. This is a good method for the preparation of dicyanostilbene as the yield is large. On heating an ethereal solution of phenylchloracetonitrile (1 mol.) with aniline (2 mols.) for some time, phenylanilidoacetonitrile is obtained.

Phenylhydroxyacetonitrile (1 mol.) is quantitatively converted into an *acetyl* derivative, $C_{10}H_{10}O_3N$, on heating with acetic anhydride (1 mol.) for three hours in a reflux apparatus. On distillation under reduced pressure, the acetyl derivative is obtained as a colourless, viscid oil, which boils at 152° under 25 mm. pressure. On slowly pouring an ethereal solution of this compound into ether containing sodium in suspension, a solid substance containing sodium separates. This is treated with dilute sulphuric acid, and leaves a residue of benzoïn, whilst a compound which crystallises from alcohol in small, tabular crystals, and melts at 115°, goes into solution. The latter substance was not analysed.

The authors were unable to prepare the mandelamide melting at 190°, described by Biedermann (this vol., p. 473), but obtained in its place a substance melting at 132°. By the action of fuming hydrochloric acid on phenylhydroxyacetonitrile, Tiemann and Friedländer (*Ber.*, **4**, 1967) obtained a compound melting at 194°, and having the composition $C_{15}H_{13}O_2N$. The authors have prepared this substance by heating the mandelamide which melts at 132° with the equivalent proportion of benzaldehyde for two hours at 130°. This compound yields no nitroso-compound, but on heating with acetic anhydride gives an *acetyl* derivative, $C_{17}H_{15}O_3N$, which crystallises from alcohol in beautiful prisms and melts at 123°. The constitution of the substance melting at 194° is therefore OH·CHPh·CO·N:CHPh.

The authors were unable to prepare ethyl mandelate melting at 79° as described by Naquet and Louguinine (*Bull. Soc. Chim.*, **5**, 255), but obtained an ethyl salt which crystallises in silky needles, melts at 34°, and boils without decomposition at 250°. They therefore conclude that Naquet and Louguinine were dealing with some other derivative of mandelic acid. W. J. P.

Ethoxyphenylsulphonic Acids. By G. Lagai (*Ber.*, **25**, 1836—1839; see also Abstr., 1891, 310).—*Lead metethoxyphenylsulphonate*, $(OEt\cdot C_6H_4\cdot SO_3)_2Pb + 2\frac{1}{2}H_2O$, crystallises in colourless, lustrous leaflets, and deliquesces in the air. The *aniline salt* is obtained by the action of aniline sulphate on the barium salt, and forms pale-yellow needles. *Metethoxyphenylsulphanilide*, obtained by heating the sulphochloride with aniline, crystallises from alcohol in lustrous, colourless needles or plates, melts at 88°, and is easily soluble in ether, alcohol, and benzene, sparingly so in water. *Ethyl metethoxyphenylsulphonate*, a pale-yellow, oily liquid, is volatile with steam, and, on distillation, is decomposed with formation of a compound having an odour resembling that of mercaptan.

Parethoxyphenylsulphonic acid was prepared by heating potassium paraphenolsulphonate, potassium hydroxide, ethyl bromide, and alcohol, for 12 hours at 100—110°. It was also prepared by sulphonating ethoxybenzene with twice the weight of concentrated sulphuric acid at 100°; in the latter case a small quantity of the ortho-acid is formed. The *sulphochloride* crystallises from ether in hard, colourless prisms, or thick plates, melts at 36·5°, and is very easily soluble in alcohol and ether. The *sulphonamide* crystallises from alcohol in colourless plates, and from water in long, white needles, and melts at 149°. The *sulphanilide* crystallises from dilute alcohol in beautiful, silky needles, and melts at 84°. *Aniline parethoxyphenylsulphonate* crystallises from water in lustrous, pale-yellow needles, and melts at 224° with decomposition. *Parethoxyphenylsulphonic acid* separates from concentrated aqueous solution in feathery crystals. The *hydrosulphide*, a colourless, highly refractive liquid, boils at 232·5°, has an unpleasant odour, is volatile with steam, and with concentrated sulphuric acid gives a yellow coloration, which changes successively to olive-green and dark-blue. With metallic sodium, the hydrosulphide yields a compound which crystallises from absolute alcohol in massive, colourless prisms, and melts at 45°. With mercuric chloride, it yields a compound of the formula $OEt\cdot C_6H_4\cdot S\cdot HgCl$, which crystallises from alcohol, in which it is sparingly soluble, in thin, silvery leaflets, and melts at 178°.

Orthoethoxyphenylsulphonic acid is obtained in small quantities by sulphonating ethoxybenzene, and is separated from the para-acid by means of the barium salt, which is extremely soluble in water. It could not be obtained crystalline. The *sulphochloride* forms a syrupy liquid. The *sulphonamide* crystallises from water in feathery needles, melts at 142°, and is easily soluble in ether, less so in alcohol, and sparingly in water.

According to Moody (Proc., 1892, 90), the orthosulphonic acid is not formed by the sulphonation of ethoxybenzene. E. C. R.

Oxidation Products of Mercapturic Acids. By G. König (*Zeit. physiol. Chem.*, **16**, 525—551; compare Baumann and Preusse, Abstr., 1879, 803; Jaffé, *ibid.*, 796; Baumann, Abstr., 1884, 1382 and 1395). — *αα-Acetamidoparachlorophenylsulphonepropionic acid*, $COOH{\cdot}CMe(SO_2{\cdot}C_6H_4Cl){\cdot}NHAc$, is prepared by dissolving chlorophenylmercapturic acid (10 grams) in normal potassium hydroxide solution (38·5 c.c.), diluting to 2 litres, and adding potassium permanganate (8 grams) in 5 per cent. solution; the mixture is allowed to remain for a day, and the filtrate subsequently neutralised with dilute sulphuric acid, evaporated to a small volume, poured into alcohol, and after filtering off the potassium sulphate, and evaporating the remainder of the alcohol from the filtrate, the residue is dissolved in a small quantity of water and strongly acidified with hydrochloric acid, when the acid separates; it is recrystallised from boiling water, and forms long, thin, colourless prisms or rhombic plates, melts at 177° with decomposition, and is soluble in 45 parts of boiling water and 700 parts of cold, readily soluble in boiling alcohol, sparingly so in the cold liquid, but insoluble in ether, benzene, and chloroform. It gives a blue and a brownish colour respectively when warmed with concentrated sulphuric acid or acetic anhydride, and is a strong, monobasic acid. The *barium* salt crystallises with $1\frac{1}{2}$ mol. H_2O in white, microscopic needles, which are deliquescent, and the *silver* salt forms small, felted needles, which blacken in the light; the salts of the heavy metals are mostly amorphous. The *ethyl* salt crystallises in small, prismatic needles, melts at 165° with decomposition, and is sparingly soluble in cold water, readily in ether, chloroform, and alcohol; it gives no coloration on warming with concentrated sulphuric acid.

αα-Acetamidoparabromophenylsulphonepropionic acid is obtained from bromophenylmercapturic acid in the same way as the chloro-derivative; it crystallises from hot water in colourless prisms, melts at 170—171°, is sparingly soluble in cold water, readily so in alcohol, and gives, with concentrated sulphuric acid, a blue coloration having a greenish shade. The *barium* salt forms silky needles containing 4 mols. H_2O.

αα-Acetamidoparaiodophenylsulphonepropionic acid, prepared from iodophenylmercapturic acid, is much more readily soluble in water than the other halogen derivatives; it separates from concentrated solutions in boiling water in felted needles an inch in length, and melts at 169—170°.

Baumann having shown (*loc. cit.*) that when halogen benzenes are administered to dogs, compounds are found in the urine which yield halogen mercapturic acids on treatment with dilute mineral acids, it seemed probable that the corresponding halogen free compound would occur in the urine when benzene itself was administered; experiments in this direction, however, led to negative results.

αα-Acetamidophenylsulphonepropionic acid,

$$COOH{\cdot}CMe(SO_2Ph){\cdot}NHAc,$$

is obtained by oxidising phenylmercapturic acid (m. p. 140°) or by reducing the preceding halogenated acids; it crystallises from hot

water in small, pointed crystals, melts at 183°, decomposes at a higher temperature, is sparingly soluble in cold water or alcohol, and insoluble in ether, chloroform, and benzene; it gives a brownish-red coloration with concentrated sulphuric acid. The *barium* salt crystallises in small, microscopic needles, containing $\frac{1}{2}$ mol. H_2O; the *silver* salt forms small, anhydrous needles, and is readily soluble in water, ammonia, and nitric acid.

α-Amidoparachlorophenylsulphonepropionic acid,

$$COOH{\cdot}CMe(SO_2{\cdot}C_6H_4Cl){\cdot}NH_2,$$

is prepared by boiling the corresponding acetamido-derivative (m. p. 177°) with dilute (1 to 2) sulphuric acid in a reflux apparatus for about 10 minutes, neutralising with ammonia, and adding an excess of ammonium carbonate, when it separates; it crystallises from boiling water in nacreous leaflets, melts at 156°, requires 1400 parts of cold water for dissolution, being insoluble in boiling alcohol, ether, chloroform, and benzene, and has both acidic and basic properties. It dissolves in concentrated sulphuric acid on warming with the production of a violet solution, and gives the acetamido-derivative on acetylation. The corresponding *bromo*-compound resembles the chloro-derivative; it melts at 163—164°, and gives a reddish-brown solution on warming with concentrated sulphuric acid.

The *hydantoic acid*, $NH_2{\cdot}CO{\cdot}NH{\cdot}C_9H_8ClSO_4$, is formed when α-amidoparachlorophenylsulphonepropionic acid (1 gram) is suspended in water (20 c.c.) and moderately heated with potassium carbimide (4 grams); it crystallises from boiling water in stellate groups of small needles, melts at 173—174° with decomposition, and is readily soluble in hot water and alcohol, but insoluble in ether and chloroform; it gives a blue coloration on warming with concentrated sulphuric acid, and undergoes violent oxidation with nitric acid.

When either α-amidoparachlorophenylsulphonepropionic acid or the corresponding acetamido-derivative is boiled with alkalis, it yields ammonia, pyruvic acid, and parachlorobenzenesulphinic acid. The bromo-derivatives behave in the same manner, and *parabromobenzenesulphinic acid* obtained from them crystallises in long, prismatic needles, melts at 103°, and dissolves in concentrated sulphuric acid on warming, with the production of a blue coloration. It is to be noted that although the mercapturic acids, which are acetamido-compounds, yield sulphones on oxidation, this is not the case with the corresponding amido-derivatives.

Parachlorophenylsulphonehydroxypropionic acid,

$$COOH{\cdot}CMe(SO_2{\cdot}C_6H_4Cl){\cdot}OH,$$

is prepared by dissolving the amidoparachlorophenylsulphonepropionic acid (2 grams) in normal sulphuric acid (20 c.c.) and water (200 c.c.), warming, to the warm solution adding sodium nitrite (0·8 gram), dissolved in water (20 c.c.) and extracting with ether. It crystallises in small, colourless, stellate groups of prisms, melts at 155—156° with decomposition, gives a brown colour when warmed with concentrated sulphuric acid, and is soluble in water, alcohol, and ether;

its salts are easily soluble in water, and do not crystallise readily. When the hydroxy-compound is boiled with alkalis, and the solution subsequently acidified, the *compound* $[COOH{\cdot}CMe{\cdot}(SO_2{\cdot}C_6H_4Cl)]_2O$ is precipitated; it melts at 153°. A. R. L.

Toluic Sulphinide ("**Methylsaccharin**"). By O. Weber (*Ber.*, **25**, 1737—1745).—*Toluic sulphinide*, $C_6H_3{}^{1}Me{<}{}^{3}_{4}{}^{SO_2}_{CO}{>}NH$, prepared from 1 : 4 : 3-amidotoluenesulphonic acid, according to German Patent 48583 (*Ber.*, **22**, Ref. 719), melts at 246°; the *silver* salt is obtained as a white precipitate on adding silver nitrate to a solution of the ammonium salt; the ethyl and methyl salts melt at 106° and 153° respectively. When the imide is dissolved in water (3 parts), heated at 80° on the water-bath with 7 per cent. potassium hypochlorite solution (10 parts) for some minutes, and, when cold, glacial acetic acid added to the solution, 1 : 4 : 3-amidotoluenesulphonic acid is precipitated. Commercial benzoic sulphinide ("saccharin"), not being a homogeneous compound, gives a mixture when similarly treated.

4 : 1 : 3-Sulphamidotoluic acid, $COOH{\cdot}C_6H_3Me{\cdot}SO_2NH_2$, is formed by boiling toluic sulphinide with water; it separates in faintly yellowish crystals, melts at 185°, and is sparingly soluble in the usual organic solvents. The *barium* salt crystallises with 2 mols. H_2O in colourless rosettes; the *ethyl* salt melts at 95°, and the *methyl* salt at 145°. On heating the acid at 210—220°, a sublimate of toluic sulphinide is obtained; whilst sulphoterephthalic acid, giving a potassium salt agreeing with that described by Hall and Remsen (Abstr., 1880, 257), is formed by oxidising it in acid solution, and terephthalic sulphinide on oxidising it in alkaline solution. The latter was found to melt at 284° instead of 297—299°, as stated by Noyes and Walker (Abstr., 1887, 728). When toluic sulphinide is twice evaporated on the water-bath with dilute hydrochloric acid, the ammonium salt, $COOH{\cdot}C_6H_3Me{\cdot}SO_3NH_4$ [4 : 3 : 1], is obtained; the corresponding acid (m. p. 181—182°) is described by Fittica (this Journal, 1874, 1166); the anhydride, $C_6H_3Me{<}{}^{CO}_{SO_2}{>}O$, melts at 70°. When the anhydride is dissolved in dry benzene and dry ammonia led through, an *ammonium* salt, $CONH_2{\cdot}C_6H_3Me{\cdot}SO_3NH_4$, is produced, and when the silver salt corresponding with this is dissolved in water, and a current of hydrogen sulphide passed through, the *acid*,

$$CONH_2{\cdot}C_6H_3Me{\cdot}SO_3H,$$

melting at 186°, is obtained.

Hydroxytoluic acid [OH : Me : COOH = 3 : 1 : 4] is formed on fusing the above-mentioned sulphoterephthalic acid with potash (3 parts) at 200—300°; it furnishes the *phenyl* salt (*homosalol*) on heating it with phenol and phosphorus oxychloride at 120°, which melts at 49°, and is hydrolysed by boiling alkali.

Methylxanthone [Me = 3], melting at 176°, is obtained from the

phenyl salt (homosalol) by Seifart's method; whilst dimethylxanthone, $C_6H_3^3Me<^{CO}_{-O-}>C_6H_3^3Me$, is produced by heating the hydroxytoluic acid with acetic anhydride; it melts at 166°. A. R. L.

Diamidosulphobenzide and its Derivatives. By C. Lauth (*Compt. rend.*, **114**, 1023—1024).—Diamidosulphobenzide is easily obtained in the following way. One part of sulphobenzide is dissolved in 3 parts of nitric acid of 48° B., and mixed with 5 parts of sulphuric acid. Heat is developed, and the temperature is maintained for half an hour. The crystalline mass which forms on cooling is washed with water, and the product recrystallised from alcohol until its melting point is 197°. The dinitrosulphobenzide is reduced by heating it with one and a half times its weight of tin, and three times its weight of hydrochloric acid, and the product is crystallised from alcohol or benzene. Diamidosulphobenzide forms rhomboïdal prisms, melting at 165—170°, and soluble in hot water, hot alcohol, or hot benzene, from all of which it crystallises on cooling.

Diamidosulphobenzide is not attacked by zinc and sulphuric acid. It readily yields diazo-derivatives, and these form the usual colouring matters with naphthols, amines, &c.

Tetrazo-colouring matters can also be formed in the usual way, but although these various colouring matters are of great beauty, they have no important advantages over the known dyes, and have very little affinity for cotton. C. H. B.

Dibenzylcarbinamine. By W. A. Noyes (*Amer. Chem. J.*, **14**, 225—230; compare Bamberger, Abstr., 1889, 892).—This base was obtained on reducing dibenzylketoxime with sodium and absolute alcohol. The alcoholic solution was distilled in a current of steam to drive off the alcohol, and the residual alkaline solution was diluted slightly, and allowed to cool, when the base, together with some unchanged oxime, separated as an oily liquid. The oil was freed from the alkaline solution, and converted into the hydrochloride by the addition of dilute hydrochloric acid. The solution was neutralised with soda, and then rendered slightly acid with acetic acid, whereby the unchanged oxime separated almost completely. The clear solution, on the addition of soda, yielded the base in an almost pure condition.

Dibenzylcarbinamine melts at 47°, and boils without decomposition at 330°; it has a strong alkaline reaction, and dissolves readily in alcohol, ether, and light petroleum, but is nearly insoluble in water. The *hydrochloride*, $C_{15}H_{15}{\cdot}NH_2,HCl$, separates in compact crystals, which group themselves in nodular aggregates, is moderately soluble in water, and melts at 205°. The *platinochloride*, $(C_{15}H_{15}{\cdot}NH_2)_2,H_2PtCl_6$, forms light-yellow, crystalline scales, which may be recrystallised from water without decomposition. The *nitrite*, $C_{15}H_{15}{\cdot}NH_2,HNO_2$, is precipitated in long, interwoven, slender needles when sodium nitrite is added to a concentrated solution of the hydrochloride. Its solution is perfectly stable at the ordinary temperature, but when a

concentrated solution is heated to the boiling point, nitrogen is evolved, and dibenzylcarbinol is formed as the chief product of the decomposition.

Dibenzylcarbinamine dibenzylcarbinaminethiocarbamate,

$$C_{15}H_{15}\cdot NH\cdot CSSH,C_{15}H_{15}\cdot NH_2,$$

is formed by the addition of dibenzylcarbinamine to carbon bisulphide. It melts at 141—143°, and simultaneously decomposes with evolution of hydrogen sulphide, and probable formation of the substituted thiocarbamine, $C_{15}H_{15}\cdot NH\cdot CS\cdot NH\cdot C_{15}H_{15}$.

Dibenzylcarbinol, $CH(CH_2Ph)_2\cdot OH$, obtained on heating the concentrated aqueous solution of the nitrite described above, is a viscous liquid, heavier than water, and of a pale-yellow colour, the colour being probably due to impurities. It boils at about 320—325°.

It appears from the above that the nitrite of dibenzylcarbinamine is more stable than the nitrites of most aliphatic amines. It has not, however, the same stability as the nitrites of the alicyclic amines, and the latter form a class distinct in their properties from all other amines at present known. G. T. M.

Formation of Aromatic Nitriles. By H. A. Michaël and J. Jeanprêtre (*Ber.*, **25**, 1615—1619).—Diphenylacetonitrile, $CHPh_2\cdot CN$, is prepared by heating phenylhydroxyacetonitrile (1 part) with benzene (2 parts) and phosphoric anhydride (1 part) on the water-bath for five hours; the product is washed with water, and the residue extracted repeatedly with benzene; the yield is one-third of the nitrile employed.

Toluene and phenylhydroxyacetonitrile yield in a similar manner tolylphenylacetonitrile, $C_6H_4Me\cdot CHPh\cdot CN$; it is desirable to employ stannic chloride instead of phosphoric anhydride as the dehydrating agent; the yield is 30 per cent. of the theoretical. The corresponding acid is obtained by heating the nitrile with concentrated alcoholic potash for six hours in a reflux apparatus.

Phenyltrimethylphenylacetonitrile, $C_6H_2Me_3\cdot CHPh\cdot CN$, is obtained by heating phenylhydroxyacetonitrile (3 parts), mesitylene (2 parts), and stannic chloride (1 part) for six hours on the water-bath; it crystallises from dilute alcohol and light petroleum in pale-yellow prisms, melts at 91°, and boils at 220—230° under a pressure of 40 mm.; the yield is 40 per cent. of the theoretical.

Naphthylphenylacetonitrile, $C_{10}H_7\cdot CHPh\cdot CN$, is prepared in a similar manner to the preceding compound, chloroform being employed as solvent; it crystallises from alcohol in colourless prisms, melts at 97°, and boils at 280° under a pressure of 45 mm.; the yield is 40—50 per cent., but is reduced to 10—12 per cent. by the substitution of phosphoric anhydride for the stannic chloride.

Naphthylphenylacetic acid, $C_{10}H_7\cdot CHPh\cdot COOH$, is obtained by heating the preceding compound with alcoholic potash, and is deposited from alcohol in colourless, prismatic crystals, melting at 141°. The *potassium salt* crystallises from water in colourless, lustrous plates. J. B. T.

Ammonium Bases of Phenylacridine. By A. Bernthsen (*Ber.*, **25**, 1746—1747).—The author has repeated his former experiments, and acknowledges the accuracy of Decker's statements (this vol., p. 881) respecting the product of the interaction of phenylacridine methiodide and sodium hydroxide. He finds that the methylphenylacridineammonium ethoxide which is obtained by crystallising the product from alcohol melts at 111°. A. R. L.

Azo- and Alkyl-compounds of Chrysaniline and the Colouring Matters derived from them. By A. Trillat and de Raczkowski (*Compt. rend.*, **114**, 1024—1026).—Diamidophenylacridine is easily prepared by dissolving commercial phosphine in a large quantity of acidified water, and pouring the liquid slowly, with constant agitation, into a dilute solution of sodium carbonate. The base separates as a yellow powder, and is easily diazotised in the usual way. The tetrazoic compound thus obtained readily combines with amines, phenols, &c. The compound obtained by the action of tetrazochrysaniline (1 mol.) on sodium naphtholdisulphonate (2 mols.) forms a green powder with a metallic lustre. It is insoluble in alcohol, but very soluble in water, forming a red solution. The colouring matters obtained with the phenolsulphonates vary in tint from rose to bright-red. Silk dyes readily, wool in an acid bath dyes badly, and non-mordanted cotton does not dye. Cotton mordanted with tannin acquires only a feeble tint. In solidity, brilliance, and resistance, the colours are inferior to those obtained with chrysaniline.

When chrysaniline is heated under pressure with methyl alcohol and methyl iodide, it yields brilliant crystals of the compound $C_{20}H_{12}Me_3N_3,2HI$, and the ethyl derivative can be obtained in a similar manner. The salts are only slightly soluble, and the solutions dye silk and cotton orange-red, but the colours are inferior to those given by the salts of chrysaniline.

Benzylchrysaniline is obtained by adding benzyl chloride to a warm alcoholic solution of chrysaniline. Sufficient lime to neutralise the hydrochloric acid is then added very gradually, and the product forms a red powder which has not yet been crystallised. It is soluble with difficulty even in dilute acids, and in tinctorial properties is very similar to the methyl and ethyl derivatives. C. H. B.

Desaurin. By W. Wachter (*Ber.*, **25**, 1727—1732).—By employing the following modification of V. Meyer and Oelkers' method of preparing deoxybenzoïn (Abstr., 1888, 703), larger quantities of material can be dealt with without minimising the yield. Benzoïn is heated on the water-bath with alcohol and granulated zinc in a reflux apparatus, a continuous current of hydrogen chloride being passed through meanwhile; 40 grams of deoxybenzoïn, sufficiently pure for direct use, is obtained from 50 grams of benzoïn. In the preparation of desaurin by V. Meyer and Wege's method (this vol., p. 340), the residue after distilling off the carbon bisulphide is well mixed with water, and washed by decantation to remove the alkali, and subsequently digested with alcohol and ether. When extracted with

ether until the latter is no longer coloured, it is sufficiently pure for use.

When desaurin is triturated with concentrated sulphuric acid (100 parts), and fuming nitric acid dropped in until a yellowish-brown solution is formed, and the latter poured into water, a yellow compound is obtained, giving, on analysis, numbers agreeing best with the formula $C_{13}H_9SN_3O_8$; whilst when desaurin (0·2 gram at most) is dissolved in fuming nitric acid (5 parts), a compound is produced resembling the first, but giving analytical values leading to the formula $C_{11}H_8SN_3O_{10}$. Both compounds melt with decomposition at 60°, and dissolve in concentrated sulphuric acid with a yellow colour; metanitrobenzoic acid is in each case simultaneously formed.

Triphenylguanidine (m. p. 127°) is obtained by heating desaurin in a reflux apparatus, for a day with aniline (10 parts); whilst on further heating and allowing the product to remain in the air, deoxybenzoïn, benzanilide, and benzile were also isolated. When desaurin is heated with hydriodic acid, or dry zinc-dust, stilbene is formed; whilst on fusing it with potash benzoic acid is produced.

A. R. L

Phenolphthaleïn Ethyl Ether. By E. Grande (*Chem. Centr.*, 1892, i, 380—381, from *Ann. Chim. Farm.*, **14**, 331—333).—The *ethyl ether of phenolphthaleïn*, $CO<\begin{matrix}C_6H_4\\O\end{matrix}>C<\begin{matrix}C_6H_4\cdot OEt,\\C_6H_4\cdot OH\end{matrix}$, is obtained by bringing phenol and phenetoïlphthaloylic acid together in presence of aluminium chloride. The ether forms a white, crystalline mass melting at 85°, and gives a red-violet coloration with alkalis. The ammonia solution decolorises more readily than that of phenolphthaleïn.

J. W. L.

Hydroxyxanthones. By S. v. Kostanecki and R. Rutishauser (*Ber.*, **25**, 1648—1653).—2-Hydroxyxanthone is obtained, together with diacetylquinol, when salicylic acid and quinol are distilled with acetic anhydride. The crude product is gently heated with concentrated sulphuric acid, and the solution poured into water, when the xanthone separates; it is extracted with warm, dilute sodium hydroxide, and reprecipitated from the solution by acid; it crystallises from aqueous alcohol in yellowish needles, and melts at 231°; the acetyl derivative forms white needles, and melts at 161°.

4-*Hydroxyxanthone* is formed, together with diacetylcatechol, when salicylic acid and catechol are distilled with acetic anhydride. The crude product is extracted with sodium hydroxide and the solution acidified, when the xanthone separates, and is purified by crystallisation from alcohol in the presence of animal charcoal; it forms small, white needles, and melts at 224°; the *sodium* salt crystallises from sodium chloride solution in citron-yellow needles; whilst the *acetyl* derivative crystallises from dilute alcohol in white, microscopic needles, and melts at 137—138°.

The so-called α- and β-hydroxyxanthones, obtained by condensing salicylic acid with resorcinol, contain the hydroxyl group in positions 1 or 3. The β-compound dissolves in concentrated sulphuric acid, forming an almost colourless solution with a bluish fluorescence,

and gives an acetyl derivative which crystallises from dilute alcohol in white, silky needles melting at 157—158°. A. R. L.

Bye-products in the Preparation of Hydroxyxanthones. By S. v. KOSTANECKI and S. SEIDMANN (*Ber.*, **25**, 1654—1658).—When the distillate obtained from salicylic acid, resorcinol, and acetic anhydride is boiled with alcohol, the xanthone and the two dihydroxyxanthones dissolve leaving a residue consisting of *dixanthone*, $C_{20}H_{10}O_4$; it crystallises from glacial acetic acid in bunches of needles, resembling xanthone, melts at 256°, and dissolves in concentrated sulphuric acid, forming a solution having a greenish fluorescence. The same dixanthone is obtained from both α- and β-hydroxyxanthone.

When the distillate from salicylic acid and phloroglucinol is boiled with alkali, 1 : 3-isoeuxanthone (Abstr., 1891, 1061) dissolves; the residue is collected and treated with hydrochloric acid, and consists of two isomeric hydroxydixanthones,

$$C_6H_4<\begin{matrix}O\\CO\end{matrix}>C_6H(OH)<\begin{matrix}O\\CO\end{matrix}>C_6H_4,$$

which may be separated as follows:—The substance is boiled with acetic anhydride and sodium acetate, and the product dissolved in boiling glacial acetic acid, when *β-hydroxydixanthone* separates on cooling, whilst *acetyl α-hydroxydixanthone* is obtained on adding water to the filtrate; the latter crystallises from alcohol in white needles, melts at 213°, and yields the *α-hydroxydixanthone* (m. p. 258°; this vol., p. 504) on boiling it with alkali, and treating the resulting sodium salt with acid; β-hydroxydixanthone crystallises from glacial acetic acid in yellow tables, melts at 326°, and remains unaltered after 24 hours treatment by the usual acetylation method. A. R. L.

1 : 4-Amidonaphthyl Ethyl Ether and some Derivatives. By P. HEERMANN (*J. pr. Chem.* [2], **45**, 545—553; compare Abstr., 1891, 1379).—1 : 4-Amidonaphthyl ethyl ether (this vol., p. 862) melts at 96°, and dissolves in the usual solvents, except water and strong hydrochloric acid; it sublimes and distils partially, and is diazotised with difficulty. The hydrochloride decomposes about 275°, and the *sulphate* melts about 240°. The *acetyl* derivative, $OEt{\cdot}C_{10}H_6{\cdot}NHAc$, is easily prepared by heating the ether with anhydrous sodium acetate, glacial acetic acid, and a couple of drops of acetic anhydride; it crystallises in silvery laminæ, melts at 192°, and dissolves easily in alcohol and glacial acetic acid, but sparingly in water; although, like phenacetine, undoubtedly antipyretic, it is not available on account of its poisonous effects. The *diacetyl* derivative, $OEt{\cdot}C_{10}H_6{\cdot}NAc_2$, obtained by the further action of acetic anhydride, crystallises in laminæ or prisms, melts at 138°, and is sparingly soluble in organic solvents and hardly at all soluble in water; ammonia or sodium hydroxide converts it into the acetyl derivative. The *benzoyl* derivative, prepared as usual from the hydrochloride, benzoic chloride, and sodium hydroxide, crystallises from alcohol in white needles, melts at 214—215°, and is very sparingly soluble in hot alcohol.

Attempts to nitrate the foregoing derivatives always resulted in the formation of α-naphthaquinone as a main product. A small quantity of *nitracetamidonaphthyl ethyl ether* [OEt : NO_2 : NHAc = 1 : 3 : 4] was, however, obtained; this crystallises in slender, yellow needles, melts at 221°, and is sparingly soluble in alcohol; its orientation was settled (1) by converting it into phthalic acid by nitric acid (sp. gr. 1·135) in a sealed tube at 180—200°, and (2) by reducing it with iron filings and hydrochloric acid, whereby *ethenyldiamidonaphthyl ethyl ether*, $OEt{\cdot}C_{10}H_5{<}^{N}_{NH}{>}CMe$, is obtained; the first experiment settles the ring in which the nitro-group is, whilst the second is evidence that the nitro-group is in the ortho-position to the acetylamido-group (compare this vol., pp. 837, 631 and 632). The last-mentioned compound crystallises in slender laminæ, melts at 179°, dissolves in alcohol and ether, and sparingly in hot water; its *bromine* derivative was prepared by brominating it in glacial acetic acid.

A. G. B.

Hydroxyquinones. By M. Kowalski (*Ber.*, **25**, 1658—1661).—Groves has already observed (this Journal, 1873, 210) that α-naphthaquinone dissolves in alkalis with the formation of a reddish-brown solution from which acids precipitate a red substance. When dilute aqueous alkali is added to finely-pulverised α-naphthaquinone, and the mixture shaken and exposed to the air for a time, the quinone dissolves, and, on boiling with barium carbonate mixed into a paste with water the precipitate obtained by adding acid to the solution and filtering while hot, a crystalline barium salt separates from the filtrate on cooling; this is purified, dissolved in water, and hydrochloric acid added to the solution, when hydroxy-α-naphthaquinone, amounting to 20 per cent. of the α-naphthaquinone employed, separates. By treating thymoquinone in a similar manner with alkali, and distilling the crude, acidified product in a current of steam, a mixture of hydroxy- and dihydroxy-thymoquinone passes over; the mixture is dissolved in alcohol and lead acetate added, when the lead salt of the dihydroxy-derivative separates, whilst the monhydroxy-compound remains in solution. Favourable results were not obtained with benzoquinone, and Woskresensky's melanic acid (*J. pr. Chem.*, **34**, 251) seems not to have the properties of a hydroxyquinone.

Whereas Kostanecki has shown (Abstr., 1889, 887) that hydroxy-α-naphthaquinone yields a quinoneoxime when treated with hydroxylamine, the author finds that when hydroxylamine hydrochloride is added to an alkaline solution of hydroxythymoquinone, and the solution is acidified with acetic acid, a flocculent precipitate separates; it crystallises from dilute alcohol in brown leaflets, melts at 190°, and is a *hydroxyamidothymoquinone*. It gives dihydroxythymoquinone on heating it with hydrochloric acid at 180°. Hydroxythymoquinone, therefore, behaves towards hydroxylamine in an analogous manner to pipitzahoic acid (see Anschütz and Leather, Trans., 1886, 721).

A. R. L.

Xanthones and Hydroxyxanthones of the Naphthalene and Quinoline Series. By S. v. Kostanecki (*Ber.*, **25**, 1640—1647).

—Dinaphthoxanthone, $C_{10}H_6<\overset{CO}{O-}>HC_{10}$, melting at 240°, and identical with the compound described by Bender (Abstr., 1881, 48), is obtained by distilling 1 : 2-naphtholcarboxylic acid with acetic anhydride; it dissolves in concentrated sulphuric acid, forming a faintly-yellow solution, having a greenish fluorescence. An isomeride melting at 216°, also described by Bender (Abstr., 1887, 38), is obtained from 2 : 1-naphtholcarboxylic acid (m. p. 157°); its solution in concentrated sulphuric acid is yellow, with a strong green fluorescence. 3 : 4-Naphtholcarboxylic acid (m. p. 216°), prepared from β-naphthol by Schmitt's method, yields a *xanthone* crystallising in yellow needles and melting at 241°, which dissolves in concentrated sulphuric acid to a brownish-yellow solution devoid of fluorescence.

Phenonaphthoxanthone, $C_6H_4<\overset{O-}{CO}>C_{10}H_6$, is obtained, together with xanthone and the above-mentioned dinaphthoxanthone, when a mixture of salicylic acid and 1 : 2-naphthocarboxylic acid is distilled with acetic anhydride; it is separated from the accompanying products by means of its more sparing solubility in alcohol, and melts at 155°; it is identical with Graebe and Früh's α-naphthophenone oxide (Abstr., 1887, 152), and its solution in concentrated sulphuric acid has a very strong green fluorescence. The isomeric compound, identical with Graebe and Früh's β-naphthophenone oxide (*loc. cit.*), is obtained in the same manner from both the above-mentioned β-naphtholcarboxylic acids. The two phenonaphthoxanthones are, however, produced in better yield by distilling α- or β-naphthol and salicylic acid with acetic anhydride.

1-Hydroxyquinoline does not give a xanthone on distillation with salicylic acid and acetic anhydride, but 4-hydroxyquinoline gives the *phenoquinolinoxanthone*, $C_6H_4<\overset{O-}{CO}>C_9NH_7$ [O : CO = 3 : 4 or 2 : 3]; it crystallises from alcohol in white needles, melts at 188°, and its solution in concentrated sulphuric acid has a faint green fluorescence; the *hydrochloride* forms white needles. Three isomeric hydroxyphenonaphthoxanthones are obtained from the three naphthocarboxylic acids mentioned above; better results are, however, obtained as follows:—Hydroxyphenonaphthoxanthone [O : CO : OH = 1 : 2 : 4′] is produced from salicylic acid and 1 : 4′-dihydroxynaphthalene; it crystallises from alcohol in yellow needles, melts at 270°, and its solution in concentrated sulphuric acid exhibits a greenish fluorescence; its sodium salt is orange-yellow, and sparingly soluble in water, and its *acetyl* derivative melts at 216°. *3′-Hydroxy-β-naphthoxanthone*, prepared from 2 : 2′-dihydroxynaphthalene, melts at 290°, forms a *sodium* salt crystallising in golden-yellow leaflets, and an *acetyl* derivative melting at 206°. A. R. L.

Xanthones and Hydroxyxanthones of the Naphthalene Series. By P. Bener (*Chem. Centr.*, 1892, i, 388; from *Schweiz. Wochenschr. Pharm.*, **30**, 29).—Of the naphtholcarboxylic acids, three are obtained commercially, one being prepared from α-naphthol, and two from β-naphthol. All three acids react with acetic anhydride, forming

naphthoxanthones, which differ from one another; also with salicylic acid, three different phenonaphthoxanthones are formed. By distilling the three carboxylic acids with dihydroxyphenols, hydroxyxanthones are formed. Those obtained from resorcinol form, with soda, intensely yellow-coloured, insoluble sodium salts. With salicylic acid, the dihydroxynaphthalenes form the corresponding dihydroxyxanthones, but the hydroxyl group is present in the naphthalene ring. The sodium salt of the hydroxyphenonaphthoxanthone, obtained from β-β_3-dihydroxynaphthalene, is sparingly soluble in water, and crystallises in golden-yellow needles. Finally, the three naphtholcarboxylic acids condense, with the dihydroxynaphthalenes, forming hydroxynaphthoxanthones. J. W. L.

Benzeneazo-α-naphthylglycocine. By A. Donner (*Ber.*, **25**, 1605—1610; compare Abstr., 1891, 191).—*Paranitrobenzeneazo-α-naphthylglycocine* is prepared by the action of a α-naphthylglycocine in hydrochloric acid solution on paranitrodiazobenzene chloride, and is almost insoluble in water, benzene, or carbon bisulphide; it melts at 125° with decomposition, has a greenish lustre, and dissolves in alcohol, acetone, or chloroform with a red colour; with sulphuric acid, a blue coloration is obtained which changes to red on dilution; in alcoholic solution, silk is dyed violet. The *hydrochloride*,

$$C_{18}H_{14}N_4O_4,HCl,$$

is a lustrous, green powder, melting at 178°, it is dichroic, and appears to be bluish-red in transmitted light.

The *potassium salt*, $3C_{18}H_{13}N_4O_4K,C_{18}H_{14}N_4O_4$, forms a dark-green powder, which melts at 224—226°, and imparts a brownish-red colour to silk.

Orthonitrobenzeneazo-α-naphthylglycocine resembles the para-compound and is obtained in a similar manner; it melts at 94—96° with decomposition, and exhibits dichroism. The *hydrochloride* melts at 147°. The *potassium salt*, $C_{18}H_{13}N_4O_4K,C_{18}H_{14}N_4O_4$, is brown and dissolves sparingly in water with a yellowish-red colour, which changes to red on the addition of acetic acid, and by adding hydrochloric acid to this solution the colour once more changes to violet.

Metanitrobenzeneazo-α-naphthylglycocine, prepared from metanitrodiazobenzene chloride and α-naphthylglycocine, is deposited in small, blue needles, which melt at 139° with evolution of gas; it is insoluble in water and in most other media, but dissolves in concentrated hydrochloric acid with a yellow colour, and in sulphuric acid with a deep-blue colour.

The *hydrochloride* is reddish-brown, and melts at 177°. The *potassium salt*, $C_{18}H_{13}N_4O_4K$, readily dissolves in water, and the solution becomes gelatinous on cooling; it crystallises in small, yellowish-brown needles which melt at 213—214°. J. B. T.

Terpenes and their Derivatives. By J. W. Brühl (*Ber.*, **25**, 1788—1796, 1796—813; compare this vol., pp. 200, 347, 624).—It has been recently suggested by Friedel (this vol., p. 500) that camphoric acid is a ketohydroxymonocarboxylic acid of the constitu-

tion $CHPr<^{CH_2\cdot CO}_{CH_2\cdot CH_2}>C(OH)\cdot COOH$; if this view is correct, it is to be presumed that camphoric acid would readily undergo oxidation, which is by no means the case. It would also be expected that the acid would be converted into a dihydroxy-compound on reduction and have numerous other properties which are not possessed by camphoric acid.

The author has investigated the behaviour of camphoric acid with sodium in boiling alcoholic and in boiling cumene solution; he finds that the acid is not reduced, although camphor, which, according to Friedel, has a constitution analogous to that of camphoric acid, is readily reduced under similar conditions. Attempts to reduce camphoric anhydride by treating it with sodium and borneol were also unsuccessful; under these conditions the anhydride is for the most part carbonised.

It was also proved that both camphoric acid and methyl camphorate do not interact with hydroxylamine or with phenylhydrazine under the conditions which are usually most favourable to the production of oximes and hydrazones.

When a neutral solution of sodium camphorate is treated with excess of sodium hydrogen sulphite, camphoric acid is liberated; camphoric acid does not reduce Fehling's solution even on boiling.

Ethyl camphorate is not acted on by phosphorus pentachloride at the ordinary temperature, nor by sodium and carbonic anhydride under the conditions previously described (this vol., p. 201) in the case of camphor.

When camphoric acid (2 mols.) is warmed with sodium carbonate (1 mol.), approximately half of the acid remains uncombined; both the ortho- and the allo-monalkyl salts of camphoric acid (see later) dissolve in sodium carbonate with liberation of carbonic anhydride, showing that both the hydroxy-groups in camphoric acid have an acid character and are not alcoholic or phenolic in function.

Picric acid does not yield an ethyl derivative on treatment with alcohol and hydrogen chloride; camphoric acid, under the same conditions, gives diethyl camphorate.

All the above facts go to show that Friedel's formula for camphoric acid is untenable; in the author's opinion the tetramethylene formula is, at present, the most probable and the one most securely based on facts.

In the following, the term "ortho-" is given to that alkyl group which is first introduced into the camphoric acid molecule; the second alkyl group is distinguished by the term "allo-."

Orthethyl allomethyl camphorate, $C_{10}H_{14}O_4EtMe$, is obtained when orthethyl hydrogen camphorate, prepared as previously described, is heated with methyl iodide and sodium methoxide at 100° for five hours. It is a yellowish, moderately mobile liquid, boils at 169·5° under a pressure of 33 mm., and at 276·5—275° under a pressure of 746 mm. Its sp. gr. is 1·0548, 20°/4°; 1·0569, 17·7°/4°. $\mathfrak{M}_a = 62{\cdot}49$, $\mathfrak{M}_{Na} = 62{\cdot}76$, $\mathfrak{M}_\gamma - \mathfrak{M}_a = 1{\cdot}47$ (compare this vol., p. 347), results which agree well with the calculated values for $C_{13}H_{22}O_2{<}O''_2$. Its specific rotatory power is $[\alpha]_D = 38{\cdot}43°$.

Orthomethyl alloethyl camphorate, prepared from orthomethyl hydrogen camphorate in like manner, is a yellowish liquid boiling at 175° under a pressure of 38 mm., and at 278° under a pressure of 747 mm.; its sp. gr. is 1·0467, 20°/4°; 1·0492, 17·1°/4°. $\mathfrak{M}_\alpha = 62{\cdot}77$, $\mathfrak{M}_{Na} = 63{\cdot}04$, $\mathfrak{M}_\gamma - \mathfrak{M}_\alpha = 1{\cdot}47$; $[\alpha]_D = 45{\cdot}49°$. It will be seen that practically the only difference between this ethereal salt and the compound just described is that the latter is more strongly dextrorotatory.

Alloethyl hydrogen camphorate, $C_{12}H_{20}O_4$, is obtained when orthomethyl alloethyl camphorate is mixed with a 16 per cent. solution of alcoholic potash (2 mols.), the mixture kept for 20 hours at the ordinary temperature, and then boiled for 15 minutes. It separates from light petroleum in transparent, rhombic, hemimorphic plates, $a : b : c = 1{\cdot}6184 : 1 : 3{\cdot}1877$, and melts at 57°. It is much more stable towards potash than the orthethyl hydrogen salt.

Diethyl camphorate, prepared by treating camphoric acid with alcohol and hydrogen chloride, has a specific rotatory power $[\alpha]_D = 36{\cdot}30°$, and is identical with the compound obtained by Friedel (*loc. cit.*) by the action of ethyl iodide on silver camphorate; on treatment with alcoholic potash under the conditions described above, it is converted into alloethyl hydrogen camphorate (m. p. 57°).

Allomethyl hydrogen camphorate, $C_{11}H_{18}O_4$, is formed when orthethyl allomethyl camphorate is boiled for 30 minutes with 16 per cent. alcoholic potash; it crystallises from hot water in long, colourless, spear-shaped forms, melts at 86—87°, and is readily soluble in alcohol, ether, light petroleum, &c.

Orthomethyl hydrogen camphorate, $C_{11}H_{18}O_4$, is obtained, together with dimethyl camphorate, when camphoric acid is treated with methyl alcohol and hydrogen chloride in the manner previously described (*Ber.*, **24**, 3409). It separates from hot water in well-defined, rhombic, hemihedric plates, $a : b : c = 0{\cdot}6316 : 1 : 1{\cdot}2870$, melts at 77—78°, and boils at 223° under a pressure of 21 mm.; it is readily soluble in ether, alcohol, light petroleum, &c., and is much less stable towards potash than the corresponding allomethyl salt.

Dimethyl camphorate, $C_{10}H_{14}O_4Me_2$, is a thick, almost colourless liquid boiling at 149·5° under a pressure of 11 mm., and at 264° under a pressure of 738 mm.; its sp. gr. is 1·0747, 20°/4°; 1·0774, 16·9°/4°. $\mathfrak{M}_\alpha = 58{\cdot}07$, $\mathfrak{M}_{Na} = 58{\cdot}32$, $\mathfrak{M}_\gamma - \mathfrak{M}_\alpha = 1{\cdot}37$, values which agree well with those calculated for $C_{12}H_{20}O_2{<}O''_2$; its specific rotatory power is $[\alpha]_D = 48{\cdot}16°$. When warmed for half an hour with dilute alcoholic potash, it is converted into allomethyl hydrogen camphorate (m. p. 86—87°).

Although the existence of the isomerides described above can be easily accounted for on the basis of Friedel's formula for camphoric acid (see above), there are certain facts which could not very well be explained in the same way, amongst others the formation of the dialkyl salts on treating the acid with hydrogen chloride and an alcohol, and the decomposition of both the isomeric monalkyl salts by dilute potash. Assuming that camphoric acid is methylpropyltetramethylenedicarboxylic acid, the existence of two series of alkyl hydrogen salts is also easily accounted for, because the two carboxy-

groups must be unequally strong. The fact that the alkyl group which is first introduced into the camphoric acid molecule is also the first to be expelled on hydrolysis, viewed in the light of the present dissociation hypothesis of electrolytes, is only what would be expected on *a priori* grounds; the orthoalkyl derivatives which are first formed are the less stable isomerides, and, therefore, when an orthoallo-salt is submitted to hydrolysis, the orthoalkyl group is the first to be eliminated.

The author has repeated Friedel's experiments on the titration of camphoric acid, employing either litmus, corallin, or phenolphthaleïn as indicator; the results show clearly that camphoric acid is a true dicarboxylic acid. In the case of litmus, the change of colour is not quite sharp, phenolphthaleïn being the best indicator; methyl-orange cannot be employed. F. S. K.

Constitution of Camphoric Acid. By F. Stohmann and C. Kleber (*J. pr. Chem.* [2], **45**, 475—499).—See this vol., p. 1040.

Eupatorin: The Active Principle of Eupatorium perfoliatum. By C. H. Shamel (*Amer. Chem. J.*, **14**, 224—225).—The dried *Eupatorium perfoliatum*, gathered at blooming time, was extracted with hot alcohol for several hours. The alcohol was distilled off, and the residue was treated with dilute hydrochloric acid, whereby a black, gummy mass separated, which was removed by filtration. The filtrate was neutralised with sodium carbonate and extracted with ether. On evaporation of the ethereal solution, the active principle was deposited either as a yellow, amorphous mass or as a yellow, microcrystalline powder. It contains no nitrogen, does not melt, but decomposes at 250°, is insoluble in water and in concentrated sulphuric and hydrochloric acids, but dissolves in dilute nitric acid forming a light-brown solution, which, when allowed to evaporate spontaneously, furnishes beautiful prisms and six-sided plates. These crystals of the *nitrate* are readily soluble in water, and the solution has a strong toxicological effect. They melt at 102—103°, and, when deprived of their water of crystallisation, give numbers, on analysis, which indicate that their formula is

$$C_{20}H_{25}O_{36},HNO_3.$$ G. T. M.

Action of Pyridine Bases on Sulphites. By G. Denigès (*Compt. rend.*, **114**, 1018—1020).—Pyridine bases do not form conjugated compounds with any metallic hydrogen sulphites, or compounds with any normal sulphites except those of zinc and cadmium.

30 grams of zinc sulphate is dissolved in 700 c.c. of water and mixed with 25 c.c. of pyridine and 60 c.c. of a solution of sodium hydrogen sulphite of sp. gr. 1·38. There is immediate formation of a white, crystalline precipitate, very slightly soluble in water. The product has the composition $ZnSO_3,C_5NH_5$, and forms quadratic needles that are optically negative. Other pyridic bases behave differently, and the precipitate consists simply of zinc sulphite, $2ZnSO_3 + 5H_2O$. Manganese sulphate also gives a precipitate of manganese sulphite alone. Possibly in these cases unstable pyridine

compounds are formed which dissociate with precipitation of the metallic sulphites.

When a 10 per cent. solution of cadmium nitrate is mixed with at least one-fifth of its volume of pyridine and one-fifth of its volume of sodium hydrogen sulphite solution of sp. gr. 1·38, there is no immediate precipitate; but on vigorous agitation and rubbing of the sides of the vessel with a glass rod, a mass of white, highly refractive, optically negative, quadratic needles gradually separates. This product has the composition $CdSO_3,C_5NH_5$, and dissociates somewhat easily into its proximate constituents. The compound can be obtained from warm solutions if the proportion of pyridine is doubled, but is less pure. If the proportion of pyridine is not increased, anhydrous cadmium sulphite alone separates. Even in the cold, if the proportion of pyridine is reduced to one-half, there is immediate formation of a very bulky precipitate of the composition $2CdSO_3 + 3H_2O$.

Zinc pyridine sulphite is much more stable than the cadmium compound. C. H. B.

Oxidation of Reduced Pyridine and Quinoline Bases. By J. Tafel (*Ber.*, **25**, 1619—1623).—Piperidine may be readily oxidised to pyridine by dissolving the pure base (2·5 grams) in 10 per cent. acetic acid (25 c.c.) and heating the solution with silver acetate (30 grams) in a sealed tube for four hours at 180°; the contents of the tube are treated with water, filtered, and the filtrate distilled over potash, the distillate, consisting of a mixture of pyridine and piperidine, is treated with sulphuric acid in slight excess and again distilled, the operation being repeated if needful; the piperidine remains behind as sulphate; the yield is 35 per cent. of pyridine and 25 per cent. of unaltered piperidine.

Conyrine may in a similar manner be obtained from coniine by heating it with the calculated quantity of silver acetate; the yield is 32·5 per cent., whilst 43—44 per cent. of unaltered coniine is recovered.

Tetrahydroquinoline (5 grams) is mixed with 5 parts of mercuric acetate, dissolved in an equal weight of water, and heated in a sealed tube for six hours at 150°; the product is distilled in a current of steam, and the oily distillate treated with hydrochloric acid and sodium nitrite. After remaining for some time, it is extracted with ether, the aqueous solution is rendered alkaline, and the quinoline separated by treatment with ether; the yield is 75 per cent. of the theoretical.

By the action of silver acetate on nicotine, a basic substance is obtained which is sparingly soluble in water, boils at 275°, and appears to be identical with a compound prepared by Cahours and Étard.

Quinoline is also formed by heating tetrahydroquinoline with mercuric oxide, silver nitrate, or silver oxide, but considerable quantities of resinous bye-products are produced. J. B. T.

1 : 4-Ethoxyacetamidoquinoline (Analgen). By G. N. Vis (*J. pr. Chem.* [2], **45**, 530—545).—The author found that the best method for preparing 1-ethoxyquinoline is that of O. Fischer and

Renouf (Abstr., 1883, 1146); he has prepared the *argentonitrate*, the *platinochloride*, the *ethiodide* (m. p. 168—169°), and the *ethochloride* (m. p. 125—127°), as also the *platinochloride* of the last named compound.

Dinitro-1-ethoxyquinoline is precipitated as microscopic, yellow needles when a mixture of 1-ethoxyquinoline (1 vol.) with nitric acid of sp. gr. 1·52 (4 vols.) is warmed on the water-bath and then poured into water (12 vols.); its melting point varies, being generally 275°. Its *platinochloride* (with 4 mols. H_2O) was prepared.

4 : 1-*Nitroethoxyquinoline* is obtained by diluting the filtrate from the dinitro-derivative with much water (3 litres for every 100 grams of original ethoxyquinoline), washing the precipitate, which separates after a time, with cold water, dissolving it in hot water, and adding ammonia, whereby the nitro-compound is thrown down in microscopic, yellow needles. It melts at 128°, is insoluble in water, but dissolves easily in hot alcohol and in acids, with which it forms salts which are stable in water. The *nitrate* crystallises in microscopic needles and in well formed prisms which melt at 100°; the *hydrochloride* forms white needles, and the *platinochloride* microscopic needles, which melt at 248° with decomposition; the *ethiodide* and the *methiodide* (m. p. 150°) were prepared.

1 : 4-*Hydroxynitroquinoline* is prepared by heating the nitroethoxyquinoline with concentrated hydrochloric acid at 180—190°. It crystallises in aggregates of needles, melts at 178°, and sublimes; hot alcohol dissolves it easily, water with difficulty. It is both basic and acid; the *hydrochloride* forms yellow needles which darken at 235°, and melt at 258°; the *ammonium* salt crystallises in brown needles and dissociates partially when heated, melting at 178°; the *lead*, *copper*, and *silver* salts, and the *platinochloride*, were prepared. The orientation of this hydroxynitroquinoline is settled (1) by the fact that it is the product of the oxidation of Lippmann's 4 : 1-nitrosohydroxyquinoline (Abstr., 1890, 265) by alkaline potassium ferricyanide, and (2) by its yielding 1 : 4-chloronitroquinoline (m. p. 145°) when heated with excess of phosphoric chloride.

1 : 4-*Ethoxyamidoquinoline*, prepared from the nitro-compound by the usual method, crystallises from hot water in beautiful, yellow laminæ (with 1 mol. H_2O) which melt at 70°; when anhydrous, it melts at 114°, and dissolves sparingly in hot water, ether, and benzene, not at all in light petroleum, but freely in alcohol and acids, forming with the latter salts which give intensely coloured solutions. The *monohydrochloride* forms rhombic laminæ and melts at 235°; the *platinochloride* (with $3\frac{1}{2}$ mols. H_2O) melts with decomposition at 255° the *dihydrochloride* was also prepared.

1 : 4-*Ethoxyacetamidoquinoline* is prepared from the amido-compound by heating it with glacial acetic acid and acetic anhydride for some minutes; it crystallises in white needles, melts at 155°, and dissolves easily in alcohol, and to the extent of about 0·7 per cent. in water at the ordinary temperature; in acids, it dissolves with the formation of salts. The *platinochloride* (with $2\frac{1}{2}$ mols. H_2O) begins to decompose at 215°, and is fully decomposed at 225°. Under the name of analgen, this compound is exhibited as an antineuralgic.

The author's experiments on dogs showed that 3 grams daily for several weeks produced no abnormal pathological conditions in the urine; a fatal subcutaneous dose for guinea pigs is $2\frac{1}{2}$—3 grams per kilo. of body weight; in man the molecule is either completely decomposed or the acetyl group only is eliminated, in which case 1 : 4-ethoxyamidoquinoline is to be recognised in the urine by the intense coloration imparted to it by hot acids. A. G. B.

Action of Sodium and Carbonic Anhydride on Antipyrine. By J. W. Brühl (*Ber.*, **25**, 1869—1875; compare this vol., p. 730).—Knorr and Taufkirch have shown (this vol., p. 708) that the substance described by the author as antipyrine alcohol is in reality β-methylamidocrotonanilide, NHMe·CMe:CH·CO·NHPh, and the author, on further investigation, has come to the same conclusion. To obtain the greatest yield of the additive sodium compound, 2 atoms of sodium and 2 mols. of carbonic anhydride are necessary, and it therefore appears probable that in the reaction the pyrazole ring is split between the two nitrogen atoms, the group COONa then combining with each of these atoms; by the action of water, the latter are replaced by hydrogen with formation of methylamidocrotonanilide.

The anilide is gradually decomposed by boiling water or alcohol, and more quickly by dilute acids with formation of acetoacetanilide; the sodium additive compound undergoes this reaction much more readily, the original product being converted by sulphuric acid at 0° into methylamine sulphate and acetoacetanilide.

β-Methylcrotonanilide is readily acted on by phenyl isocyanate and by benzoic chloride with formation of the *phenylcarbamido*-derivative. NHPh·CO·NMe·CMe:CH·CO·NHPh, and the *benzoyl* derivative,

NBzMe·CMe:CH·CO·NHPh,

respectively; the former crystallises in colourless needles melting at 173°, and the latter in small, white needles melting at 175°.

Attempts were made to convert the sodium additive derivative into an ethyl compound, but without success. It was found, further, that methylphenylpyrazole undergoes no change when treated with sodium and carbonic anhydride, which is in favour of Knorr's view that the constitution of the ring in this compound and in antipyrine is not identical. H. G. C.

Condensation of Orthamidobenzaldehyde. By J. Eliasberg and P. Friedländer (*Ber.*, **25**, 1752—1760).—*Orthamidobenzaldehydephenylhydrazone*, $NH_2·C_6H_4·CH:N_2HPh$, crystallises from alcohol in yellowish needles, and from benzene in small plates, melts at 222°, and turns brown on exposure to the air.

When sodium nitrite is carefully added to a solution of orthamidobenzaldehyde in well-cooled concentrated hydrochloric acid, *orthodiazobenzaldehyde* is formed; if the reddish-yellow solution is now treated with sodium hydrogen sulphite, the colour changes to light-yellow, and a crystalline compound, which melts at 146·5° and is probably identical with Fischer and Kuzel's indazole, is produced in small quantities.

A compound melting at 67·5°, which is very probably $\alpha\beta$-dimethylquinoline, is obtained when a few drops of dilute soda are added to a mixture of ethyl methyl ketone and a dilute aqueous solution of orthamidobenzaldehyde; it crystallises from ether in prisms, is volatile with steam, and dissolves freely in mineral acids and in the ordinary organic solvents. The *platinochloride*, $(C_{11}H_{11}N)_2,H_2PtCl_6$, crystallises in light-yellow needles.

Ethylmethylquinoline, prepared from diethyl ketone in like manner, crystallises from light petroleum in prisms, melts at 57°, is volatile with steam, and is only sparingly soluble in water; the *platinochloride*, $(C_{12}H_{13}N)_2,H_2PtCl_6$, separates from water in crystals.

Naphthylquinoline, $C_9NH_6{\cdot}C_{10}H_7$, can be obtained by heating a mixture of orthamidobenzaldehyde and naphthyl methyl ketone with alcoholic soda; the yield is quantitative. It separates from alcohol in colourless crystals, melts at 161°, and is only sparingly soluble in alcohol, and insoluble in water. The sparingly soluble *sulphate*, the *hydrochloride*, and the *chromate* crystallise in slender needles. The *platinochloride* crystallises from alcohol in microscopic, yellow needles, and is very sparingly soluble in water.

α-Methyl-β-acetylquinoline, $C_{12}NH_{11}O$, is formed by the condensation of orthamidobenzaldehyde and acetylacetone in aqueous solution in presence of soda at the ordinary temperature; it crystallises from light petroleum in long, thick needles, melts at 74°, and boils at 306°; it separates from dilute alcohol and from wet ether in crystals melting at 57·5°, which retain some of the solvent. The *hydrochloride* and the *sulphate* are readily soluble in water and alcohol, but the *chromate* is only sparingly soluble, and crystallises in long, yellow needles; the *platinochloride* has the composition $(C_{12}NH_{11}O)_2,H_2PtCl_6$. The *oxime*, $C_{12}NH_{11}{:}NOH$, crystallises from benzene in thick prisms, melts at 143°, and is soluble in soda. The *hydrazone*, $C_{12}NH_{11}{:}N_2HPh$, crystallises from benzene in almost colourless needles, melts at 130°, and quickly decomposes on exposure to the air; its *hydrochloride* forms small, red needles, and is only sparingly soluble in water.

A compound of the composition $C_{20}H_{16}N_2$, probably a dimethyldiquinoyline, is gradually deposited in crystals when a dilute aqueous solution of orthamidobenzaldehyde is treated with a slight excess of acetonylacetone and two drops of soda; it crystallises from dilute alcohol in lustrous stellate groups of needles which contain 2 mols. H_2O and melt at 104—105°; it loses its water at 105—110°, the anhydrous substance melting at 144°. It dissolves freely in hydrochloric acid and in sulphuric acid, but its chromate is only sparingly soluble, and forms forked crystals. The *platinochloride* has the composition $C_{20}H_{16}N_2,H_2PtCl_6$.

When orthamidobenzaldehyde is warmed with phloroglucinol and very dilute soda and the solution then acidified with acetic acid, a voluminous, red substance is precipitated; this product has both basic and acid properties, and is very sparingly soluble in almost all ordinary solvents. The *hydrochloride* crystallises in slender, yellow needles and is decomposed by water, in which it is only moderately easily soluble. The *platinochloride*, $(C_{13}H_9NO_2)_2,H_2PtCl_6$, crystallises from hot dilute hydrochloric acid in red needles containing 2 mols.

H_2O, which are expelled at 130—135°. The *dibenzoyl* derivative, $C_{13}H_7NO_2Bz_2$, prepared by shaking the condensation product with soda and benzoic chloride, crystallises from acetone in almost colourless needles, melts at 163°, and is soluble in acids and in the ordinary organic solvents, but insoluble in water and alkalis, and almost insoluble in light petroleum. The original condensation product is probably a dihydroxyacridine. F. S. K.

Azonium Compounds. By F. Kehrmann and J. Messinger (*Ber.*, **25**, 1627—1636; compare Abstr., 1891, 1109).—By the action of diacetyl on phenylorthophenylenediamine in alcoholic solution, a basic compound is obtained which has the formula $C_{16}H_{14}N_2$, crystallises in light yellow plates, and melts at 180—190°. The substance dissolves in sulphuric acid with a yellow colour, which disappears on dilution; it is very unstable when moist, being readily converted into a dark-red, insoluble powder, which is also formed by boiling the yellow compound with alcohol or treating it with ammonia.

On treatment of orthophenylenediamine hydrochloride with pyruvic acid in aqueous solution, *ketomethylphenyldihydrophenoquinoxaline*, $C_6H_4<\begin{matrix}N{:}CMe\\NPh—\end{matrix}>CO$, is formed; it crystallises from alcohol in short, thick plates, melts at 195°, and is insoluble in water, dilute acids, ammonia, or dilute alkalis; the compound dissolves sparingly in ether, glacial acetic acid, and benzene; with sulphuric acid or concentrated hydrochloric acid, it gives a greenish-yellow coloration.

Ketodimethyldihydroquinoxaline, $C_6H_4<\begin{matrix}N{:}CMe\\NMe—\end{matrix}>CO$, is prepared in a similar manner to the preceding compound, and is deposited from water at 50° in colourless, fibrous masses, which contain 2 mols. H_2O and melt at 63—64°; on heating at 100°, the anhydrous base is formed; this boils at 308°, crystallises on cooling, and melts at 87°.

Ketomethylethyldihydroquinoxaline, $C_6H_4<\begin{matrix}N{:}CMe\\NEt—\end{matrix}>CO$, is obtained in a similar manner to the preceding compound, which it closely resembles, being, however, somewhat more sparingly soluble; it crystallises from water with 2 mols. H_2O in almost colourless, transparent prisms melting at 77°; the anhydrous base melts at 96—97° and boils at 303°.

Ketomethylbenzyldihydroquinoxaline, $C_6H_4<\begin{matrix}N{:}CMe\\NBz—\end{matrix}>CO$, crystallises from dilute alcohol in small, slender, colourless, concentric needles, melts at 99—100°, and boils above 350° with partial decomposition; it is insoluble in water, but readily dissolves in ether or benzene.

In the formation of the preceding compounds, the pyruvic acid reacts with alkyl orthodiamines as a ketonic alcohol, whilst with simple orthodiamines it behaves as an orthodiketone.

By the action of benzile on methyl orthophenylenediamine hydrochloride in alcoholic solution, *diphenylmethylethophenazonium hydroxide*, $C_6H_4<\begin{matrix}N=CPh\\NMe(OH)\end{matrix}>CPh$, is formed, and is purified by means

of the nitrate; it is amorphous, and decomposes at 70°; the base is soluble in benzene with a yellow colour and a bluish-green fluorescence, and in alcohol with a yellowish-green fluorescence; with sulphuric acid, an orange-red coloration is produced, which changes to yellow on the addition of water. The *nitrate* crystallises with 3 mols. H_2O in large, yellow plates, which readily dissolve in water and are precipitated by the addition of nitric acid.

Diamidodiphenylamine, $C_6H_3(NH_2)_2{\cdot}NHPh$ [= 2 : 4 : 1], is prepared by the reduction of the corresponding nitro-derivative with tin and hydrochloric acid; on treatment with benzile in dilute alcoholic solution, *amidotriphenylethophenazonium hydroxide*,

$$NH_2{\cdot}C_6H_3{<}\begin{matrix}N = CPh\\ NPh(OH)\end{matrix}{>}CPh,$$

is produced; this is orange-yellow in colour, melts at 98°, and dissolves in water with a red colour; sulphuric acid produces a red coloration, which changes to green and then to red on dilution. The *ferrichloride* is deposited from alcohol in large, transparent, ruby plates.

By the action of benzile on triamidodiphenylamine,

$$C_6H_3(NH_2)_2{\cdot}NH{\cdot}C_6H_4{\cdot}NH_2$$

[$NH : NH_2 : NH_2 = 1 : 2 : 4$; $NH : NH_2 = 1 : 4$], a compound is formed which dissolves in water with a red colour; the solution in alcohol, ether, or benzene is yellowish-red, and shows no fluorescence; the base is amorphous, and has the formula

$$NH_2{\cdot}C_6H_3{<}\begin{matrix}N = CPh\\ N(C_6H_4{\cdot}NH_2)(OH)\end{matrix}{>}CPh;$$

it is related to the phenosafranines. The *hydrochloride*, $C_{26}H_{21}N_4Cl + H_2O$, crystallises from water in dark-red plates.

Dimethyltriamidodiphenylamine, $C_6H_3(NH_2)_2{\cdot}NH{\cdot}C_6H_4{\cdot}NMe_2$

[$NH : NMe_2 = 1 : 4$; $NH : NH_2 : NH_2 = 1 : 2 : 4$],

prepared from the corresponding dinitro-compound by reduction with tin and hydrochloric acid, also reacts with benzile; the resulting product crystallises readily, but has only feeble tinctorial powers.

J. B. T.

Action of Iodine on Thiobenzamide. By A. W. v. Hofmann and S. Gabriel (*Ber.*, **25**, 1578—1589).—By the action of iodine on thiobenzamide in alcoholic solution, a compound is formed which was believed to have the formula $S{<}\begin{matrix}CPh{:}N\\ CPh{:}N\end{matrix}$; the following results prove, however, that the substance is *dibenzenylazosulphime*, $S{<}\begin{matrix}N = CPh.\\ CPh{\cdot}N\end{matrix}$

Attempts to synthesise the substance by the action of sulphur on benzalazine at 200°, and of hydrazine on thiobenzoic anhydride, were unsuccessful. On heating the thio-derivative with a mixture of glacial acetic acid and fuming hydrochloric acid for seven hours at about 220°, benzoic acid, ammonia, and sulphur are formed.

The compound $C_{14}H_{14}N_2$, which is prepared by the reduction of the

thio-compound, melts at 77—78°, instead of 71°, as previously stated (*Ber.*, **2**, 645), and proves to be *benzylbenzenylamidine*,

$$CH_2Ph\cdot NH\cdot CPh{:}NH;$$

it may be prepared from benzimidoether and benzylamine; on heating with hydrochloric acid at 180°, it yields benzyl chloride, benzoic acid, and ammonia, whilst, on heating the compound alone, it decomposes into benzonitrile, benzylamine, and kyaphenine.

The authors suggest that the diazothioles prepared by Hector (compare Abstr., 1890, 526) are really azosulphimes analogous to the above compound; they have prepared a diazothiole from methylphenylthiocarbamide, which crystallises from dilute alcohol, melts at 94—95°, and, on reduction with zinc and hydrochloric acid, yields methylaniline and other compounds, which are being further investigated.

The substance described by Gebhard as piperidinethiocarbamide (m. p. 92°) proves to be *piperidine thiocyanate*. J. B. T.

So-called Dibenzimidine. By A. Pinner (*Ber.*, **25**, 1624—1627).—The author has recently prepared difurylmethylcyanidine from furfuramidine and acetic anhydride (this vol., p. 1006), and finds that, in properties, it closely resembles "dibenzimidine," formed by the interaction of benzamidine and acetic anhydride; he has, therefore, caused new analyses of the latter compound to be made, and finds it to be *dimethylphenylcyanidine*, $CMe\begin{matrix}<\\<\end{matrix}\begin{matrix}N\cdot CPh\\N{:}CPh\end{matrix}\begin{matrix}>\\>\end{matrix}N$; this substance has, however, already been obtained by Krafft and v. Hausen by the action of aluminium chloride on a mixture of benzonitrile and acetic chloride, and has been termed by them methyldiphenyl tricyanide.

"Ditolenylimidine" and "β-dinaphthenylimidine" are, therefore, really *ditolylmethylcyanidine*, $C_{18}H_{17}N_3$, and *dinaphthylmethylcyanidine*, $C_{24}H_{17}N_3$, respectively. J. B. T.

Pseudopelletierine. By G. Ciamician and P. Silber (*Ber.*, **25**, 1601—1604).—Tanret's observations on pseudopelletierine are confirmed; it crystallises from light petroleum in colourless, prismatic plates, and is unacted on by nitrous acid. The *aurochloride* is deposited from water in pale-yellow crystals; the *picrate* crystallises from water in long, lustrous, yellow needles; the *mercurochloride* is crystalline and colourless. A pale-yellow precipitate is formed with phosphomolybdic acid, and with iodine, in potassium iodide solution, pale-brown needles are deposited. The *cadmioiodide* crystallises from water in colourless groups of needles; the corresponding *bismuth* compound is deposited in scarlet crystals; the *mercuroiodide* crystallises in small, pale-yellow plates.

The *methiodide*, $C_9H_{15}NO,MeI$, crystallises from dilute alcohol in small, colourless cubes, which remain unmelted at 280°, and readily dissolve in water. On heating the compound with potash, dimethylamine is evolved, and an oily substance is formed, which may be purified by extraction with ether and distillation with steam in acid solution; it has an odour resembling that of acetophenone, and

yields a compound with phenylhydrazine acetate which melts at 76—77°. J. B. T.

Cystin and Cysteïn. By K. Brenzinger (*Zeit. physiol. Chem.*, **13**, 552—558).—Cysteïn reacts with mercuric chloride, forming the compound $C_6H_{14}N_2S_2O_4Hg_3Cl_6$. This salt, when treated with ethyl iodide, yields *ethylcysteïn*, $C_3H_6NO_2{\cdot}SEt$, which forms nacreous plates and melts at 226—228°. Like phenylcysteïn, ethylcysteïn, when boiled with sodium hydroxide and Fehling's solution, is decomposed into mercaptan and ammonia. It is, however, more slowly decomposed than phenylcysteïn. By the use of alkalis, and also by nitrous acid, pyruvic acid is not obtained from ethylcysteïn, as this acid is so easily further changed.

Cystin forms a benzoyl derivative which is decomposed by hydrochloric acid into benzoic acid and cystin. With isocyanic acid, cystin forms an uramido-acid, which with the loss of water, easily passes into the corresponding hydantoïn.

A number of unsuccessful efforts to form cystin synthetically were made. W. D. H.

Nitrated Silk. By L. Vignon and P. Sisley (*Bull. Soc. Chim.* [3], **6**, 898—904).—When silk is immersed in ordinary nitric acid (sp. gr. 1·133) at 45° for one minute, and is subsequently washed in water, it is coloured intensely yellow, and the colour is unaffected by exposure to air and light, whilst it is deepened by the action of dilute alkali solutions. Nitric acid free from nitrous compounds does not cause this coloration, which is found to vary in intensity directly with the amount of nitrous compounds present, and with the temperature and specific gravity of the acid used. The deepening of colour by alkaline solutions is independent of their causticity, whilst the silk increases in weight and takes up a certain amount of the base.

Silk treated with a mixture of hydrochloric acid and sodium nitrite is coloured pale yellow; the colour is rapidly browned on exposure to air and light, or by the action of boiling water or alcohol, whilst cold alkaline solutions turn it reddish-brown. Silk which has been subjected to the action of nitrous acid, or of nitric oxide, in an atmosphere of carbonic anhydride, and subsequently well washed, is colourless, but is coloured a stable yellow by nitric acid. Nitric peroxide colours silk yellow at once. Silk heated with nitrous acid, and then oxidised with potassium permanganate and hydrochloric acid, is coloured exactly as by nitric acid (impure), from which it seems that the yellow coloration is dependent on the action of nitrous compounds, and subsequently of an oxidising agent.

The yellow colour is discharged by acidified stannous and chromous chloride solutions. Analyses of the nitrated silk show that about 2 per cent. of nitrogen is fixed in the reaction, probably, primarily, as the nitroso-group, which the further action of the nitric acid converts into the nitro-group, a carboxyl group being displaced. The properties of the product somewhat resemble Mulder's xanthoproteïc acid, but this contains more carbon and less nitrogen, and results from a more intense action. Sulphuric acid dissolves ordinary silk

gradually to a slightly coloured solution, whereas nitrated silk is converted into a pale-yellow, viscid mass. Aqueous potash dissolves ordinary silk in the cold, and nitrated silk on heating; neither solution is precipitated by dilution with water, and both evolve ammonia when heated. Both varieties of silk are dissolved by hydrochloric acid and by zinc chloride solution.

Ammoniacal vapours are evolved on distillation of each variety, and a carbonaceous residue is left. On ignition, nitrated silk burns more rapidly than ordinary silk. T. G. N.

Physiological Chemistry.

Fibrin Ferment. By C. A. Pekelharing (*Verhand. d. Kon. Akad. van Wetenschappen te Amsterdam, Tweede Sectie*, Deel **1**, No. 3, 1892).—In continuation of a previous research (this vol., p. 87), it is now found that the substance described as the zymogen of fibrin ferment is not a globulin, but a nucleo-albumin. It can be precipitated from plasma by dilute acetic acid. It is convertible into fibrin ferment by union with calcium. Other nucleo-albumins, called tissue fibrinogens by Wooldridge, will similarly yield the ferment by treatment with calcium chloride. Caseïnogen, also a nucleo-albumin, although it hastens the coagulation of solutions of fibrinogen, to which a calcium salt has been added, will not, like the "tissue fibrinogens," produce intravascular coagulation. W. D. H.

Coagulation of Blood. By A. Griesbach (*Centralbl. med. Wiss.*, 1892, No. 27).—Although accepting, in the main, the conclusions of Arthus and Pagès, and of Pekelharing, as to the part played by calcium salts in coagulation, the author believes that he has succeeded in showing the important part played by the amœboid cells of the blood, by the fact that reagents, like weak osmic acid, which fix these cells, prevent the blood from coagulating.

Experimenting with crab's blood, the conclusion arrived at is, that the material liberated from the cells is a nucleo-albumin. This originates from the cytoplasm, not from the nucleus. Lilienfeld's (*Archiv Anat. u. Physiol.; physiol. Abth.*, 1892, 115) recent work, in which he considers that the nucleus plays an important part in the process, is adversely criticised. W. D. H.

Calcium Salts and Coagulation. By S. Ringer (*J. Physiol.*, **13**, 300—308).—In contradiction to what was stated in a former paper (Abstr., 1891, 954), it is now found that calcium salts do not promote the heat coagulation of albumin. They, however, cause heat coagulation of alkali-albumin. In some solutions they act partly by lessening the alkalinity of the solution. They have, however, a further and more powerful action, for they precipitate alkali-albumin in strongly alkaline solutions. Whether they act by diminishing the

solvent power of the menstruum, or whether they alter the proteïd molecule, and so render it less soluble, is not yet explained.

W. D. H.

Plasma and Serum. By A. E. Wright (*J. Pathol. and Bacteriol.*, **1**, 120—122).—It is pointed out that in fluids which form fibrin slowly, the fluid squeezed out by the contracting clot is not serum in the true sense of the word, but plasma, from which only part of the fibrin has been deposited. When the clotting is very perfect in blood, as when it is induced by the addition of calcium chloride, the clot is large and not very retractile, and the serum obtained is small in amount. By receiving blood into sodium oxalate solution, coagulation may be wholly or partially stopped, according to the amount of oxalate used. To obtain a maximum of serum, a small quantity of oxalate, which produces partial decalcification, should be used. Serum thus obtained is susceptible of a secondary coagulation, but may be freed from fibrinogen entirely by heating to 60° and filtering. W. D. H.

Formation of Sugar and Lactic Acid in the Organism. By T. Araki (*Zeit. physiol. Chem.*, **16**, 453—459; compare Abstr., 1891, 1125, 1392).—Exposure of animals to a low temperature leads to the appearance of albumin, sugar, and lactic acid in the urine. This fact is confirmed by the present research on rabbits and dogs placed for some hours in snow. It is believed that it is explicable on the ground of insufficient oxidation processes. The administration of veratrine to frogs leads to the appearance of sugar and lactic acid in their urine. W. D. H.

Retiform Tissue. By R. A. Young (*J. Physiol.*, **13**, 332—334).—The fibres of retiform tissue, which are in great measure concealed by the cells that surround them, resemble the white fibres of areolar tissue in histological characteristics, and, in fact, in many situations, are continuous with them. Mall, however, has recently stated that they do not yield gelatin on boiling. It is pointed out that Mall's methods are not free from error, and, moreover, it is shown that it is perfectly easy to obtain small but weighable quantities of gelatin from the structures (mucosa of intestine, lymphatic glands) where the tissue in question occurs, care being taken that all areolar tissue is removed. W. D. H.

Acids of Butter. By E. Koefoed (*Bied. Centr.*, **21**, 202—204; from *Bull. acad. roy. danoise*, 1891).—The filtered butter (785 grams) was saponified with a solution of sodium hydroxide (200 grams) in water (500 c.c.), and when cold treated with a mixture of strong sulphuric acid (300 grams) and water (500 c.c.), and digested on a water-bath; it was then heated on a sand-bath until the solution was complete. This was done in a reflux apparatus and in an atmosphere of carbonic anhydride. The amount of fatty acids was 720 grams. After extraction with ether and evaporation of the ether, a residue was left consisting almost entirely of butyric acid (6 grams). The aqueous residue was distilled under 30 mm. pressure, and the distil-

late (54 grams) fractionally precipitated with silver nitrate; it was found to contain caprylic and caproic acids. The residue in the flask was dissolved in alcohol (500 c.c.) and recrystallised from alcohol. A crystalline mass (100 grams) was obtained. The united alcoholic filtrates were treated with acetic acid (30 grams) and an alcoholic solution containing lead acetate (600 grams). The precipitate was dried, and afterwards treated with hot hydrochloric acid and the free fatty acids added to a crystalline substance already obtained; the weight was now 314 grams. When distilled under 30 mm. pressure, the acids were found to be palmitic, myristic, lauric, and capric acids.

The filtrates from the lead precipitate were made alkaline with ammonia, when a semi-fluid lead salt separated, most probably containing oxyoleïc acid. The filtrate from this salt contained oleïc acid and a monobasic acid of the formula $C_{15}H_{28}O_4$.

The results show that the acids of butter, other than $C_nH_{2n}O_2$, are oleïc acid, an acid $C_{15}H_{28}O_4$, and, most probably, Gottlieb's oxyoleïc acid, $C_{29}H_{54}O_5$ (?). The acids of the composition $C_nH_{2n}O_4$ are normal constituents of butter, and include all those from C_4 to C_{18} which have an even number of carbon atoms. The acids $C_nH_{2n}O_2$ occur in the following percentage amounts:—Stearic acid, 2; palmitic acid, 28; myristic acid, 22; lauric acid, 8; capric acid, 2; caprylic acid, 0·5; caproic acid, 2; butyric acid, 1·5. N. H. M.

Presence of Myristic Acid in Ox Gall. By Lassar-Cohn (*Ber.*, **25**, 1829—1835).—In the preparation of cholic acid by the Mylius method (*Ber.*, **25**, 803), the foreign acids are separated by precipitation with barium chloride in a solution containing 20 per cent. of alcohol. The author has examined the mixed barium salts so obtained, and has separated from them myristic, palmitic, stearic, and oleïc acids. He finds about 0·004 per cent. of myristic acid calculated on the bile taken.

The following method of separation was employed:—The mixed barium salts from 100 litres of bile are boiled with water (6 litres) and sodium carbonate (400 grams). The mixture is filtered, the filtrate evaporated to dryness, the residue extracted with alcohol, and the alcoholic solution evaporated to dryness. 100 litres of bile yield 480 grams of the crude sodium salts. The sodium salts are dissolved in water and fractionally precipitated with barium acetate. The successive separations of barium salts are severally decomposed with hydrochloric acid, and the fatty acid separated from the aqueous liquor, dissolved in 90 per cent. alcohol, a little ammonia added, and fractionally precipitated with a 10 per cent. solution of magnesium acetate. The magnesium salts are decomposed with hydrochloric acid, and the free fatty acid crystallised from 70 per cent. alcohol.

The pure magnesium salt of the myristic acid may be more readily obtained by completely precipitating the crude sodium salts with barium acetate, decomposing the mixed barium salts with hydrochloric acid, and fractionally precipitating the acids so obtained with magnesium acetate in alcoholic solution. E. C. R.

Phosphoric Acid in Urine. By P. Carles (*J. Pharm.*, [5], **25**, 497—499).—In normal cases the urine in the bladder is distinctly acid in its reaction. This is due to gastric juice, sarcolactic acid from the muscles, hippuric, oxalic, and especially uric acid, formed by the oxidation of proteïds and the waste of organic tissue. Lastly, according to Bouchard, phosphoglyceric acid is also a factor of this acidity. These acids naturally occur in combination in the blood, and if they exist free in the bladder, this is due to their secretion by the kidney. Phosphoric acid is in the same case; it is found as a normal or alkaline phosphate in the vessels. There is no evidence that it is separated by the kidney in any other form; but in the bladder its base is shared amongst the other acids, and the phosphates become normal or acid. When the urine is voided, it comes under the influence of bacilli which transform urea, traces of proteïds, creatine, and other nitrogenous products into ammonium carbonate, and the phosphate gradually becomes basic again. In special cases the urine may become alkaline in the bladder. In analysing urine, it appears most rational to estimate the total phosphoric acid, noting the reaction of the urine at the moment of its secretion, or at the latest when delivered. J. T.

Catechol in the Urine of Hydrophobic Rabbits. By R. Moscatelli (*Virchow's Archiv*, **128**, 181).—In rabbits, during the hydrophobic state induced by the injection of Pasteur's material, it appears that the urine always contains a considerable quantity of catechol. W. D. H.

Action of Quinone and of Quinone Derivatives. By O. Schulz (*Chem. Centr.*, 1892, i, 413—414; from *Inaug. Diss. Rostock*).—The investigations deal with the action of quinone and some of its derivatives on animal substances and on the living organism.

With both α- and β-glutin, quinone appears to unite after several days to form strongly coloured substances, and a similar compound is obtained from egg-albumin, whilst in each case some quinol was formed. With hæmoglobin, quinone is first reduced to quinol, whilst the hæmoglobin is changed to methæmoglobin; some of the hæmoglobin is at the same time decomposed, and a quinonehæmatin compound is precipitated; the latter is a very permanent substance.

Subcutaneously injected, quinone does not act as a poison in every case. But when taken internally as a 0·6 per cent. solution in sodium chloride, the nervous system is immediately strongly affected. The intestinal canal is also strongly affected, food cannot be digested for some days, and is vomited unchanged again. The urine on the second day is dark brownish-green coloured, and contains both albumin and quinolglycuronic acid.

With fresh blood, trichloro- and tetrachloro-quinone cause the formation of methæmoglobin; the trichloroquinone acting the more energetically of the two.

With dogs, given in doses of 1·5—2·0 grams, both trichloro- and tetrachloroquinone cause violent purging, and in the case of tetrachloroquinone, tetrachloroquinol combined with glycuronic acid and

sulphuric acid is probably formed. They both act less energetically than quinone, probably because they are insoluble in water.

Dichlorodihydroxyquinone is partly reduced, probably to dichlorotetrahydroxybenzene; its action is principally on the kidneys.

Dichloramidohydroxyquinone is reduced first to dichlorodihydroxyquinone, and then further to dichlorotetrahydroxybenzene.

Toluquinone acts in like manner to quinone. J. W. L.

Soluble Naphthol Compound. By Stackler (*Compt. rend.*, **114**, 1027—1028).—The calcium salt of β-naphthol-α-sulphonic acid is obtained in a state of purity if care is taken to start with pure β-naphthol and to isolate perfectly the α- and β-modifications. It has been called *asaprol*. It is neutral, very soluble in water or alcohol, is not affected by heat, is not an irritant, is but slightly poisonous, and is tolerated by the digestive organs and passes rapidly into the urine.

Doses of 160 milligrams per kilo. of body weight injected every two or three days for 15 days, or doses of 66 milligrams injected every three or four hours for two months are well supported by rabbits. A dose of 285 milligrams per kilo. injected all at once is injurious, and 500 miligrams caused death in a few hours. In comparatively large quantity the compound prevents the development of various bacteria, including those of Asiatic cholera, typhoid, and anthrax.

When administered by ingestion to man in doses of 1 to 4 grains, it does not reduce, but often increases, the quantity of urine. It acts as an antipyretic in various infectious diseases, in typhoid, and in acute polyarticular rheumatism, and rapidly reduces the latter.

C. H. B.

Thymolglycuronic Acid. By F. Blum (*Zeit. physiol. Chem.*, **16**, 514—524).—If thymol is administered to human beings, it leaves the body partly by the fæces as such, and partly by the urine, appearing there as the chromogen of a green pigment, as thymolsulphuric acid, as thymolglycuronic acid, and as thymolquinolsulphuric acid. W. D. H.

Putrefaction of Milk. By H. Winternitz (*Zeit. physiol. Chem.*, **16**, 460—487).—Milk retards the putrefaction of proteïds, and thus causes delay in the appearance of the first and last product of the decomposition of the proteïd molecule. This is due to the lactose it contains, and is independent of the formation of lactic acid. In this way milk exercises considerable influence on putrefaction processes in the intestine leading to a lessening of ethereal hydrogen sulphates in the urine; it thus diminishes the splitting of proteïd food into products which are of no value, and are perhaps harmful to the organism.

The so-called "bromine-substance" is detectable in the intestine below the entrance of the pancreatic duct. In the upper intestinal regions it is the result of the ferment activity of pancreatin; in the lower regions, perhaps, of putrefaction organisms also. It is not present in the large intestine nor in the fæces, and, therefore, like

leucine and tyrosine, which originate simultaneously with it, it undergoes complete absorption by the walls of the small intestine.

W. D. H.

Treatment of Chlorosis by Hydrochloric Acid. By W. H. White (*Guy's Hosp. Rep.*, **48**, 1891).—Bunge, Hamburger, and others state that inorganic compounds of iron are not absorbed by the alimentary canal. Bunge considers that the utility of iron salts in chlorosis is due to their forming an insoluble sulphide, and this allows the organic iron compounds (hæmatogen) to be absorbed, which would otherwise be destroyed by putrefaction processes. Bunge also lays stress on the antiseptic action of gastric juice. In the present communication, five cases are described, which were, therefore, treated with hydrochloric acid. The results were negative, or at any rate the improvement was not greater than occurs when the treatment is simply rest with good food. They, however, rapidly improved on treatment with sulphate of iron. W. D. H.

A Case of Anthrax in Man. By S. Martin (*J. Pathol. and Bacteriol.*, **1**, 21—25).—In previous papers on anthrax in animals, the chemical poisons found in the blood and organs, or obtained by artificial cultures, were albumose and an alkaloïd. In the present case, which occurred in a man, the blood contained the base, but no albumose; the spleen contained albumoses, but only a trace of the base. The amount of the poisons compared with that found in sheep was small. Considerable quantities of both poisons were found in the urine of the present case. The kidney is thus the channel by which excretion of the poison takes place. There was also glycosuria, but this may have been an accidental concomitant.

W. D. H.

Mucin in Myxœdema. By W. D. Halliburton (*J. Pathol. and Bacteriol.*, **1**, 90—94).—It is believed that the term myxœdema is a misnomer, and that the increase of mucin found in certain cases is explicable on the ground of simple overgrowth of connective tissues. When these tissues are first formed they are always richer in mucin due to the preponderance of matrix than when later this is replaced by fibrous (colligenous) or adipose deposit. In the present paper, the estimation of mucin in the organs of a case of myxœdema is described; special attention is directed to the skin, which contained less mucin than normal, and the heart (especially the heart tendons of calves), which contained considerable excess. A number of normal hearts (human and sheep) were also examined. The following conclusions are drawn:—

1. The percentage of mucin in normal heart tendons, although variable, as in most connective tissues, is on the average greater than in other connective tissues, *e.g.*, skin = 0·38; skeletal tendons = 0·5.

The average percentage of mucin in normal human heart tendons is rather less than in those of the sheep, 1·03 : 1·35.

The percentage of mucin (1·7 to 1·9) in the cardiac tendons of myxœdematous patients, leaving out of account the present case, in all instances exceeds the normal mean of that in non-myxœdematous cases, but not very greatly.

4. It is most important to notice that such slight excess of mucin is by no means pathognomonic of myxœdema, as in three out of the nine non-myxœdematous hearts examined there was a similar slight excess in the percentage of mucin.

5. The present case, however, stands apart from these, the increase in mucin (5·2 per cent.) being so marked that there can be no mistake that we have here to deal with a condition of myxœdema, using the word in its literal sense. W. D. H.

Hæmatoporphyrinuria. By Sobernheim (*Deut. Med. Woch.*, June 16, 1892).—This condition, although often a result of sulphonal poisoning, is not invariably so. In a case of a boy suffering from enteric fever, which is described, it occurred, although no sulphonal was given. It probably originated from a hæmatoma in the rectus abdominis muscle. W. D. H.

Cobra Poison. By A. A. Kauthack (*J. Physiol.*, **13**, 272—299).—The albumose of cobra poison is best separated by extracting with water poison which had remained for a week under absolute alcohol. In its properties it closely resembles proto-albumose. Alkaloïds are absent. Light apparently does not impair its activity; very prolonged boiling is necessary for this purpose. Chlorine-water destroys its poisonous action completely, so also do caustic alkalis. Iodine trichloride, potassium permanganate, phenol, and pancreatin are less powerful in destroying the poison. Silver nitrate, mercuric chloride, lauric acid, and alcohol destroy the toxic properties of the poison by precipitating the albumose. Ammona, citric acid, and pepsin have very little anti-toxic power.

Experiments to establish immunity against cobra poison were wholly inefficient. Strychnine, recently recommended as a cure, is neither a chemical nor a physiological antidote.

Cobra poison does not contain a globulin, although certain observers have stated that it does. A substance with some of the properties of globulin and of heteroalbumose may be obtained after certain manipulations. It is regarded as an artificial product.

W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

The Absorption and Digestion of Fat Oils by Plants. By R. H. Schmidt (*Bied. Centr.*, 1892, 113—115).—Experiments with moulds (*Aspergillus, Penicillium, Mucor, Phycomyces*) growing in a solution containing grape sugar, almond oil, pure oleïc acid, and glycerol, in addition to the necessary inorganic salts, show that neutral fats as well as free oleïc acid are able to support the growth, but not glycerol. Fungoïd growths flourish in glycerol and the fatty acids, but absorb the first the most rapidly. Addition of ammonium tartrate increases the rapidity of growth. Solid fats and fatty acids serve well as food for such growths, and mosses absorb oil and oleïc

acid, and oil is also absorbed by many germinating plants, such as peas. E. W. P.

Development of Cereals. By A. Hébert (*Ann. Agron.*, **18**, 33—47).—The author discusses the results arrived at by Dehérain, Nantier, Meyer, and himself in the light of recent experiments and analyses, and especially bearing in mind the discovery of vasculose in the straw by Dehérain and straw gum by himself (compare Abstr., 1891, 1285). The first period of cereal growth after germination is that of root activity, during which nitrogenous compounds and minerals are largely assimilated. Tables are given showing the progressive fall in the percentages of these substances as the crop matures, and similar statements are true of tannins, gums, and vegetable acids precipitable by lead acetate. The next period is that of leaf assimilation, during which cellulose, vasculose, and straw gum are largely produced. Starch is *not* produced during this first period of assimilation, what was entered as such in older analyses being all carbohydrates producing a reducing sugar by hydrolysis with acids. The third period, or ripening, commences as soon as the stem has acquired strength and rigidity enough to support the spike, and consists in the assimilation of soluble carbohydrates in the leaves for transformation into starch in the grain. There is no store or reserve of starch or starch-producing material in the stem, as formerly supposed, and the production of starch and consequent value of the crop depend on leaf action still going on, and therefore on weather permitting of maintenance of vitality in the leaves. So it happens that in seasons characterised by a very dry July, like 1889 in contrast to 1888, for example, the normal quantity of starch cannot be formed, the crop is very short in weight, whilst the proteïds, having been stored up at an earlier period, are in excessive proportion to the starch in the grain. Thus in 1888 Paturel found in square-head Scholey wheat 12·63 per cent. proteïds to 77·20 per cent. starch; in 1889, 15·53. The yields were per hectare:—

	1888.	1889.	
Grain.....	34·84	29·22	metric quintals.
Proteïds	438·9	447·0	kilos.
Starch	2689·0	1808·0	„

In 1891 comparative analyses of the wheat plant were made at different dates, which can be summarised thus:—

Proteïds and Carbohydrates per hectare in Goldendrop Wheat, 1891.

	June 16.	July 3.	July 21.	Aug. 3.	Aug. 19.
	kilos.	kilos.	kilos.	kilos.	kilos.
Dry matter.....	183·97	3718·3	4922·8	4381·1	3832·2
Proteïds	140·2	216·9	?	267·2	220·0
Reducing sugars	48·9	103·6	130·8	39·3	30·8
Dextrin.....	9·9	62·9	192·1	85·0	53·7
Straw gum reckoned as xylose	334·4	792·2	1246·8	1852·5	1729·8
Starch.....	none	48·5	517·7	665·1	452·1

Between August 3, the date of full maturity, and August 19 there was a serious loss of weight, especially of starch, the quantities being—

	August 3.	August 19.
Weight of grain per hectare ..	895·7	756·7 kilos.
Proteïds in grain	114·7	94·6 ,,
Starch in grain	582·2	432·3 ,,

The yield of grain, about 9 metric quintals per hectare, was singularly small, and the ratio of proteïds to starch large, as in 1889. On August 13 this ratio was 12·81 per cent. : 65·30 per cent.; on August 19, 12·50 per cent. : 57·14 per cent. Small yields of cereals are therefore due to lack of starch, and this is due to want of leaf action during the later stages of growth. J. M. H. M.

Presence and Function of Phloroglucinol in Plants. By T. Waage (*Ann. Agron.*, **18**, 204—206).—In the course of his researches, the author has examined 185 different plants. The reagent used is a solution of vanillin in hydrochloric acid (0·005 to 4·0), a drop of which will detect 0·001 milligram of phloroglucinol. Gymnosperms are rich in phloroglucinol, monocotyledons and gamopetalous plants poor, and polypetalous plants have none. Woody plants contain more than herbaceous: the distribution is almost the same in roots, stem, and leaves. When cells containing this substance divide, the new cells contain it also, so that in making a longitudinal section one meets with lines or chains of these cells. As to the mode of formation of this substance, see a former paper by the same author (Abstr., 1891, 605).

According to the author, phloroglucinol is an accessory or bye product of plant growth. It is interesting as entering into the molecule of very complex substances, such as phloroglucides and phloroglucosides; it takes part in the formation of phlobaphenes and colouring matters such as anthocyanin and erythrophyll. Plants which contain tannin contain phloroglucinol also. J. M. H. M.

The Proteïds of the Oat Kernel. By T. B. Osborne (*Amer. Chem. J.*, **14**, 212—224; compare Abstr., 1891, 1285 and 1390).—The proteïds of the oat undergo great change in contact with water or sodium chloride solution. The substance extracted by direct treatment of ground oats with alcohol differs much in properties and composition from that extracted by alcohol after the ground oats have for some time had contact with water or with sodium chloride solution.

Direct treatment of the ground oats with sodium carbonate solution yields the same globulin as that obtained by direct treatment with hot sodium chloride solution, but different to that obtained by direct treatment with cold sodium chloride solution. Sodium carbonate solution also extracts another proteïd—the same as that yielded by direct extraction with dilute potash-lye—which again is distinct in composition from that obtained after the oats have been in contact with water. It is remarkable that all these transformations are the

result of the use of water or sodium chloride solution as contrasted with the use of alcohol, alkali, or heat, three agents known to suspend or destroy fermentation. The fact that the globulin extracted after treatment of the ground oats with alcohol has the same composition as that obtained by direct treatment with sodium chloride would indicate that alcohol temporarily suspends a fermentation which is induced by water or solutions of neutral salts.

It is probable that the primary proteïds originally contained in the oat kernel are the three following substances:—

	Alcohol-soluble proteïd.	Salt-soluble proteïd or globulin.	Alkali-soluble proteïd.
Carbon.....	53·01	52·19	53·56
Hydrogen....	6·91	7·00	7·09
Nitrogen	16·43	17·86	16·20
Sulphur.....	2·26	0·65	0·90
Oxygen.....	21·39	22·30	22·25
	100·00	10·000	100·00

Of the above substances, the alcohol-soluble proteïd forms about 1·25 per cent., the globulin about 1·5 per cent., and the alkali-soluble proteïd the remainder of the proteïds contained in the oat kernel, with the possible exception of extremely small amounts of proteose and acid-albumin. The latter two substances are very probably the results of change occurring during extraction, but the evidence on this point is not conclusive.

The three other proteïds, obtained evidently by the alteration of the primary proteïds, and probably through fermentation when the ground oats are subjected to contact with water or solutions of neutral salts, are as follows:—

	Alcohol-soluble proteïd.	Salt-soluble proteïd or globulin.	Alkali-soluble proteïd.
Carbon.....	53·70	52·34	52·49
Hydrogen....	7·00	7·21	7·10
Nitrogen	15·71	16·88	17·11
Sulphur.....	1·78	0·88	0·80
Oxygen.....	21·83	22·69	22·50
	100·00	100·00	100·00

G. T. M.

Influence of the Nature of the Soil on Vegetation. By J. Raulin (*Compt. rend.*, **114**, 1119—1122).—The author has grown potatoes (Early Rose) in the following kinds of soil:—A. A mixture of equal parts of B, C, D, and E. B. Turf soil containing 64 per cent. of humus. C. Soil containing 73 per cent. of limestone. D. Earth containing 47 per cent. of clay. E. Soil containing 75 per cent. of sand. One half (0·5 are) of each patch was treated with a quantity of chemical manure containing phosphoric acid (0·80 kilos.), nitrogen (0·70 kilos.) as ammonium sulphate, potassium (0·80 kilos.),

as sulphate, and plaster (1 kilo.). The potatoes were planted in April, 1891, and gathered in September. The weights of the resulting tubers are given in the following table :—

	With manure.	Without manure.
A.	203·40 kilos. per are.	148·00 kilos. per are.
B.	146·10 ,, ,,	57·90 ,, ,,
C.	125·90 ,, ,,	72·60 ,, ,,
D.	73·10 ,, ,,	25·00 ,, ,,
E.	43·50 ,, ,,	10·60 ,, ,,

Twelve lots of nine tubers each were planted in soils of widely varying composition in order to discover the soil of maximum fertility. This seems to consist of 2·64 per cent. of clay, 23·30 per cent. of humus, 67·20 per cent. of sand, and 6·86 per cent. of limestone.

W. J. P.

Pea-Nut. By L. P. Brown (*Exper. Stat. Record*, **3**, No. 1, 1891).—The yield of pea-nuts in the United States amounted to 2,700,000 bushels in 1889, and was still greater in 1890. Two kinds are cultivated, the white and the red; the latter ripen better because earlier. The following tables show (1) the percentage composition of nuts grown in Tennessee, and (2) the percentage composition of the ash :—

	Water per cent.	Per cent. in dry substance.				
		Proteïn.	Crude fat.	Non-nitrogenous extract.	Crude fibre.	Crude ash.
Pea-nut kernels (1888)	3·87	28·65	49·35	17·23	2·37	2·40
,, ,, (1889)	4·86	27·07	48·60	19·30	2·52	2·51
,, meal	10·64	49·63	6·33	31·67	6·06	6·31
,, hulls (1)	8·81	6·42	1·34	17·14	73·07	2·03
,, ,, (2)....	7·81	7·94	2·17	13·36	65·81	3·63
,, hay	7·83	11·75	1·84	46·95	22·11	17·04

	P_2O_5.	K_2O.	Na_2O.	CaO.	MgO.	SO_3.	SiO_2.
Kernels	38·90	39·85	2·85	4·11	1·83	10·40	0·20
Hulls	5·63	31·78	7·85	27·01	12·60	8·89	4·13
Leaves	4·85	15·00	7·26	50·77	10·89	3·57	5·60
Stalks	5·34	19·23	7·52	25·80	19·67	7·42	9·93

Good crops can only be obtained with carefully selected seeds, well tilled soil, and careful treatment of the plants. The pea-nut belongs to the richest of all known foods, the meal being equal to cotton-seed meal, but the hulls have only a slight manurial value. Pea-nut hay

is a nutritious food, and is a very suitable substitute for clover hay, especially for cattle. According to experiments in Virginia and North Carolina, a moderate amount of artificial manures and farmyard manure seem to be profitable; a manure containing about 15 lbs. of nitrogen, 10 lbs. of soluble phosphoric acid, and 20 lbs. of potash per acre might be tried. N. H. M.

Fermentations of Farmyard Manure. By T. Schloesing (*Ann. Agron.*, **18**, 5—18).—In that part of a manure heap to which air has access, as the temperature is gradually raised by aërobic fermentations, a purely chemical oxidation sets in, which goes on with increased rapidity after the temperature has risen high enough to stop the fermentations by killing the microbes. Experiments in flasks traversed by a current of air at different temperatures, with cattle manure sterilised in some instances, and unsterilised or inoculated with bacteria in others, show that the bacterial fermentations go on with great energy, even at 72·5°, since at that temperature they yield more than 15 times the quantity of carbonic anhydride proceeding from purely chemical oxidation. At 81° the bacterial oxidation ceases, and the inoculated or unsterilised manure yields no more carbonic anhydride than the sterilised manure. No combustible gas is contained in the products of oxidation.

Similar experiments on the anaërobic fermentations of farmyard manure, made by substituting a current of nitrogen gas for air, show that methane is found amongst the products only at temperatures below 66°, and in presence of organisms. The carbonic anhydride produced is much less than in presence of air, but is greater when organisms are present than in the sterilised samples, and in the latter case is greater at 66° than at 52°. The following statistics of the fermentation at 52° in an atmosphere of carbonic anhydride of 124·4 grams of fresh manure may be cited as typical. The fermentation was allowed to proceed for two months, and furnished nearly 9 litres of gas; the maximum evolution of gas, 16·3 c.c. per hour, being on the sixth day. The manure underwent no change in colour or in odour, and the straws were yellow and lustrous as at the commencement, but more friable. A little hydrogen (15·8 c.c.) was found in the first tube of gases, but the remainder consisted of 4217·5 c.c. CO_2 and 4577·4 c.c. CH_4, containing together 4·720 grams C, 6·033 grams O, and 0·819 gram H. The loss suffered by the manure was determined by analysis of the fresh manure and the residue, after drying in a vacuum, to be as follows:—

	Carbon.	Hydrogen.	Oxygen.	Nitrogen.	Minerals.
Before fermentation	12·67	1·653	10·70	0·453	3·69
After fermentation	7·92	1·125	7·08	0·392	3·79
Loss	4·75	0·528	3·70	0·061	0·10 (gain)

No nitrogen gas was found amongst the products of fermentation. The 61 milligrams of nitrogen lost were converted into ammonia,

actual determinations of ammonia showing an excess of 51·7 milligrams N in the products over that in the fresh material, due allowance being made for ammonia extracted by the vacuum drying. Thus there is considerable production of ammonia during the anaërobic fermentation, which ammonia is not fixed in organic combinations.

The oxygen contained in the carbonic anhydride evolved exceeds by 2·333 grams that contained in the dry, fresh manure; and the hydrogen in the methane, ammonia, and free hydrogen produced exceeds by 0·305 gram that in the fresh, dry manure. It follows from these excesses, and from the proportion of the oxygen to hydrogen (nearly 8 : 1), that water enters into the reaction and furnishes the oxygen and hydrogen necessary for the formation of carbonic anhydride and ammonia. J. M. H. M.

Analytical Chemistry.

Improved Pipette for Gas Absorptions. By A. H. Gill (*Amer. Chem. J.*, **14**, 231).—The author employs a simple gas pipette fitted with a rubber bag, after the manner of the pipettes in the Orsat gas apparatus, as furnished by Muencke. This is found to preserve the reagents better, and to have the additional advantage of being much more easily filled and handled. G. T. M.

Preservation of Solutions of Metaphenylenediamine and its Employment as a Reagent. By G. Denigès (*J. Pharm.* [5], **25**, 591—594).—Two grams of the hydrochloride is dissolved in 100 c.c. of ammonia in a stoppered flask, and 5 grams of powdered animal black is added to the solution. The whole is well shaken three or four times at intervals of an hour, and allowed to remain until next day. If the solution is not quite colourless, the shaking is repeated. The liquid can be preserved indefinitely over the animal black, and the portion withdrawn for use by means of a pipette can easily be seen to be quite limpid. To detect hydrogen peroxide, 1—2 c.c. of the reagent is heated to boiling during one minute with some drops of the liquid to be tested; in presence of the peroxide, a blue colour, more or less intense, is produced, which is perceptible after two minutes' boiling if the liquid only contains a few milligrams per litre. This coloration becomes red on the addition of soda or potash. For the detection of nitrous acid, 5 drops of the reagent is placed in a tube with 5 c.c. of 10 per cent. sulphuric acid; the mixture should not be coloured; 100 c.c. of the water to be tested is added, and heated to boiling during five minutes; a yellow colour, apparent on looking down the tube, indicates the presence of nitrites. The nitrites may be quantitatively estimated by adding nitrite solution of known strength to distilled water and comparing as in nesslerising.

J. T.

Estimation of Hydrochloric Acid in the Contents of the Stomach. By G. Langermann (*Virchow's Archiv*, **128**, 408—412). It is pointed out that most of the methods at present used for estimating the hydrochloric acid in the gastric juice only take into account the free acid; the chlorine, combined with proteïd matter, and the metallic chlorides should also be estimated in order to obtain more trustworthy results. The method recommended is that of Hayen and Winter (*Du chimisme stomacal*, Paris, 1891). Into each of three vessels, *a*, *b*, and *c*, 5 c.c. of the material to be tested is placed; excess of concentrated solution of sodium carbonate is added to *a*, and all three are evaporated on the water-bath; *b* is heated an hour longer to drive off all free hydrochloric acid; sodium carbonate is then added, and it is once more concentrated; *c* is dried, and then incinerated, and thus all combined (*i.e.*, with proteïd) chlorine is given off. All three are raised for a few minutes to a red heat when dry. The residues are taken up with distilled water, a little nitric acid is added, and the mixture boiled to drive off carbonic anhydride. The chlorine is estimated in each in the usual way by silver nitrate; *a* gives the total chlorine; *b* gives the fixed and combined chlorine; *c* gives the fixed chlorine only. The difference between *a* and *b* gives the value of the free hydrochloric acid. The difference between *b* and *c* gives the value of the combined hydrochloric acid.

W. D. H.

Estimation of Nitrogen. By V. Edwards (*Chem. News*, **65**, 241, 265). The use of an iron flask for the distillation operation in the Kjeldahl method is recommended as rapid, convenient, and advantageous; a small correction, however, has to be made owing to the absorption of a small amount of nitrogen from the air by the moist iron oxide, which is given off as ammonia during the distillation. For nitrates, the author employs the iron flask and 10 grams of zinc grains, 5 grams of iron filings, 0·5 gram of the nitrate, 100 c.c. of 30 per cent. solution of potash, and 50 c.c. of water; after an hour 100 c.c. more water is added, and the ammonia distilled off into standard acid. Blank determinations are first made with the iron filings for the reason stated above.

D. A. L.

Report on Phosphoric Acid. By W. B. Burney (*Chem. News*, **65**, 229—230; from the *Proc. of the 7th Annual Convention of the Association of Official Agricultural Chemists, Washington*).—In the first part of this report attention is drawn to Hundeshagen's molybdate method (Abstr., 1889, 762), to Hughes's suggestions relating to the analysis of concentrated superphosphates (*ibid.*, 1245), to Reitmair's results and views on the citrate method (*ibid.*, 1890, 416; 1891, 243), to the estimation of phosphoric acid in slags (*ibid.*, 1890, 290), and to its estimation in the presence of silica (*ibid.*, 1890, 825). During the past year, a sample of superphosphate and a sample each of a fertiliser with and without added organic matter were sent to various chemists for analysis; the results show great discrepancies, which are largely attributed to the carelessness of the operator, but, nevertheless, it is recommended that the American official method should be modified so that the washing of the phos-

phate, when estimating the water-soluble phosphoric acid, should be continued until there is 300 c.c. of filtrate, and in the estimation of the citrate-soluble phosphoric acid the solution should be filtered hot and rapidly, and the residue washed twice with half strength ammonium citrate and then with water at the ordinary temperature; whilst for the estimation of the total phosphoric acid, it is recommended to prepare the solution by the magnesium nitrate method when cotton-seed meal or other organic matter is present, but in other cases by the 30 c.c. nitric and hydrochloric acid method.

D. A. L.

Differences in the Determination of Reverted Phosphoric Acid by the American Official Method of Analysis. By C. Gibson (*Chem. News*, **65**, 209—210, 221).—Having observed serious discrepancies in the results obtained by different chemists in the estimation of reverted phosphate by the American official method, the author has investigated the matter, and observed that the variation in the character of the ammonium citrate solution could account for the differences. He prepared a solution of ammonium citrate, A, in careful accordance with the official directions, neutralising with ammonia until the solution showed no reaction with either very delicate red or blue litmus or with rosolic acid. Another solution, B, was made by adding ammonia to a portion of solution A until it showed a very faint alkalinity with delicate red litmus-paper, whilst a third, and strongly alkaline solution, C, was prepared according to the directions of H. Joulie. In the first series of experiments, calcium phosphate (South Carolina rock phosphate) was digested with each of these solutions, following the official directions with solutions A and B, and Joulie's directions with C, but digesting only half an hour and at the ordinary temperature. The second series of experiments was conducted in exactly the same way as the first, only the digestion was continued for one hour. The third and fourth series were the same as the first and second, but with aluminium instead of calcium phosphate. The mean numbers obtained with each of these solutions for the percentage of reverted phosphoric acid in the 1st and 2nd, and for the percentage of available phosphoric acid in the 3rd and 4th series of experiments, were as follows:—

	A.	B.	C.
1st series.....	0·913	0·746	0·746
2nd „	1·846	0·761	0·760
3rd „	19·77	31·66	26·91
4th „	31·39	34·73	34·73

But the aluminium phosphate could be almost completely dissolved in all three solutions, if sufficient time was given. The results show the efficiency of the alkaline ammonium citrate solution for the separation of soluble from insoluble calcium phosphate, but they also show that the American official method is not always to be trusted. Therefore the author suggests that that method should be modified to permit of ammonia being added to the ammonium citrate solution until a faint alkalinity is perceptible with red litmus-paper, and of

the digestion being continued for one hour at 65°. He further suggests that Joulie's ammonium citrate method, with or without the modification of weighing as magnesium pyrophosphate, should be recognised as an alternative method. D. A. L.

Action of Ammonium Citrate on High Grade Aluminium Phosphate. By H. A. Huston (*Chem. News*, **65**, 241—242; from the *Proc. of the 7th Annual Convention of the Association of Official Agricultural Chemists, Washington*).—To study the action of ammonium citrate on aluminium phosphate, a sample containing 45·46 per cent. of phosphoric acid, none being water-soluble, and 7·25 per cent. of silica, was submitted to various experiments by varying the conditions used in the American official method for available phosphoric acid. Firstly, the effect of increasing the time of digestion was tried, and 2 grams of phosphate digested with 100 c.c. of citrate solution yielded up 21·24 per cent. in half an hour, 31·70 in one hour, 36·92 in two hours, 40·80 in four hours, 41·00 in six hours, and 42·70 per cent. in 10 hours; secondly, employing the same quantities of materials and digesting for half an hour at different temperatures, it was found that 2·18 per cent. was dissolved at 40°, 5·52 at 50°, 21·24 at 65°, 32·90 at 75°, and 39·52 at 85°; whilst digesting different quantities of phosphate with 100 c.c. citrate solution for half an hour at 65° showed that 16·80 per cent. was dissolved from 0·5 gram, 18·26 from 1 gram, 21·24 from 2 grams, 23·22 from 3 grams, 24·66 from 5 grams, and 28·64 from 10 grams of the phosphate; this point is being further investigated. The next experiments were made to ascertain the effect of acidity or alkalinity. 2 grams of phosphate digested for 30 minutes with 100 c.c. of citrate solution, to which was added either citric acid or ammonia; the former decreased, the latter increased, the solvent action of the citrate solution (compare preceding abstract). D. A. L.

Estimation of Silicic Acid in Fluorides. By W. Hampe (*Chem. Zeit.*, **15**, 1521—1522).—The estimation of silicic acid in minerals containing fluorine is generally done by Berzelius' method, which is also the one employed by Rose, or by a process devised by Fresenius and Hintz. Berzelius fuses the substance with sodium carbonate, and estimates the silicic acid both in the aqueous solution and the insoluble residue. Fresenius and Hintz analyse cryolite by heating this fluoride with sulphuric acid in a leaden tube while passing a current of dried air, and condense the mixture of hydrogen fluoride and silicon fluoride in ammonia. The contents of the leaden tube are exhausted with water, and any insoluble residue fused with soda and further treated similarly to Berzelius' plan.

When dealing with a substance containing both silicic acid and fluorine, which is not readily decomposed by fusion with sodium carbonate or potassium hydroxide, or sulphuric acid, neither of these methods are applicable, although Fresenius' process might be improved by fusing the substance with potassium hydrogen sulphate in a platinum apparatus, which, however, would be difficult to construct.

The author has now devised a process for the estimation of silicic acid in strongly ignited alumina containing fluorine, which will be useful to those engaged in the aluminium industry. 1 gram of the substance is fused in a platinum crucible with 10 grams of dehydrated borax, which must be, of course, free from silicic acid. The bottom of the crucible is well lined with borax, the intimate mixture of the sample and borax is introduced, the whole well covered with borax, and then fused for about 20 minutes. The fused mass is poured into a platinum dish, the crucible in which the fusion took place is also put inside this, and the mass is then treated with hot water until it is completely disintegrated, which generally takes two days. 5 grams of ammonium chloride is now added, and the mixture heated until the smell of ammonia has nearly disappeared. The precipitate, consisting of silicic acid and aluminium borate, or, perhaps, calcium borate, is filtered through a platinum or india-rubber funnel and well washed. The filtrate is evaporated to dryness in a platinum basin, the residue is heated to a little above 100°, and then taken up with water. The liquid, which has an acid reaction, is rendered alkaline with ammonium carbonate, and the precipitate filtered off as before. The filtrate is again and again evaporated, &c., until no further precipitate is obtained. The joint precipitates are burnt with the filters, and the ash fused with four times the weight of sodium carbonate. From the alkali silicate so obtained, the silicic acid is separated in the usual way by evaporation with hydrochloric acid.

The author has confirmed the accuracy of the process by experimenting with made up mixtures of silicic acid and a large excess of pure cryolite. The silicic acid was practically recovered.

L. DE K.

Estimation of Silicic Acid in Fluorides. By F. REGELSBERGER (*Chem. Zeit.*, **15**, 1714).—The author has analysed a sample of calcined alumina containing 4·8 per cent. of fluorine and 0·73 per cent. of silica, according to the method described by Hampe (preceding abstract), and recovered 0·70 per cent. of silica. The process seems, therefore, well suited for technical purposes, although it is a pity that it takes such a long time.

The author will, in due course, publish the details of a process on which he is still engaged, and which is a modification of the one proposed by Fresenius and Hintz. The operation is conducted in a specially constructed platinum apparatus, and aims at a correct estimation not only of the silica, but also of the fluorine.

L. DE K.

Estimation of Carbonic Oxide by means of Cuprous Chloride. By L. DE ST. MARTIN (*Compt. rend.*, **114**, 1006—1009).—The solution of carbonic oxide in cuprous chloride solution seems to take place in accordance with the law of Dalton and the absorption formulæ of Bunsen. One treatment with the liquid does not remove the whole of the carbonic oxide from a gaseous mixture containing a small proportion of it. If, however, the gaseous mixture is agitated with four successive quantities of the cuprous chloride solution, and

the latter is boiled in a vacuum, and the expelled gas analysed, 98·1—98·4 per cent. of the carbonic oxide actually present is obtained. The treatment of the gas with cuprous chloride is effected in a flask provided with a stopcock, the copper solution being pumped out of this flask into the vessel in which it is to be boiled. The latter vessel is also provided with a stopcock, and the two are connected by india-rubber tube whilst the solution is being transferred.

C. H. B.

Volumetric Estimations and Analytical Separations by means of Potassium Ferrocyanides and Ferricyanides. By C. Luckow (*Chem. Zeit.*, **15**, 1491—1492).—The use of potassium ferrocyanide is somewhat restricted, as so many ferrocyanides are insoluble. For instance, in the important titration of zinc ores (compare this vol., p. 915), it is necessary to remove iron and other metals before titrating with the ferrocyanide. The author, therefore, has made an attempt to introduce ferricyanide instead. Having prepared a potassium ferricyanide free from sulphates and chlorides, it was found that this substance may be used in acid solutions even in presence of ferric oxide, and that no precipitates are formed in presence of mercuric, lead, manganous, uranic, and stannic salts.

These different properties of the two double iron cyanides render it possible to estimate some metals volumetrically in presence of one another, or to estimate them gravimetrically, as most ferricyanides may be readily filtered off. Zinc, for instance, may be accurately estimated either volumetrically or gravimetrically by means of potassium ferricyanide in its acetic or nitric acid solution, even in presence of lead, which may then be titrated in the filtrate with potassium ferrocyanide. Tin may be titrated by means of potassium ferrocyanide, even in presence of arsenic and antimonic acids, after the solution has been evaporated with oxalic acid and then mixed with a little dilute sulphuric acid.

The ferricyanide solution should give no coloration with a uranium solution, and no precipitate with a lead salt. If it should do so, it must be mixed with a little chlorine-water, and the salt recrystallised.

When titrating with ferrocyanide or ferricyanide, it is not possible to add the indicator straight to the liquid under examination, but use must be made of test papers. The indicator used must show either the disappearance of the last trace of the metal or else the slightest excess of the precipitant.

The author prepares his test papers as follows:—A moderately thick but dense and smooth kind of filter paper is cut into strips of 30 cm. in length and 15 cm. in width. Across the narrow part, at a distance of about 4 cm. from each other, stripes are made with the solution of the indicator, which consists of cupric acetate or ferric chloride, if ferrocyanide is used; or cobaltous or ferrous sulphate, when a ferricyanide is employed in the titration. When both are used in succession, a mixture of ferrous ammonium sulphate and ferric chloride is used.

When apparently enough of the ferrocyanide or ferricyanide solution has been added to the solution to be tested, a little drop is taken out

by means of a thin pencil and put at a distance of about 5 mm. from one of the stripes, when the reaction will make its appearance if the least excess is present.

The author recommends using for the titration not more than 30 c.c. of liquid containing about 0·15 gram of metal. The process may also be performed by adding an excess of the reagent and titrating this in the usual manner. But amongst the ferrocyanides, there are some, like the zinc, nickel, and cobalt salts, which are very difficult to filter off, although this presents no difficulty with mercury, lead, and silver salts. The ferricyanides are, however, more easily filterable. L. DE K.

Detection of Normal Carbonate in Hydrogen Alkali Carbonates. By G. PATEIN (*J. Pharm.* [5], **25**, 448—451).—Magnesium sulphate does not precipitate a normal alkali carbonate in presence of a hydrogen alkali carbonate if the normal salt does not exceed the amount required to form sesquicarbonate. A better reagent than magnesium sulphate is found in a very dilute alcoholic solution of phenolphthaleïn. A solution of pure hydrogen alkali carbonate gives no colour with phenolphthaleïn, or only a very faint rose tint disappearing on the addition of a few drops of carbonic anhydride solution; but the presence of traces of normal carbonate causes a decided rose coloration, which only disappears on the addition of an amount of carbonic anhydride solution proportional to the amount of normal salt present. J. T.

Analysis of Aluminium. By A. E. HUNT, G. H. CLAPP, and J. O. HANDY (*Chem. News*, **65**, 223—225, 235).—For general purposes, a solution containing 35 per cent. of hydrochloric acid, sp. gr. 1·2, is regarded as the best solvent for aluminium. To determine the total silicon, combined and uncombined, about a gram of the metal is dissolved in 15 c.c. of nitric acid, sp. gr. 1·2, and 2 c.c. of concentrated hydrochloric acid, another 2 c.c. of the latter acid being added as soon as the first action has ceased; when the metal is dissolved, the solution is stirred and rapidly evaporated with 20 c.c. of concentrated sulphuric acid until fumes of sulphuric anhydride appear, but is not allowed to spirt. When cool, 75 c.c. of water and 10 c.c. of hydrochloric acid are stirred in, the whole boiled for five minutes, the precipitate of silica and silicon collected, well washed with hydrochloric acid and water, ignited, fused with 3 grams of sodium carbonate or fusion mixture, decomposed with hydrochloric acid, then evaporated with 15 c.c. of strong sulphuric acid until sulphuric fumes appear. When cool, it is boiled up with 75 c.c. of water and 10 c.c. of hydrochloric acid, filtered, thoroughly washed, ignited, and weighed. The dehydration with sulphuric acid is not only rapid and efficient, but also leaves the silica in good condition for filtering. When both the combined and uncombined silicon are required, and inasmuch as the latter is found to suffer slight oxidation on ignition, any method involving burning filter papers becomes inadmissible for collection of the silicon and silica, and a platinum filter is suggested for the purpose, upon which the precipitate could be well washed, dried at 80°,

weighed, treated with sulphuric and hydrofluoric acids, washed, dried at 80°, and weighed again; the difference between the two weighings would be due to the silica, the last weighing being the silicon; the ratio of the silica to the silicon is less the more total silicon the metal contains.

For determining iron and copper, the hydrochloric acid solution is diluted, boiled, and saturated with hydrogen sulphide. The copper is determined by any method in the precipitate, the iron by titration with dichromate in the solution after boiling down. To estimate the aluminium, the hydrochloric acid solution, containing 1 gram dissolved in 25 c.c., is saturated, after the removal of the silicon and silica, with hydrogen sulphide, the copper sulphide filtered off and washed, the hydrogen sulphide boiled from the filtrate, and the solution made up to 250 c.c.; 50 c.c. of this is then nearly neutralised with ammonia, treated with 5 c.c. of a saturated solution of ammonium phosphate and 10 c.c. of a saturated solution of sodium thiosulphate, and boiled until free from sulphurous acid. After filtering and washing with hot water, the aluminium phosphate is redissolved in dilute hydrochloric acid, reprecipitated with slight excess of ammonia and a little ammonium phosphate, boiled, filtered, washed, ignited, and weighed as $AlPO_4$.

For the estimation of chromium in chromium-aluminium alloy, 2 grams of the alloy is treated with 50 c.c. of 10 per cent. potassium hydroxide solution, and the solution ultimately boiled and filtered. The residue, after burning the filter paper, is treated with 1 c.c. of concentrated sulphuric acid and 5 c.c. of hydrofluoric acid, evaporated until sulphuric fumes arise, then mixed with 4 grams of potassium hydrogen sulphate, fused for about 20 minutes at a low temperature, finishing over a blast to drive off most of the free acid; it is then cooled, rendered alkaline with sodium carbonate, some potassium nitrate added, the whole fused, dissolved in hot water, and filtered. The filtrate is warmed with ammonium chloride, filtered, the filtrate reduced with sodium sulphite or sulphurous acid, ammonia added, the chromium hydroxide redissolved in hydrochloric acid, diluted, reprecipitated with ammonia, well washed, and weighed as Cr_2O_3.

For the analysis of titanium aluminium, 2 grams of the alloy is dissolved in 50 c.c. of a 10 per cent. solution of potassium hydroxide, boiled for 10 minutes, diluted to about 125 c.c., boiled and filtered quickly, and washed 10 times with boiling water. The residue is ignited, crushed in an agate mortar, fused with 6 grams of potassium hydrogen sulphate, raising the temperature gradually and shaking the crucible round occasionally, finishing after 25 minutes with five minutes more at the full heat of the flame; when cool, the mass is brought to homogeneous fusion with 2 grams more of potassium hydrogen sulphate, and the fused mass is subsequently digested with water, and, if the residue is found to consist of silica only, it is rejected, if otherwise, it is again fused with potassium hydrogen sulphate. The filtrate is treated with ammonia to slight precipitation without re-solution, and the precipitate is dissolved by adding dilute sulphuric acid; the acid solution is diluted to 250 c.c. and saturated with sulphurous anhydride, it is then boiled gently for

three-quarters of an hour, more sulphurous acid is added to keep the iron in the ferrous state, the solution filtered, and the precipitate washed, ignited, and weighed as TiO_2. The iron in solution is precipitated with ammonia, redissolved in hydrochloric acid, and titrated with dichromate. D. A. L.

Estimation of Manganese by the Chlorate Method. By W. Hampe (*Chem. Zeit.*, **15**, 1579—1580).—The author strongly protests against a modification of his chlorate method which has been proposed by the Committee of the German Ironmasters' Association, and points out several defects in the Committee's mode of procedure, such as using impure chemicals, and working on far too small quantities of material. L. de K.

Estimation of Manganese by the Chlorate Method. By M. A. v. Reis (*Chem. Zeit.*, **15**, 1791).—The author attempts to justify the action of the Committee (see preceding abstract), and points out that, although Hampe's original process has been tried many times, it is now only used in two small works. The reason is not far to seek. Hampe's original process is attended with much evolution of unpleasant fumes, and there is often a loss through the violent bumping of the nitric acid and chlorate mixture. As modified by the Committee (use of a weaker acid and addition of the potassium chlorate all at once), no trouble is experienced in that direction. L. de K.

Colorimetric Estimation of Iron. By J. Riban (*Bull. Soc. Chim.* [3], **6**, 916—920).—In reference to the suggested employment of colorimetric methods to determine small amounts of iron in blood, the author publishes the results of numerous experiments made by him with Duboscq's colorimeter on the thiocyanate, acetate, and alkaline tartrate of iron, which prove the inaccuracy of the method to be due to the dissociation of these salts on dilution with water. T. G. N.

Nickel and Cobalt Reactions. By Terreil (*Bull. Soc. Chim.* [3], **6**, 913—916).—Solutions of nickel and cobalt salts are precipitated by hydrogen sulphide in presence of many organic salts, the precipitation varying inversely as the amount of free acid present. Oxalic acid and the oxalates are without effect, since these form insoluble oxalates which hydrogen sulphide does not decompose. Alkali sulphites, hydrogen sulphates, thiosulphates, phosphates, and pyrophosphates, even in slightly acid solutions, enable hydrogen sulphide to precipitate the metallic sulphides by double decomposition of the primarily formed nickel and cobalt salts.

On addition of a cold solution of sodium thiosulphate to a rose-coloured cobaltous solution, a blue coloration is produced, which, on subsequent dilution with water, is altered to pink. Warming, or spontaneous evaporation of the liquid, occasions the precipitation of cobalt sulphide, and the dry residue is completely transformed into sulphide on heating at 100—120°. Nickel solutions similarly yield a greenish-yellow solution, which rapidly deposits the sulphide.

On treating mixed solutions of nickel and cobalt with thiosulphate and then with alcohol, the solution forms two layers, the lower con-

taining crystals of the double salts. which, after well washing with absolute alcohol, may be distinguished by the nickel compound turning brown on exposure to the air, whereas the blue cobalt salt remains unaltered for some time. Sodium hypochlorite solution slightly acidified with hydrochloric acid precipitates cobalt sesquioxide after one or two minutes, and nickel sesquioxide after half to one hour, from their respective solutions. T. G. N.

Qualitative Test for Chromium. By L. W. McCay (*Chem. News*, **65**, 221).—The author points out that, when testing insoluble mixtures or salts for chromium by fusion with sodium carbonate and nitrate, some nitrite is formed, and passes into solution during the subsequent digestion of the fused mass with water. Consequently, when the yellow solution is acidified, it assumes, owing to the reducing action of the liberated nitrous acid, a greyish-blue colour, instead of the reddish-yellow colour set down by some authorities as the special indication of chromium in this test. D. A. L.

Molybdic Acid as a Reagent for certain Aromatic Hydroxy-compounds. By J. Stahl (*Ber.*, **25**, 1600—1601).—Ammonium molybdate or molybdic acid gives colorations ranging from yellow to dark-brown with aromatic orthodihydroxy-compounds, whilst with the corresponding meta- and para-derivatives, no coloration is formed.

The presence of bromo- or nitro-groups in the nucleus is without influence on the reaction, but ortho-, methoxy-, or ethoxy-compounds do not show any coloration.

Sodium tungstate behaves like ammonium molybdate.

J. B. T.

Estimation of Uric Acid. By A. Haig (*J. Physiol.*, **13**, 320—331).—Tbe author defends his views and the process he has adopted (Haycraft's) against certain criticisms recently passed thereon (this vol., p. 365). W. D. H.

Detection of Sesame Oil in Olive Oil. By A. Gassend (*Chem. Centr.*, 1892, i, 459; from *Rev. internat. sci. fals. aliment.*, **5**, 98).—Some specimens of African olive oil give a red coloration with the sugar and hydrochloric acid test similar to that obtained with sesame oil. Spectroscopically, they are easily distinguished. Chemically, they may be distinguished by adding a little of a 10 per cent. solution of sodium hydrogen sulphite. The red coloration produced by olive oil is discharged very quickly, whereas that produced by sesame oil is not discharged for 12—40 minutes. J. W. L.

Detection of Vegetable Oils in Lard. By P. Welmans (*Chem. Centr.*, 1892, i, 417; from *Pharm. Zeit.*, **36**, 798—799).—The reaction depends on the presence of alkaloïds in the vegetable oils. To 1 gram, or 25 drops, of the lard is added 5 drops of chloroform and 2 c.c. of phosphomolybdic acid solution, together with a few drops of nitric acid, the mixture being well shaken. The presence of alkaloïds or of

glucosides causes reduction, accompanied by a green coloration. Purified oils do not react in this way.

Picric acid in ethereal solution, when shaken with 10 c.c. of the oil, gives, after allowing the ether to separate, a brown coloration.

J. W. L.

Estimation of Fat in Milk by Schmid's Method. By J. Pinette (*Chem. Zeit.*, **15**, 1833).—The author has slightly modified this process, and operates as follows:—10 c.c. of milk is heated in an Erlenmeyer flask with 10 c.c. of common hydrochloric acid until the caseïn has redissolved and the fatty drops float on the top. It makes no difference if small flakes of albumin remain undissolved; in fact, too long heating is injurious, as it causes charring of the fat. After cooling somewhat, the mixture is put into a burette which has a glass stopcock at the bottom and a glass stopper on the top. The flask is rinsed out several times with a mixture of equal volumes of ether and light petroleum, and this is introduced into the burette up to the top division. The ether being added to the still warm mixture suffers some evaporation, whereby the acid solution is rendered sufficiently cold. The burette is now closed and thoroughly shaken for some time, until one is sure that all the fat has passed into solution. The whole is now allowed to remain quiet until the ethereal layer has separated perfectly clear, which takes a longer time than in Röse's process. An aliquot part of the ethereal mixture is now pipetted off, evaporated in a weighed flask, and the fat is finally dried and weighed. If the ethereal layer is not quite clear, and contains small globules of water, it must, after pipetting off, be passed through a dry filter, but it is, of course, better to wait a while until it has become perfectly clear.

The process is very accurate and rapid. As the ethereal mixture can be readily recovered by distillation, it is also a very economical one.

L. de K.

Estimation of Fat in Yolk of Eggs. By S. Bein (*Bied. Centr.*, **21**, 138—139).—The average percentage of crude fat capable of being extracted from yolk of eggs by ether amounts to 30 per cent., but when one-tenth of salt is mixed with the yolk this percentage falls to 27, and after the mixture has been kept for 4—5 months the percentage further falls to 22—20. As salicylic acid and other preservatives exert no such reducing action, it is evident that salt forms some compound with the fat. The practical importance of this observation is great, for a loss of oil must also ensue in those manufactures, as of glove leather, where yolks are employed and are preserved in salt.

E. W. P.

Separation of the Xylenes. By J. M. Crafts (*Compt. rend.*, **114**, 1110—1113).—A sample of crude coal tar xylene boiling at 138—140° containing metaxylene (55—56 per cent.), paraxylene (21·5 per cent.), orthoxylene (9 per cent.), ethylbenzene (1·2 per cent.), and a little paraffinoïd hydrocarbon (0·8 per cent.), was analysed by the following process:—

The crude xylene (10—20 grams) is heated in a sealed tube

with concentrated sulphuric acid (2·5 parts) at 120° for an hour with continual agitation. A mixture (3—4 parts) of hydrochloric acid (1 part) and water (1 part) is then added, the unchanged hydrocarbon separated, and the heating with sulphuric acid repeated. The hydrocarbon subsequently separated is the paraffinoïd hydrocarbon insoluble in sulphuric acid. The acid liquors are now heated in a sealed tube at 122° for 20 hours; 97 per cent. of the metaxylenesulphonic acid is thus hydrolysed, and the hydrocarbon then measured. The acid mother liquors, on again heating in a sealed tube at 175° for 20 hours, liberate the ortho- and para-xylenes and the ethylbenzene. These are dissolved in sulphuric acid, and, on adding concentrated hydrochloric acid, paraxylenesulphonic acid, $2C_8H_9SO_3H,3H_2O$, crystallises out, and is filtered, washed with hydrochloric acid, dried, and weighed. The mixture (1 part) of orthoxylene and ethylbenzene is separated by treatment with bromine (20 parts) and iodine: under these conditions, the xylenes yield tetrabromides which are almost insoluble in ether and light petroleum, whilst ethylbenzene gives less highly brominated and more soluble substances. The metaxylene obtained by the above method crystallises at −51°.

Benzenesulphonic acid is not hydrolysed on heating its sulphuric acid solution with steam. Very pure toluene which does not crystallise at −95° may be prepared by heating its solution in sulphuric acid with steam at 160°. W. J. P.

Estimation of Creatinine in Urine. By J. Moitessier (*Bull. Soc. Chim.* [3], **6**, 907—908).—The author objects to the process of Gautrelet and Vieillard for the determination of creatinine in urine, which is dependent on the differential decomposition of urea, uric acid, and creatinine by alkaline hypobromite, both on account of the small amounts of nitrogen which the two latter compounds yield, and because lead urate is held in solution if an excess of lead subacetate is employed to remove the uric acid from the urine, and, again, creatinine is not completely precipitated from its dilute solutions by means of zinc chloride, as much as 90 per cent. being retained in solution, and even where Hoppe-Seyler's method is employed the author finds 70 per cent. is not precipitated. The only process which affords accurate and concordant results is that of Neubauer. T. G. N.

Estimation of Tannin. By G. Fleury (*J. Pharm.* [5], **25**, 499—500).—White of egg is dried at a moderate temperature and very finely powdered. This powder is washed with 10 per cent. alcoholised water faintly acidified with tartaric acid, and, when again dried, is preserved in a flask. The solution of tannin is placed in a flat-bottomed vessel with a weighed portion of the powder, seven or eight times the amount of tannin supposed to be present. The absorption takes 48 hours with frequent shaking; further, the solution should be acid. The solution is tested with ferric chloride. Finally, the powder is collected, dried at 100°, and weighed; a small sample of the powder is also dried and weighed at the same time. The tannin in nut galls cannot be determined by this method; the absorption is too slow. It is applicable to the tannin contained in

wine and in the petals of red roses. When gallic acid accompanies the tannin, its effect on ferric chloride must be considered, and it must be remembered that this acid is not absorbed. J. T.

Method of Analysis of Chlorophyllic Extracts. Nature of Chlorophyllane. By A. Étard (*Compt. rend.*, **114**, 1116—1118).—The author proposes to separate the colouring and other principles of plants by successive extractions with cold carbon bisulphide, alcohol, and alkalis. No definite results are given. W. J. P.

Estimation of Peptones in the Stomach Contents. By S. Riva-Rocci (*Chem. Centr.*, 1892, i, 344; from *Centr. Klin. Med.*, **12**, 897—899).—The total proteïds are first estimated by precipitation with absolute alcohol. In a second portion the amount of coagulable proteïds is determined by means of Devoto's method; and in a third portion the peptones are precipitated by means of magnesium sulphate and a little acetic acid. After weighing, the peptone precipitate is burned, 15 per cent. is added to the ash, and the difference is equivalent to the peptones. J. W. L.

Detection of Hæmatoporphyrin in Urine. By O. Hammarsten (*Zeit. anal. Chem.*, **31**, 233—235).—Owing, it would seem, to the increased use of sulphonal, cases of hæmatoporphyrinuria are becoming more frequent. The following is the method employed by the author for examining an urine in which the colour and spectroscopic characters indicated the presence of hæmatoporphyrin. The urine was first precipitated with barium acetate, and the filtrate from this precipitate treated with barium acetate and sodium carbonate alternately, until a filtered sample gave a white precipitate with these reagents. The precipitates were washed and extracted with acidified alcohol. The acid extract was shaken with an equal volume of chloroform and several times its bulk of water, when most of the colouring matter passed into the chloroform. This was rapidly withdrawn from the weak alcohol, washed well with water, and evaporated in shallow basins in the dark. The brown residue was soluble in chloroform with splendid purple colour, and could be crystallised from warm alcohol in needles resembling Nencki and Sieber's hæmatoporphyrin hydrochloride. It was insoluble in cold water and in highly dilute acids, sparingly soluble in cold alcohol, in these respects, and in the situation of the absorption bands, which were slightly nearer to the red end of the spectrum, differing from Nencki and Sieber's product (Abstr., 1888, 971). In only one case out of the four met with did the substance obtained appear to be identical with that of Nencki and Sieber; in another case the chromogen of a similar colouring matter was observed. Of the four absorption bands in the spectrum of a solution of hæmatoporphyrin in ammonia and zinc chloride, those between C and D, and between *b* and F disappear within 24 hours, the former first. The other two bands are permanent. M. J. S.

General and Physical Chemistry.

Behaviour of Optically Active Substances in Mixtures of Two Solvents. By E. Rimbach (*Zeit. physikal. Chem.*, **9**, 698—708).—The substances used in this investigation were camphor and turpentine. Solutions of the former of different degrees of concentration in ethyl acetate and in benzene were first examined, and then solutions in mixtures of the two solvents were taken. Turpentine was examined in like manner in alcohol and in acetic acid and in mixtures of the two. In the case of camphor, it was found that with solutions containing about 50 per cent. the results obtained with the mixed solvents agreed with those calculated from observations with the simple solutions, on the assumption that the optical rotation is in no way influenced by mixing the two solvents. If the percentage of active substance is decreased, the calculated specific rotation is found to be somewhat smaller than the observed, the difference between the two being greater the less the amount of active substance present. The turpentine solutions behave in like manner, but in this case the differences between the observed and calculated values are so small as to fall very nearly within the limits of experimental error.

In order further to ascertain whether the presence of an optically inactive solid substance in a solution would produce the same effect as an optically inactive liquid, solutions of dextrose in water containing magnesium chloride and calcium chloride in different proportions were examined. In calculating the results, the inorganic salts were treated as playing the part of inactive solvents. Magnesium chloride is found to exercise practically no influence whatever on the rotation of dextrose solutions. The presence of calcium chloride, on the other hand, produces a considerable increase in the specific rotation, but the observed do not in this case agree with the above calculated values. The increase depends on the concentration of the salt solution, but is independent of the amount of dextrose present or independent of the concentration of the dextrose solution.

H. C.

Colour of the Ions. By W. Ostwald (*Zeit. physikal. Chem.*, **9**, 579—602).—The author has investigated the absorption spectra of solutions of various series of coloured salts, measuring the position of the bands, and also photographing the entire spectrum. From his observations, it appears that the spectra of dilute solutions of salts with the same coloured ion are identical. For instance, the series of permanganates at a dilution of 500 litres gave the numbers (on an arbitrary scale) in table, p. 1138, for the absorption lines.

At this stage of dilution, then, at which the metallic permanganates are completely dissociated, the spectra of the solutions are identical, as may also be seen in the photographic reproductions, the spectra of the different salts being given side by side. Besides the permanganates,

Metal.	I.	II.	III.	IV.
1. Hydrogen	2601	2698	2804	2913
2. Potassium	2600	2697	2803	2913
3. Sodium	2602	2698	2803	2913
4. Ammonium	2601	2698	2802	2913
5. Lithium	2602	2700	2804	2914
6. Barium	2600	2699	2804	2914
7. Magnesium	2602	2700	2802	2912
8. Aluminium	2603	2699	2804	2914
9. Zinc	2602	2699	2802	2912
10. Cobalt	2601	2698	2803	2912
11. Nickel	2603	2700	2804	2913
12. Cadmium	2600	2700	2803	2913
13. Copper	2602	2699	2803	2913

the author studied the fluoresceïn salts, eosin salts, iodoeosin salts, dinitrofluoresceïn salts, orcinphthaleïn salts, and the salts of its tetrabromo-derivative, the salts of rosolic acid, of diazoresorcin, of diazoresorufin, the chromoxalates, safrosin salts, the salts of pararosaniline, of aniline violet, of chrysaniline, and of chrysoïdine. The results are in general the same as for the permanganates, any deviations being attributable to the formation of insoluble compounds, or to the hydrolysis of the salts of very feeble acids or bases.

J. W.

Physical and Chemical Phenomena at very Low Temperatures. By R. Pictet (*Compt. rend.*, **114**, 1245—1247).—By using powerful compressers and aspirators a mixture of sulphurous and carbonic anhydrides will give a temperature of −110°, nitrous oxide and ethylene will give about −150°, and air will give a minimum temperature of −210° to −213°. The low temperatures are measured with a dry hydrogen thermometer, and afterwards with thermometers containing alcohol or ether, these latter being verified by means of the hydrogen thermometer.

The author finds that the very long ether waves corresponding to very low temperatures pass readily through almost all bodies, and a vessel at −110°, for example, will cool with practically the same rapidity, whether it is enveloped in a layer of cotton wool 2 cm., 10 cm., or 50 cm. in thickness.

Very peculiar phenomena are observed in the solidification of chloroform. When immersed in nitrous oxide at −120°, the thermometer in the chloroform sinks to −68·5°, and crystallisation begins. If now the vessel is placed in sulphurous and carbonic anhydride at −80°, the thermometer falls to −80°, but the crystals of chloroform melt again. If put back into the liquid at −120°, the thermometer rises to −68·5°, and crystallisation begins again. At −83·5° the crystals remain stationary; if the temperature falls, they increase; if it rises, they melt. When the vessel is cooled at −120°, crystallisation takes place on the inner wall of the vessel, and it seems probable that the thermometer in the middle is affected by the latent heat of crystallisation, and at −68·5° is in dynamic equilibrium with the medium

in which it is immersed. At −80° no crystals are formed, and the thermometer is affected only by radiation. C. H. B.

Melting Points of Mixtures. By A. Miolati (*Zeit. physikal. Chem.*, **9**, 649—655).—The melting points of mixtures in all proportions of naphthalene (80°) with phenanthrene (96°), with diphenylmethane (25·6°), and with anthracene (213°) were determined. The results are given in tabular and curve form. The melting point of the pure substance is in all cases depressed by the addition of the foreign material, and falls until a minimum point is reached which is below the melting points of either of the constituents of the mixture. The position of the minimum apparently depends on the difference between the melting points of the substances present. If the two substances have nearly the same melting point, the mixture of lowest melting point contains the two in nearly equimolecular proportions. In other cases the minimum is always nearest to the melting point of the lower melting constituent. The depression of the melting point is in all cases approximately proportional to the number of molecules of the foreign material present, but as an examination of the curves expressing this relation shows, the proportionality is only approximate. H. C.

Heats of Combustion and Formation of Ethyl Alcohol, of Formic Acid, and Acetic Acid. By Berthelot and Matignon (*Compt. rend.*, **114**, 1145—1149).—The authors have re-determined the heats of combustion of ethyl alcohol, formic acid, and acetic acid by means of the calorimetric bomb, using all the precautions indicated by later investigations.

	Heat of combustion.		Heat of formation.		
	Constant volume.	Constant pressure.	Solid.	Liquid.	Dissolved.
	Cal.	Cal.	Cal.	Cal.	Cal.
Ethyl alcohol	325·1	325·7	—	69·9	72·4
Formic acid	62·8	62·5	+103·3	+100·8	+100·9
Acetic acid	209·4	209·4	+119·7	+117·2	+117·6

Heat of formation of gaseous formic acid at 100° = +96·0 Cal.; at 200° = +90 Cal. (approx.).

Heat of formation of gaseous acetic acid at 120° = 112·1 Cal.; at 250° = 107·1 Cal.

The formation of potassium formate by the action of carbonic oxide on potassium hydroxide is exothermic by reason of the heat of neutralisation of the formic acid by potash. The energy required for the decomposition of formic acid in presence of concentrated sulphuric acid is furnished by the hydration of the latter.

The decomposition of acetic acid into methane and carbonic an-

hydride will be exothermic above 250°, and in presence of an alkali will develop still more heat, because the carbonic anhydride formed will combine with two equivalents of alkali. C. H. B.

Dibromomalonic Acid. By G. Massol (*Compt. rend.*, **114**, 1200—1201).—This acid was obtained by the direct action of bromine on anhydrous malonic acid in presence of chloroform. It forms slender, silky, anhydrous needles, deliquescent and extremely soluble in water; heat of dissolution +2·02 Cal. *Potassium hydrogen dibromomalonate* forms brilliant, white, anhydrous crystals which are easily decomposed by heat; heat of dissolution −5·60 Cal. *Potassium dibromomalonate* forms a non-crystallisable mass which becomes anhydrous at 100° and decomposes at 120°; heat of dissolution −9·94 Cal.

$C_3O_4Br_2H_2$ diss. + KOH diss. = $C_3O_4Br_2HK$ diss.	develops	+15·49 Cal.
$C_3O_4Br_2H_2$ diss. + 2KOH diss. = $C_3O_4Br_2K_2$ diss.	„	+29·44 „
$C_3O_4Br_2H_2$ sol. + KOH sol. = $C_3O_4Br_2HK$ sol. + H_2O sol.	„	+37·00 „
$C_3O_4Br_2HK$ sol. + KOH sol. = $C_3O_4Br_2K_2$ sol. + H_2O sol.	„	+32·18 „
$C_3O_4Br_2H_2$ sol. + 2KOH sol. = $C_3O_4Br_2K_2$ sol. + $2H_2O$ sol.	„	+69·18 „

These values are about 10 Cal. higher for each acid function than the corresponding values for malonic acid. Similar differences have already been observed by Louguinine between acetic and trichloracetic acid. C. H. B.

Thermochemistry of Bibasic Organic Acids: Methylmalonic Acid and Methylsuccinic Acid. By G. Massol (*Compt. rend.*, **114**, 1373—1374).—The results obtained were as follows:—

Methylmalonic (isosuccinic) acid:—

$C_4H_6O_4$ sol. + KOH sol. = $C_4H_5O_4K$ sol. + H_2O sol.	develops	+28·16 Cal.
$C_4H_5KO_4$ sol. + KOH sol. = $C_4H_4O_4K_2$ sol. + H_2O sol.	„	+20·76 „
$C_4H_6O_4$ sol. + 2KOH sol. = $C_4H_4O_4K_2$ sol. + H_2O sol.	„	+49·12 „
$C_4H_6O_4$ sol. + 2NaOH sol. = $C_4H_4O_4Na_2$ sol. + H_2O sol.	„	+40·50 „

Methylsuccinic acid:—

$C_5H_8O_4$ sol. + KOH sol. = $C_5H_7KO_4$ sol. + H_2O sol.	develops	+24·85 Cal.
$C_5H_7KO_4$ sol. + KOH sol. = $C_5H_6K_2O_4$ sol. + H_2O sol.	„	+20·33 „
$C_5H_8O_4$ sol. + 2KOH sol. = $C_5H_6K_2O_4$ sol. + $2H_2O$ sol.	„	+45·18 „

The heat of neutralisation of methylmalonic acid,

$$COOH{\cdot}CHMe{\cdot}COOH,$$

is practically the same as that of malonic acid, $COOH{\cdot}CH_2{\cdot}COOH$, and the heat of neutralisation of methylsuccinic acid,

$$COOH{\cdot}CHMe{\cdot}CH_2{\cdot}COOH,$$

is practically the same as that of succinic acid,

$$COOH{\cdot}CH_2{\cdot}CH_2{\cdot}COOH.$$

The degree of separation of the two carboxyl groups is similar in the two members of each pair, and the results confirm the author's view that the heat of neutralisation is a function of the degree of separation of the carboxyls. C. H. B.

Glutaric (Normal Pyrotartaric) Acid. By G. Massol (*Compt. rend.*, **114**, 1437—1438).—Heat of dissolution, at about 20°, of glutaric acid −5·36 Cal., of anhydrous potassium hydrogen glutarate +13·73 Cal., of anhydrous potassium glutarate +4·57 Cal. The heats of neutralisation are as follows:—

$C_5H_8O_4$ diss. + KOH diss. = $C_5H_7O_4K$ diss. + H_2O	develops	+13·73 Cal.
$C_5H_7O_4K$ diss. + KOH diss. = $C_5H_6O_4K_2$ diss. + H_2O	„	+12·65 „
$C_5H_8O_4$ diss. + 2KOH diss. = $C_5H_6O_4K_2$ diss. + $2H_2O$	„	+26·38 „
$C_5H_8O_4$ sol. + KOH sol. = $C_5H_7O_4K$ sol. + H_2O sol.	develops	+26·70 Cal.
$C_5H_7O_4K$ sol. + KOH sol. = $C_5H_6O_4K_2$ sol. + H_2O sol.	„	+17·53 „
$C_5H_8O_4$ sol. + 2KOH sol. = $C_5H_6O_4K_2$ sol. + $2H_2O$ sol.	„	+44·23 „

These results confirm the author's previous conclusion that in the oxalic series the heat of neutralisation decreases as the molecular weight increases, and when they are combined with previous results (preceding abstract), they also confirm the conclusion that the heats of formation of salts of normal bibasic organic acids are lower than in the case of their non-normal isomerides. C. H. B.

Substitution of Radicles in union with Carbon and Nitrogen respectively: Explosives. By C. Matignon (*Compt. rend.*, **114**, 1197—1199).—The author has previously shown (this vol., p. 106; see also p. 4) that the substitution of an alkyl radicle in connection with nitrogen increases the heat of combustion by a greater quantity (163—165 Cal.) than the substitution of a radicle in connection with carbon (155—156 Cal.). In the second case, substitution is effected by the union of atoms of the same kind, but in the first case by the union of atoms of different kinds, and it seems probable that

this is the explanation of the difference in the thermal values, the exchange of valencies between different atoms involving a smaller loss of energy than a similar exchange between similar atoms.

With a view to decide this point, the behaviour of nitro-derivatives was investigated. In ordinary cases, the NO_2 group is united with carbon, and there is an exchange of valencies between dissimilar atoms. Berthelot has shown that the heat developed by this substitution has a mean value of +36 Cal.

From a thermochemical study of the nitroguanidine described by Thiele, the author finds that the heat developed by the substitution of NO_2 in this case is only +30·3 Cal. The nitro-group must be united with nitrogen, and it follows that the explanation suggested above will not hold good; for the introduction of NO_2 in connection with nitrogen increases the heat of combustion to a greater extent than the introduction of NO_2 in connection with carbon. It would follow from this result, however, that nitro-explosives containing the NO_2 group in connection with nitrogen should be more powerful than those in which this group is united with carbon. As a matter of fact, nitroguanidine explodes violently when small quantities are projected on to a heated surface. C. H. B.

Thermochemistry of Guanidine and Nitroguanidine. By C. Matignon (*Compt. rend.*, **114**, 1432—1434).—*Guanidine nitrate*:—Heat of dissolution at 10° = −10·15 Cal.; heat of combustion at constant volume (in calorimetric bomb) +207·8 Cal.

$$C + O_3 + H_6 + N_4 = CN_3H_5,HNO_3 \text{ sol. develops } +93{\cdot}5 \text{ Cal.}$$

Guanidine sulphate is obtained by the action of the calculated quantity of sulphuric acid on guanidine carbonate. It is very soluble in water, and crystallises with half a molecular proportion of water, which it loses at 110°. Heat of dissolution of the anhydrous salt at 10° = −6·75 Cal.

$2CN_3H_5,H_2SO_4$ diss. + $Ba(OH)_2$ diss. = $BaSO_4$ ppt. + $2CN_3H_5$ diss. + $2H_2O$ ..	develops + 5·8 Cal.
CN_3H_5 diss. + HNO_3 = CN_3H_5,HNO_3 diss.	„ +14·12 „
CN_3H_5 sol. + HNO_3 sol. = CN_3H_5,HNO_3 sol.	„ +32·1 „
$C + N_3 + H_5 = CN_3H_5$ sol.	„ +19·2 „

The thermal value of the basic function of guanidine, +32·1 Cal., is intermediate between that of barium hydroxide, +31·7 Cal., and that of sodium hydroxide, +36·4 Cal. No thermochemical evidence could be obtained of the existence of a second basic function of the guanidine.

Nitroguanidine, obtained by Thiele's method, is very soluble in hot water, from which it separates on cooling in anhydrous, white needles. Its heat of combustion at constant pressure is +210·3 Cal., and hence its heat of formation from its elements is +22 Cal., and

CN_3H_5 sol. + HNO_3 liq. = $CN_3H_4{\cdot}NO_2$ sol. + H_2O liq.	develops + 30·3 Cal.

The heat developed by nitrification is lower than in the case of nitro-derivatives in which the nitrogen of the nitroxyl group is directly united with carbon (compare preceding abstract).

C. H. B.

Thermochemistry of Hydrazine and of Hydroxylamine. By J. Thomsen (*Zeit. physikal. Chem.*, **9**, 633—635).—Bach (this vol., p. 933) has commented unfavourably on the method of oxidation by means of silver nitrate, for the purpose of determining the heat of formation of hydroxylamine and of hydrazine. The author shows that the apparent want of agreement in the case of hydroxylamine rests on a misunderstanding, and is of opinion that water and nitrogen are not the only products of oxidation obtained from hydrazine and silver nitrate.

J. W.

Formulæ for Calculating the Heating Power of Coal. By Scheurer-Kestner (*Compt. rend.*, **114**, 1269—1272).—The author quotes further examples to show that the actual heating power of coal cannot be accurately calculated from its percentage composition by means of Dulong's formula, the possible error being as much as 12 per cent.

Berthier's method of assay also gives results which differ widely from, and have no definite relation to, the results obtained with the calorimetric bomb.

C. H. B.

Temperatures of Saturated Vapours of various Liquids under the same Pressure. By E. Colot (*Compt. rend.*, **114**, 653—654). The temperatures t and θ of the saturated vapours of any two liquids at the same pressure are connected by the linear equation

$$t = A\theta + B,$$

when A and B are constants for the particular liquids. The experimental values of these constants for 20 different pairs of liquids are given, and hold good for very wide ranges of pressure. The maximum error is 0·71°.

Jn. W.

Viscosity of Liquids. By A. Handl and R. Přibram (*Zeit. physikal. Chem.*, **9**, 529—539).—The authors in this paper discuss the methods of calculation, &c., adopted by Gartenmeister (Abstr., 1891, 380), and uphold certain rules connecting the viscosity of liquids with their composition and constitution against objections raised by him.

J. W.

Theories of Osmotic Pressure and of Electrolytic Dissociation. By M. Planck (*Zeit. physikal. Chem.*, **9**, 636—637).—The author upholds (against Arrhenius) his thermodynamical proof of the law for the lowering of the freezing point and of the vapour pressure of solutions, and disclaims any pretensions on his part to priority in the discovery of the electrolytic dissociation theory.

J. W.

Determination of the Electrolytic Dissociation of Salts by means of Solubility Experiments. By A. A. Noyes (*Zeit.*

physikal. Chem., **9**, 603—632).—According to the principles laid down by Nernst (*Zeit. physikal. Chem.*, **4**, 372), it is possible, from experiments on the solubility of a sparingly soluble salt in aqueous solutions of another salt containing one ion in common with it, to calculate the degree of dissociation of the one salt, provided that that of the other is known. The author has taken as his standard substance thallous chloride, which he assumes to be equally dissociated with the chlorides of the alkali metals in equally strong solution. Proceeding from this basis, he has calculated from solubility experiments the degree of dissociation for a large number of salts. His results are by no means in accordance with those derived from a consideration of the electrical conductivity of the salt solutions, as the following example shows:—

Percentage Dissociation of Potassium Chloride.

Concentration.	From conductivity.	From solubility.
0·016 normal	93·3	93·8
0·03 „	91·0	88·7
0·05 „	89·1	84·3
0·1 „	86·1	74·8
0·2 „	82·8	65·2

The chlorides of the alkali metals are equally dissociated, and the chlorides of magnesium, barium, calcium, manganese, zinc, and copper (cupric) are also nearly equally dissociated, the degree of dissociation being slightly less than in the case of the alkali chlorides. Cadmium chloride is much less dissociated than these. Thallous chloride forms with lead chloride an insoluble double compound having the formula $PbCl_2,3TlCl$. J. W.

Dissociation in Dilute Solutions of Tartrates. By R. v. Sonnenthal (*Zeit. physikal. Chem.*, **9**, 656—668).—While investigating the influence of concentration on the rotatory power of dilute solutions of certain normal and acid tartrates, the author found that although the specific rotation decreases in all cases with decreasing concentration up to a certain point, a change occurs as the solutions become very dilute, and the specific rotations begin to increase slowly and regularly with further dilution. This change takes place in the case of the neutral tartrates with solutions of about 0·3 per cent. to 0·4 per cent. concentration, and for the acid tartrates with the concentration 0·2 to 0·3 per cent. The occurrence and magnitude of the change depends on the nature of the metal or radicle present in the salt, the greater the atomic weight of the metal or molecular weight of the radicle, the more readily will the change take place, and the greater will be the influence of decreasing concentration. The change is also to a certain extent a function of the time, as freshly prepared solutions have a lower specific rotation than those which have been for some time prepared, the rotation increasing with the time that the solution has

been prepared until a certain limit is reached. The influence of time appears to depend solely on the solubility of the salt in water, as the above limit is reached more rapidly in the case of the more soluble salts than with those of lesser solubility. From the above facts, the author concludes that this change which takes place in the rotation of very dilute solutions of tartrates is due to dissociation of the salt molecules with rising dilution. H. C.

Interval of Change. By W. Meyerhoffer (*Zeit. physikal. Chem.*, **9**, 641—648).—The author determines the solubility of the system $CuCl_2,2H_2O,2KCl + KCl$, for temperatures from 0° to 90·5°. To represent the results the temperatures are taken as abscissæ, and as ordinates the ratios of the amounts of the two simple salts $KCl \mid CuCl_2$ in the saturated solutions. In this method of representation, the solubility curves of pure double salts appear as straight lines. The author formerly supposed that the curve for the solubility of the above system would cut the theoretical curve for the solubility of the pure double salt at low temperatures, but this is not found to be the case. With falling temperature the solubility curve for the system $CuCl_2,2H_2O,2KCl + KCl$ approaches the (theoretical) solubility curve for the double salt $CuCl_2,2H_2O,2KCl$, but at the temperature 39° a maximum is reached by the former, and the curves recede from one another on passing this point. This result would seem to show that a saturated solution of the pure double salt is incapable of existing at any temperature.

The author applies the above mode of representation to the results of Schreinemakers with the double iodide of potassium and lead, $PbI_2,2KI,2·5H_2O$. For this salt there are two different intervals of change, the temperature at which water no longer decomposes the salt being reached in the one case with rising, and in the other with falling, temperature, the intervals being therefore positive and negative. The two curves cut one another at 69° where $K_2I_2 \mid PbI_2 = 3·7$. The system $PbI_2 + 3·7K_2I_2$, therefore, evidently exists in two different conditions of solubility. Other peculiarities of the curves are pointed out, and the author also criticises Trevor's work on the double sulphates of copper and potassium. H. C.

Polybasic Acids. By W. Ostwald (*Zeit. physikal. Chem.*, **9**, 553—562).—From a study of the electrolytic conductivity of bibasic acids at different dilutions, it appears that in some cases the first replaceable hydrogen atom is split off as an ion almost entirely, before the second hydrogen atom begins to be attacked. In other cases the second replaceable hydrogen atom begins to come off when only about 50 per cent. of the first is dissociated. The author considers the phenomenon in connection with the behaviour of different polybasic acids with respect to indicators, pointing out that many feeble acids, such as sebacic acid, may be sharply titrated, while much stronger acids, such as phosphorous acid, give no sharp end point. The explanation he gives is as follows:—A bibasic acid, $R''H_2$, dissociates first into $\overset{+}{H}$ and $R''\overset{-}{H}$, which latter in its turn dissociates into

$\overset{+}{H}$ and $\overset{=}{R''}$. As the radicle R″H is already charged with one unit of negative electricity, which is associated with the atom to which the positive ion of the undissociated compound was attached, there will be more or less difficulty in effecting the introduction of a second negative charge into this radicle, according as this second charge is nearer or further from the first charge. Consequently, the nearer the charges of the bivalent ion $\overset{=}{R''}$ are to each other, the less will be the tendency of the second hydrogen atom to dissociate. But when two replaceable hydrogen atoms are near each other in the molecule, the acid is, *cæteris paribus*, a strong one, and when they are far removed from each other, it is a feeble one; so that there may often be a reluctance on the part of a moderately strong acid to dissociate a second hydrogen atom. The author illustrates his theory by means of numerous examples. J. W.

Chemical Equilibrium in Solutions. By G. Charpy (*Compt. rend.*, **114**, 665—667).—As a general rule, the additive character of the physical properties of mixed solutions holds only for low concentration, and one of the conditions necessary for the extended application of the additive property is that the particular property under consideration must be a linear function of the concentration. The density is such a property, for, by considering the density of solutions of ammonium, potassium, barium, and cupric chlorides as a function of the concentration, experimental results were obtained showing this function to be sensibly linear, the greater error being 1/40th of the molecular concentration in the case of copper chloride.

On making similar measurements with a mixture of potassium and sodium chloride solutions, it was found that the density could be represented as a linear function of the molecular concentration of one of the salts, the molecular concentration of the other being constant.

Jn. W.

The Formation of Layers in Solutions of Salts in Mixtures of Water and Organic Liquids. By C. E. Linebarger (*Amer. Chem. J.*, **14**, 380—398; compare Abstr., 1888, 783).—Part I of the author's work deals with the behaviour of salts towards mixtures of water and methyl alcohol, ethyl alcohol, propyl alcohol, and acetone, respectively, as regards the formation of layers.

The organic liquid was added by degrees to a saturated solution of a salt in water contained in a test tube, with vigorous agitation, until either a layer formed or the salt was precipitated. A table shows the results when 70 typical salts were experimented with. From this, certain regularities in regard to the formation of layers are to be noted. Chlorides do not generally exhibit this phenomenon; the alkaline chlorides, however, form layers in a mixture of acetone and water, and, save lithium chloride, in a mixture of propyl alcohol and water. The smaller the molecular mass of the alkaline chloride, the less pronounced is the peculiarity of layer-formation. The reverse is true of the chlorides of the alkaline earths; here the smaller the molecular mass, the more readily does the layer-formation occur. The acetates and nitrates do not as a rule cause a separation into

layers. The sulphates and carbonates exhibit the peculiarity of layer-formation in the most marked degree. Taking the organic liquids into consideration, it is found that methyl alcohol forms layers only with potassium carbonate, and that when any salt forms layers in a mixture of ethyl alcohol and water, it does so also in mixtures of propyl alcohol and water and of acetone and water. It would thus seem that, the greater the molecular mass of an alcohol, the more pronounced the formation of layers. No such relationship can be detected between the alcohols and acetone. The layer-formation seems to depend upon the nature of the acid part of the salt and not upon that of the basic part.

Part II deals with the limits of the formation of layers under varying conditions of temperature and concentration. The upper limit of layer-formation, that is, the quantity of organic liquid present when a further addition of it prevents the layer from forming, was determined by adding successive small portions of the organic liquid to a certain volume of a titrated solution of the salt; the tube was shaken after every addition and the volumes of the layers noted after two hours. It was found that potassium carbonate is the only salt which is not precipitated by the solvent before this upper limit is reached. As a mean of two experiments, the upper limit for alcohol with 5·4 of water and 0·592 of potassium carbonate was 53·9. The lower limit, that is, the point where a layer ceases to form on account of the presence of excess of water, can be very accurately determined. A little of the organic liquid was run into a known volume of the titrated salt solution and enough water added to clear up any cloudiness; the bottle was then placed in a thermostat, and when its contents had acquired the desired temperature, enough of the organic liquid was added to produce a cloudiness. The bottle was then replaced in the thermostat and if the contents became clear a little more organic liquid was added. This was repeated until a *drop* of water would clear up the cloudiness caused by a drop or two of the organic liquid. The lower the temperature, the more water is necessary to bring about the disappearance of the layers; the temperature employed was 20°. The numbers obtained in individual experiments are given and represented in curves, but the author reserves discussion of them until he has completed his determinations of the composition of the layers. A. G. B.

Reaction of Hydrogen with Chlorine and Oxygen. By J. A. Harker (*Zeit. physikal. Chem.*, **9**, 673—697).—Dixon and the author have shown that, in contradiction to what was formerly held to be the case, hydrogen when exploded with oxygen and excess of chlorine does not unite only with the chlorine, but that water is formed at the same time. The experiments were, however, incomplete, and more particularly left quite undecided the question of whether the ordinary laws of mass action hold for this case as for others of gaseous combination. The author has, therefore, continued them with the view of elucidating this point. Great difficulty was at first experienced in the carrying out of the experiments, and special apparatus had to be devised, a full description of which is given in

the paper. The results comprise 18 experiments, in which the volume of chlorine added to 50 vols. H_2 and 50 vols. O_2 varied from 9·08 to 95·83. In all cases a division of the hydrogen between the chlorine and oxygen takes place. This division takes place in such a manner that the product of the number of molecules of hydrogen chloride and of those of oxygen divided by the product of number of molecules of water vapour and of those of chlorine is practically constant, the mean value of the constant taken from the experiments being 23. It, therefore, appears that the Guldberg-Waage law of mass action holds for this as for other cases.

Equilibrium of Chemical Systems under Unequal Pressures. —By W. Spring (*Zeit. physikal. Chem.*, **9**, 744—745).—Remarks on a paper by Le Chatelier on the same subject (this vol., p. 937), in which the author claims priority for having shown that compression of solid substances beneath the surface of liquids will bring about their union far more readily than will compression of the dry material.

H. C.

Hydrolysis of Substituted Ethyl Acetates. By P. C. Freer and F. L. Dunlap (*Amer. Chem. J.*, **14**, 366—376).—Ostwald has shown (Abstr., 1890, 818) that the substitution of a negative radicle for hydrogen in an acid increases the avidity of that acid. Thus in the three chloracetic acids there is an increase of avidity for each atom of chlorine :—Acetic acid, $k = 0·00189$; chloracetic acid, $k = 0·155$; dichloracetic acid, $k = 5·17$; trichloracetic acid, $k = 121$.

The authors find that a similar relationship exists in the rate of hydrolysis of the ethyl salts of these acids, that displaying the highest constant as determined by Ostwald being the most readily saponified.

The *modus operandi* was as follows :—The ethyl acetate was weighed in a small bulb, such a quantity being taken as could be saponified by 5 c.c. of a solution of barium hydroxide saturated at 15°. This bulb was dropped into a large test tube inserted in a Beckmann's apparatus for determining molecular weights by the cryoscopic method (Abstr., 1891, 784), and 75 c.c. of a diluent (equal parts of alcohol and water), having the same temperature as the bath, was added. After adding a few drops of phenolphthaleïn, the bulb was broken by a glass rod and the mixture stirred; 5 c.c. of the barium hydroxide solution were then run in from a burette, specially adapted to exclude carbonic anhydride, and the interval of time necessary for the disappearance of the colour of the indicator noted, together with the temperature of the bath. The experiments were repeated at different temperatures ranging from 0° to 60°, beyond which too much of the alcohol was volatilised. The results are given in detail and represented as curves; they show that, although the relationship between the times of hydrolysis at any given temperature is not similar to that obtaining between the avidities as developed by Ostwald, yet the same relative position is maintained, the ethyl salts

of those acids with the greatest avidities being most readily saponified. The results at 0° are here given:—

Ethyl chloracetate	84	minutes.
Ethyl dichloracetate	9·5	„
Ethyl trichloracetate	7·5	„
Ethyl bromacetate	90	„
Ethyl dibromacetate	19·5	„
Ethyl tribromacetate	17	„

The introduction of the second chlorine or bromine atom exerts a much greater influence than that of the third.

It is found that an increase of temperature has a greater relative effect on the speed of hydrolysis of the mono-substituted than it has on the di-substituted acids; this is easily accounted for by the greater increase of velocity caused, among the lighter molecules, by an increase of temperature. A. G. B.

Spheres of Condensation and Evaporation. By O. Lehmann (*Zeit. physikal. Chem.*, **9**, 671—672).—The author points out that Beyerinck, in his paper on the "Action at a Distance of Aqueous Solutions on Water Vapour" (this vol., p. 956), has failed to notice a description of the formation of spheres of condensation in vapours around substances which are capable of absorbing these vapours, contained in the author's "Molekularphysik," i, 318 and 337. The formation of these spheres is similar to that of the spheres formed in solutions round growing crystals, and is due not to action at a distance, but to equilibrium being gradually established between absorption and evaporation in the sphere in question. H. C.

Studies on Energetics. By W. Ostwald (*Zeit. physikal. Chem.*, **9**, 563—578).—The author emphasises the fact that energy is the only magnitude common to all branches of physics, mass being confined, strictly speaking, to dynamics. He therefore proposes that in an absolute system of measurement, mass should be replaced as a fundamental unit by energy, so that all physical magnitudes should be expressed in terms of time, length, and energy. The following table exhibits the dimensions of various magnitudes in the old and new systems:—

	Old units.	New units.
Energy	$[ml^2t^{-2}]$	$[e]$
Mass	$[m]$	$[el^{-2}t^2]$
Momentum	$[mlt^{-1}]$	$[el^{-1}t]$
Force	$[mlt^{-2}]$	$[el^{-1}]$
Surface tension	$[mt^{-2}]$	$[el^{-2}]$
Pressure	$[ml^{-1}t^{-2}]$	$[el^{-3}]$
Power	$[ml^2t^{-3}]$	$[et^{-1}]$

Proceeding from the principle of virtual velocities, the author arrives at the following general energy principle, which may be applied to all branches of physics and chemistry:—

In order that a system containing any forms of energy may be in

equilibrium, it is necessary and sufficient that for every displacement of the system consistent with its conditions of existence, the sum of the quantities of energy which appear and disappear should be zero.

The author rejects the substantial existence of matter, and defines mass as the capacity of an object for energy of motion. J. W.

Apparatus for Hot Filtration. By T. Paul (*Ber.*, **25**, 2208—2210).—The apparatus consists of a glass or metal flask fitted with an air condenser and three side tubes. One side tube is used for introducing and withdrawing liquids. Of the other two side tubes, one takes the vapour of the liquid in the flask to the spiral jacket of the filter-funnel; the other takes the condensed vapour back into the flask. A tube splayed out at the top is fused into the inside of the neck of the flask between the two last-mentioned side tubes, and reaches to the bottom of the flask. This tube is closed at the lower end, but about 1 mm. up has a number of holes arranged in rings.

E. C. R.

Lecture Experiment illustrating the Effusion of Gases. By P. C. Freer (*Zeit. physikal. Chem.*, **9**, 669—670).—The apparatus, of which a sketch is given in the paper, consists of a U-tube of about 200 c.c. capacity, one limb of which is closed by a stopcock, and is graduated, the other limb being connected with a graduated tube, about 500 mm. in height, and of suitable bore. The stopcock communicates with a short tube which is drawn out to a fine capillary. The graduated limb of the U-tube is filled with the gas under examination, the other limb containing mercury. On opening the stopcock, the gas escapes through the capillary and the mercury falls, the time which the mercury takes to fall through a certain distance being noted, and the results with different gases compared. H. C.

Inorganic Chemistry.

Formation of Plastic Sulphur from Sulphur Vapour. By J. Gal (*Compt. rend.*, **114**, 1183—1184).—When sulphur vapour is condensed on the surface of a cold liquid such as water, dilute nitric acid, dilute hydrochloric acid, or a solution of sodium hydroxide, plastic sulphur is formed in thin, pale-yellow plates which under the microscope are seen to be formed of transparent, rounded grains. The plates consist of a mixture of soluble and insoluble sulphur; if heated at 100° for an hour, 13·6 per cent. remains insoluble in place of the 0·3 per cent. in the case of ordinary plastic sulphur, and 23 per cent. in the case of flowers of sulphur.

The proportion of insoluble sulphur in plastic sulphur formed from vapour varies with the conditions, and especially with the temperature of vaporisation. The percentage of insoluble sulphur at various temperatures above 200° is given in the following table.

Temperature.....	215°	230°	245°	260°	275°	290°	305°	320°
Per cent. insoluble.	18	22	25	28	31	34	36	37

C. H. B.

Formation of Sulphuric Acid by Burning Illuminating Gas. By E. Přiwoznik (*Ber.*, **25**, 2200—2205).—The author discusses the work of other authors on this subject. He has made experiments which show that sulphuric acid and ammonium sulphate are produced by luminous and non-luminous gas flames. By allowing the upper portion of a non-luminous flame to impinge on to the bottom of a platinum dish filled with water, a condensate is formed in concentric rings. The inner ring, which is about as big as a half-kreuzer, consists of ammonium sulphate. It is surrounded by a ring of sulphuric acid, and this by a ring of ammonium sulphate. The author supposes that the ammonia in the outside ring of the condensate is derived from the atmosphere. E. C. R.

Synthesis of Hydrogen Nitride. By W. Wislicenus (*Ber.*, **25**, 2084—2087).—The author has obtained hydrogen nitride by the action of nitrous oxide on ammonia in the presence of metallic sodium. Sodamide, $NaNH_2$, is first formed, and then breaks up into sodium nitride, sodium hydroxide, and ammonia. Potassium amide and zinc amide behave in a similar way. About $\frac{1}{4}$ to $\frac{1}{2}$ gram of sodium, in a porcelain boat, is put into a glass tube and cautiously heated in a stream of ammonia. When all the sodium is converted into amide, a current of dry nitrous oxide is passed over the product heated at 150—250° as long as ammonia is evolved. About 50 per cent. of the theoretical yield is obtained. The same reaction takes place when a mixture of ammonia and nitrous oxide is passed over melted sodium, but the yield is not so good, and small explosions take place. When zinc amide is employed, the yield is very poor. The hydrogen nitride was obtained from the product by the method described by Curtius (Abstr., 1891, 56), whose observations the author confirms.

The author is engaged in examining the action of other oxides on sodamide. E. C. R.

Action of Nitric Oxide on Metals and Metallic Oxides. By P. Sabatier and J. B. Senderens (*Compt. rend.*, **114**, 1429—1432).—The authors have investigated the action of nitric oxide on metals and metallic oxides at temperatures below 500°, or, in other words, below the point at which nitric oxide begins to decompose under the influence of heat alone.

Metals, such as silver and platinum, that do not oxidise when heated in air do not oxidise in nitric oxide. Mercury vapour is not oxidised at 450°, and aluminium remains unchanged. Oxidisable metals like copper, iron, cadmium, and zinc, whether fused or in the form of sheets, or even filings, are but superficially oxidised in nitric oxide even at a dull red heat. Lead, on the other hand, oxidises rapidly, and yields yellow litharge.

Metals obtained in a finely divided state by reduction in hydrogen

are, however, readily oxidised by the nitric oxide, but, as a rule, the products are different from those obtained by heating the same metals in air. Nickel at 200° becomes incandescent, and yields the greenish-yellow monoxide without any sesquioxide; cobalt at 150° becomes incandescent, and yields the maroon monoxide; iron at 200° yields the black monoxide, also with incandescence; copper at 200° yields homogeneous cuprous oxide with a cochineal-red colour, and the same oxide is obtained, with a brighter colour, at a dull red heat, the mass becoming incandescent. Palladium sponge, previously saturated with hydrogen, is not appreciably affected by nitric oxide in the cold, but at 200° it becomes incandescent, and the nitric oxide is completely converted into water and ammonia without any oxidation of the metal.

The behaviour of lower oxides, obtained, as a rule, by reducing higher oxides in hydrogen, was also examined. In many cases the products are different from those obtained by heating the same oxide in air. Yellowish-green manganous oxide, MnO, yields pale-brown Mn_3O_4; brown tungsten dioxide, WO_2, becomes incandescent below 500°, and yields the blue pentoxide W_2O_5; maroon uranium dioxide, UO_2, becomes incandescent below 500°, and is converted into the black oxide U_2O_5; molybdenum sesquioxide, Mo_2O_3, is converted with incandescence into the violet dioxide MoO_2; titanium sesquioxide, Ti_2O_3, yields the white titanic anhydride, TiO_2, without incandescence; stannous oxide below 500° becomes incandescent, and yields stannic oxide. Cuprous oxide and vanadium sesquioxide, V_2O_3, are not oxidised by nitric oxide. C. H. B.

Phosphorus Chloronitride and Phosphamide. By A. Besson (*Compt. rend.*, **114**, 1264—1267).—The formula $PCl_5,8NH_3$, previously ascribed to the compound of phosphorus pentachloride and ammonia (Abstr., 1891, 398), is confirmed by subsequent analyses. If this compound is slowly heated, it loses ammonia. Between 175° and 230° under a pressure of 50 mm. crystals sublime, and if this product is again sublimed under similar conditions, it has the composition PCl_2N. This compound is formed by the action of heat on the compound $PCl_5,8NH_3$, and does not pre-exist in it, for the latter does not sublime below 175°, whereas the chloronitride is distinctly volatile at 100° under reduced pressure. The chloronitride forms highly refractive crystals melting at 106°. The compound obtained by Gladstone $(PCl_2N)_3$ is a polymeride, and melts at 210°.

If after the expulsion of the chloronitride the heating is continued, ammonium chloride begins to sublime at 200°, and after heating at 250—300° for some time, a greyish-white residue of phosphamide, PNH_2, is left. If this is further heated in a current of nitrogen or simply in a tube closed at one end, it gives off ammonia, and the proportion of nitrogen in the residue gradually decreases. At a bright red heat in a vacuum, or in a current of nitrogen, the compound is completely decomposed with liberation of phosphorus.

Phosphamide is partially decomposed at the temperature (a red heat) at which, according to Gerhardt, it is formed, and the nitride

PN_2 described by Liebig and Wöhler does not seem to be the final product of the action of heat on the compound of ammonia and phosphorus pentachloride. C. H. B.

Amorphous Boron. By H. Moissan (*Compt. rend.*, **114**, 617—622). —A summary of the properties of pure amorphous boron. Boric acid is twice treated with less than the theoretical quantity of magnesium powder, and the product, on treatment with an acid, leaves amorphous boron.

Amorphous boron is a bright, maroon-coloured powder which stains the fingers, and can be compressed into a cake. Its sp. gr. is 2·45. It does not fuse at the temperature of the electric arc, but shrinks slightly and increases in density when heated to 1500° in an atmosphere of hydrogen. Its electrical conductivity is very low, the specific resistance being 801 megohms.

Boron takes fire in the air at 700°, and burns in oxygen with a brilliant green flame having little actinic power; in either case the combustion is soon stopped by the formation of a layer of boric anhydride on the surface of the boron. It combines energetically with sulphur at 610° to form a sulphide which is decomposed by water with evolution of hydrogen sulphide; it behaves in the same way with selenium, but does not combine with tellurium.

Boron burns in dry chlorine at 410°, and in bromine vapour at 700°, with the formation of boron chloride and bromide. It is dissolved by bromine water, and more readily by a solution of bromine in potassium bromide solution, but it does not combine with iodine.

It combines with nitrogen at 1230°, but not directly with phosphorus, arsenic, or antimony. Neither does it combine directly with carbon or silicon, although a boron carbide is formed when boron is heated in the electric arc in an atmosphere of hydrogen.

The alkali metals have no action on boron, but magnesium combines with it at a red heat. Iron and aluminium form borides only at high temperatures, whilst silver and platinum combine with it quite readily.

Acids react energetically with boron; sulphuric acid is reduced at 250°; the action of nitric acid is so vigorous as to raise the temperature to incandescence; phosphoric anhydride is reduced to phosphorus at 800°; arsenious and arsenic acids are reduced to arsenic at a dull red heat; iodic acid in solution is reduced to iodine in the cold, and a mixture of the dry acid with boron becomes incandescent, and iodine is evolved; chloric acid is reduced to chlorous acid.

The hydracids react with greater difficulty. Hydrogen fluoride is not attacked until a dull red heat is reached, when boron fluoride is formed and hydrogen liberated. Hydrogen chloride is attacked only at a bright red heat, whilst its aqueous solution has no action whatever on boron.

Sulphurous anhydride is reduced to sulphur at an incipient red heat. Steam is not attacked until a full red heat is attained, but the action, once started, proceeds with great energy, boric acid being formed and hydrogen set free. Carbonic oxide is reduced to carbon at 1200°. Silica is reduced to silicon when heated in a forge. Nitrous oxide is

decomposed by boron at a dull red heat, boron nitride and boric acid being formed; nitric oxide is not affected by it.

Metallic oxides are more readily reduced by boron than by carbon. When, for instance, a mixture of boron and cupric oxide is heated in a glass tube, the reaction which ensues is so violent as to melt the glass. Stannous oxide, litharge, antimonious and bismuth oxides are all readily reduced. A mixture of boron and lead peroxide detonates violently when triturated in a mortar. Ferric and cobaltous oxides are reduced at a red heat, but the oxides of the alkaline earths are not affected. Hydrogen is liberated by boron from fused potassium hydroxide. A mixture of boron, sulphur, and nitre deflagrates at a dull red heat, whilst small quantities of boron projected into fused potassium chlorate burn with a most dazzling flame.

Boron acts very energetically on the metallic fluorides; it decomposes the fluorides of the alkalis and alkaline earths at a bright red heat; zinc fluoride at a dull red heat, boron fluoride being formed; and it acts with even explosive violence on lead and silver fluorides. Its action on the metallic chlorides is not so energetic. The chlorides of the alkalis, the alkaline earths, zinc, and lead are not attacked at a red heat, but mercurous chloride is reduced to mercury at 700°. Lead, zinc, cadmium, and copper iodides are not reduced by boron, but tin and bismuth iodides are reduced with facility. Potassium, sodium, calcium, and barium sulphates are reduced by boron at a red heat to the corresponding sulphides.

Notwithstanding its great affinity for oxygen, boron may be immersed in fused potassium nitrate without any reaction occurring, provided that the temperature is below that at which oxygen is disengaged. Fused potassium nitrite, however, is decomposed by it with great violence. Sodium carbonate is reduced at a dull red heat, potassium carbonate at a somewhat higher temperature, and calcium and barium carbonates not at all.

The arsenites, arsenates, and chromates are all reduced at a dull red heat.

Boron behaves also as a reducing agent in the wet way. It reduces potassium permanganate solution, partially in the cold, entirely on heating. It reduces ferric chloride to ferrous chloride. It precipitates silver from silver nitrate solution in fine crystals, and reduces palladium, platinum, and gold from solutions of the chlorides of these metals.

Boron thus combines with the non-metals much more readily than with the metals. It is a more powerful reducing agent than either silicon or carbon, and on the whole is most nearly allied to the latter element. Jn. W.

Boron Iodide. By H. Moissan (*Compt. rend.*, **114**, 622—623).—A criticism of Besson's work (this vol., p. 771). The "active boron" of that author is probably a mixture of iron and sodium borides. A question of priority is also discussed. Jn. W.

Behaviour of Molecular Compounds on Dissolution. By G. Bodländer (*Zeit. physikal. Chem.*, **9**, 730—743).—If a solution of silver

chloride in aqueous ammonia is brought to crystallise by evaporation, silver chloride alone separates out, owing to a portion of the ammonia which holds the salt in solution being carried off along with the water. If, on the other hand, a concentrated solution of ammonia, containing at least 8·5 per cent. NH_3, is heated in a closed vessel with excess of silver chloride, and the clear solution then cooled, crystals separate out which differ altogether in appearance and properties from those of silver chloride. Similar crystals can be obtained by the addition of alcohol to a concentrated aqueous solution of silver chloride in ammonia. These crystals begin to decompose as soon as they are removed from the solution, losing ammonia and leaving nothing but silver chloride behind. The determination of their composition is therefore attended with some difficulty, but by analysing the solution from which they were separated, and thus determining the amounts of silver chloride and ammonia which had been removed, their composition was found to be $2AgCl,3NH_3$.

The solubility of silver chloride in water containing ammonia is known to depend on the amount of ammonia present, and at first increases very rapidly as more and more ammonia is added. When the solution, however, contains about 5 gram-molecules of NH_3 per litre, the solubility of the silver chloride is found to have reached a limit, and on further increasing the amount of ammonia very little more goes into solution. This fact may be explained by assuming that this point corresponds with a saturated solution of $2AgCl,3NH_3$, and if this is the only soluble compound formed by silver chloride and ammonia, it is evident that the saturated solution would be incapable of taking up more silver chloride. The compound $2AgCl,3NH_3$, is quite insoluble in alcohol, and silver chloride therefore does not dissolve in alcohol containing ammonia.

If lead acetate is added to a solution of silver chloride in aqueous ammonia, a precipitate of lead chloride is formed; potassium iodide causes a precipitate of silver iodide, and ammonium sulphide throws down silver sulphide. It therefore appears that the silver and chlorine in this compound are present as free ions, and that the compound is not a complex salt but a true molecular compound. This view is further confirmed by the determination of the reduction of the freezing point of water by this compound. The molecular reduction is found to be two to three times greater than the normal 18·5, and therefore decomposition of the substance must have taken place on solution. This decomposition cannot be into the constituents NH_3 and AgCl, as in this case the silver chloride would have separated from the solution, and can therefore only be electrolytic in character and due to the dissociation of the AgCl into its ions. This view is confirmed by the determination of the molecular conductivity of the compound, the values of Van't Hoff's coefficient i obtained in this manner agreeing with those calculated from the reduction of the freezing point. A further confirmation is obtained from the fact that the addition of NH_4Cl or $AgNO_3$ reduces the solubility of the compound $2AgCl,3NH_3$ in water, in accordance with Nernst's law of the influence of the presence of one of its ions in solution on the solubility of an electrolyte. It is evident, therefore, that the com-

pound $2AgCl,3NH_3$ is a true molecular compound which undergoes electrolytic dissociation, but does not decompose on being dissolved in water.

The very small solubility of silver bromide in aqueous ammonia prevents the preparation of a crystalline compound of the two, but from the similarity in the behaviour of silver bromide towards solutions containing varying amounts of ammonia, the formation of a compound similar to that above described is highly probable.

H. C.

Strontium Phosphates. By L. Barthe (*Compt. rend.*, **114**, 1267—1269).—Normal strontium phosphate is obtained by adding a cold ammoniacal solution of 90 parts of crystallised sodium phosphate to a cold ammoniacal solution of 100 parts of crystallised strontium chloride, both quite free from carbonate. The precipitate is colloïdal and has a bluish tinge; after drying at 100°, it is anhydrous.

Distrontium hydrogen phosphate is obtained by adding a slightly acid solution of 70 parts of crystallised strontium chloride to a similar solution of 100 parts of crystallised sodium phosphate at a temperature not exceeding 50°. It is at first gelatinous, but gradually becomes granulo-crystalline. When heated in a gas and air blowpipe, it yields the pyrophosphate, $Sr_2P_2O_7$, which has a bluish tinge.

Strontium dihydrogen phosphate, $SrH_4(PO_4)_2 + 2H_2O$, is obtained by mixing equal volumes of decinormal solutions of phosphoric acid and strontium hydroxide at any temperature between 15° and 100°. If a cold solution of distrontium phosphate in phosphoric acid is concentrated at a temperature not exceeding 50°, it yields nacreous tabular crystals of the composition $2SrO,H_2O,3P_2O_5 + H_2O$, soluble in water. If the temperature exceeds 50°, the composition of the product varies; it is only slightly soluble in water. The strontium dihydrogen phosphate is obtained in spherical masses of crystals by diluting 10 grams of 50 per cent. phosphoric acid with 90 grams of water, allowing it to remain in contact with excess of distrontium hydrogen phosphate for 24 hours, filtering, and allowing the solution to evaporate spontaneously under a bell jar for several weeks.

C. H. B.

Basic Zinc Nitrates. By J. Riban (*Compt. rend.*, **114**, 1357—1358).—When pure zinc is dissolved in nitric acid diluted with about its own volume of water, zinc nitrate is first formed, but if the solution is boiled with excess of the metal, a white, basic salt separates, and if the liquid is filtered and allowed to cool, it gradually deposits further quantities of a basic salt. The first portion of the deposit from the filtrate consists of a mixture of tabular and acicular crystals, whilst the last portion consists of very short needles in stellate groups, of the composition $6ZnO,N_2O_5,8H_2O$.

The salt crystallising in plates can be separated from the acicular crystals by dissolving the mixture in the mother liquor, or, better, heating it with the mother liquor in sealed tubes at 150° for several hours. It then separates in nacreous lamellæ of the composition

$6ZnO,N_2O_5,7H_2O$. They belong to the rhombic or monoclinic system, and are almost insoluble in cold water. C. H. B.

Cadmium Hydrosilicate. By G. Rousseau and G. Tite (*Compt. rend.*, **114**, 1262—1264).—The layer that forms on the inner surface of the glass tubes in the preparation of basic cadmium nitrate is freed from the cadmium salt by treatment with alcohol, and is removed from the glass by prolonged treatment with warm water. It forms long scales which, when rubbed between the fingers, break up into microscopic needles, showing longitudinal extinction in parallel light. It has the composition $2CdO,2SiO_2,3H_2O$, and is soluble in hydrochloric acid with separation of pulverulent silica. At a dull red heat it loses very little water, but when heated to orange-redness it melts and then intumesces in consequence of the escape of water. If the heating is continued, cadmium oxide is volatilised, and after prolonged heating a residue of silica alone remains. It would seem that the presence of water is essential to the stability of the molecule.

It is singular that the only two metals which have formed silicates during the preparation of basic nitrates, namely, silver and cadmium, are also the two that hitherto have not yielded any definite silicates. The silver compound is a nitrosilicate (this vol., p. 684), but the cadmium hydrosilicate and basic cadmium nitrate show no tendency to combine. C. H. B.

Basic Nitrates. By G. Rousseau and G. Tite (*Compt. rend.*, **114**, 1184—1186).—The hydrated nitrates were heated in sealed tubes between 100° and 350° in presence of fragments of marble, or, in the case of calcium nitrate, quick lime.

Nickel nitrate, at 350°, yields the salt $5NiO,N_2O_5,4H_2O$ in beautiful, green crystals that act on polarised light, and are not decomposed by boiling water.

Zinc nitrate yields the salt $5ZnO,N_2O_5,6H_2O$ in acicular crystals, which show longitudinal extinction in parallel light. The basic salt is slowly decomposed by cold water and rapidly by hot water, with formation of zinc hydroxide. This decomposition seems to have been unnoticed before, and it is probable that many of the basic nitrates described are mixtures of the hydroxide and this crystallisable basic salt.

Cadmium nitrate, between 300° and 350°, yields nacreous, white lamellæ of the composition $5CdO,2N_2O_5,8H_2O$. They show longitudinal extinction in parallel light, and are immediately decomposed by cold water with separation of amorphous cadmium hydroxide.

Calcium nitrate, in presence of the oxide at 180—200°, yields a basic salt, $2CaO,N_2O_5,2H_2O$, in needles which show longitudinal extinction. They are insoluble in alcohol, but are rapidly decomposed by water. C. H. B.

Compounds of Cuprous Iodide and Ammonium Thiosulphate. By E. Brun (*Compt. rend.*, **114**, 667—668).—When powdered cuprous iodide, or a solution of it in ammonium iodide, is added to a large excess of 50 per cent. ammonium thiosulphate solution, it

at first dissolves, but the solution soon becomes cloudy, and a well-crystallised white powder is thrown down. When this is dried by means of the filter-pump and recrystallised, it forms white crystals, having the composition $Cu_2I_2,2NH_4I,8(NH_4)_2S_2O_3$, stable at the ordinary temperature, decomposing slowly at 100°, and at a higher temperature giving off vapours of sulphur, iodine, ammonia, and sulphurous anhydride. Its solution decolorises iodine with precipitation of cuprous iodide, and is decomposed when boiled, cuprous sulphide being precipitated.

By adding a solution of cuprous iodide in ammonium iodide to one of the previous compounds, or to a more dilute solution of ammonium thiosulphate, until a slight permanent precipitate appears, a precipitate of pale yellow, crystalline needles is thrown down, having the composition $7(NH_4)_2S_2O_3,Cu_2S_2O_3,4Cu_2I_2,4H_2O$. It is insoluble in water, very unstable, and yields the same products of decomposition as the first compound.

Finally, when a concentrated solution of ammonium thiosulphate is slowly added to one of ammonium iodide saturated with cuprous iodide, taking care to avoid excess of thiosulphate, a third colourless substance is obtained, which crystallises in needles, is insoluble in water, and has the composition $Cu_2I_2,(NH_4)_2S_2O_3,H_2O$.

Potassium and sodium thiosulphates, and other iodides, such as those of silver and lead, form analogous products. Jn. W.

Graphical Chemistry of Glass. By E. Nickel (*Zeit. physikal. Chem.*, **9**, 709—721).—Roughly speaking, and neglecting chance impurities, the composition of an ordinary glass may be expressed by a formula such as $mNa_2O + nCaO + pSiO_2$, and glasses may be compared one with another by comparing the values of m, n, and p, or better still, by fixing one of the values, say that of n, as unity and then comparing the other two m/n and p/n. In cases where other metals are present, the expression is somewhat more complicated, but leaving out of account oxides such as those of iron and aluminium, may still be given in a somewhat similar manner, for instance, with $m_1Na_2O + m_2K_2O + n_1CaO + n_2PbO + n_3MgO + pSiO_2$, where, instead of m/n we may write $(m_1 + m_2)/(n_1 + n_2 + n_3)$, or generally $\Sigma m/\Sigma n$. A useful method of comparing different glasses with one another would now be given by plotting the values of m/n graphically against those of p/n. Better still, however, it is to regard the glass as of the composition $Na_{2m}Ca_nSi_pO_{(m+n+2p)}$ and to employ the quantity $(m + n + 2p)$, the oxygen ratio, in place of p in the comparison.

The author gives the graphic representation of a large number of different glasses in accordance with the above plan, and discusses the relationships which this mode of representation renders apparent. There does not appear to be any justification for a "normal" formula for glass, such as that proposed by Beurath, $R'_2O,CaO,6SiO_2$.

H. C.

Nickel. By P. Schützenberger (*Compt. rend.*, **114**, 1149—1154).—Pure nickel sulphate, carefully crystallised from a solution containing no free acid, was heated at 440° until it ceased to lose weight. A weighed quantity of the anhydrous sulphate was then heated for

some time between dull redness and bright redness, care being taken that the flame was always an oxidising flame. The nickel oxide left was weighed; Ni = 58·57—58·72.

The nickel oxide thus obtained was reduced in hydrogen; Ni = 58·50—58·53.

When the greenish-yellow oxide formed between dull redness and bright redness is heated almost to a white heat it contracts considerably, acquires a deeper green tint, and loses 0·4 to 0·5 per cent. in weight. This loss takes place even in an atmosphere of nitrogen, and cannot be attributed to reduction, neither does it seem to be due to dissociation. If the deep green oxide is reduced in hydrogen, the results give Ni = 59·8.

Cobalt oxide shows a similar loss of weight when very strongly heated, and analysis of the product leads to Co = 60·0.

If the strongly heated nickel oxide is reduced in hydrogen, the residue retains a small quantity of oxygen, but if allowed to remain at the ordinary temperature for 24 hours and again heated in hydrogen, a small quantity of water is immediately produced. Two or three repetitions of this process are required in order to remove the whole of the oxygen. If the first quantity of reduced nickel from this oxide is treated with warm dilute sulphuric acid the unreduced oxide remains as a very finely-divided, pale yellow powder. The reduced nickel from the strongly heated oxide does not agglomerate when heated. C. H. B.

Nickel and Cobalt Fluorides. By C. Poulenc (*Compt. rend.*, **114**, 1426—1429).—When an anhydrous metallic chloride is heated to fusion with an excess of ammonium fluoride for about a quarter of an hour, a double fluoride of ammonium and the particular metal is obtained. The whole mass is soluble in water, but the ammonium chloride formed can be removed by repeated washing with boiling alcohol. The double fluoride,* MF_n, nNH_4F, is amorphous, and when heated to redness in an atmosphere of inert gas yields an amorphous anhydrous fluoride. When the latter is heated in an atmosphere of dry hydrogen fluoride, it becomes crystalline.

Nickel fluoride, NiF_2.—The double ammonium salt is a yellowish, amorphous powder, soluble in water but insoluble in alcohol. The simple amorphous fluoride is also yellow and is almost insoluble in water. When heated in hydrogen fluoride at 1200—1300°, it is converted into beautiful, green, elongated prisms, which partially volatilise, without fusion, during their production. They are almost insoluble in water, quite insoluble in alcohol and ether, and are not attacked by warm nitric, hydrochloric, or sulphuric acid; sp. gr. = 4·63. The fluoride is converted into the oxide when heated in presence of air, into the sulphide when heated with sulphur, and into metallic nickel when heated in hydrogen. Water vapour converts it into the black oxide, or at a higher temperature into the green oxide, the crystalline form of the fluoride being retained in both cases; hydrogen

* The formulæ of the double potassium fluorides given in a previous paper (this vol., p. 781) are incorrect; they should be $NiF_2,2KF$, and $CoF_2,2KF$.

sulphide, at a red heat, yields the yellow crystalline sulphide; hydrogen chloride, on heating, converts the fluoride into the chloride; fused alkaline carbonates yield nickel oxide and alkaline fluorides.

Cobalt fluoride, CoF_2, when amorphous, is a rose-coloured powder, somewhat soluble in water. When heated in hydrogen fluoride at 1200—1300°, it melts to a ruby-red, translucid mass with a distinctly crystalline fracture, but sublimes with great difficulty even at 1400°, and in this respect differs markedly from the nickel salt. The crystallised fluoride forms small, rose-coloured prisms; sp. gr. = 4·43. It is slighly soluble in water, but insoluble in alcohol or ether. Nitric, hydrochloric, and sulphuric acids attack it slowly in the cold, and more rapidly on heating, but in other respects its properties are similar to those of the nickel compound. C. H. B.

Permolybdates. By E. Péchard (*Compt. rend.*, **114**, 1358—1361). —*Sodium Permolybdate.*— Fused sodium dimolybdate is finely powdered and mixed with hydrogen peroxide solution. On gently heating, the salt dissolves readily, and, if the yellow solution is concentrated, the permolybdate, $NaMoO_4 + 3H_2O$, separates in yellow, prismatic crystals. This salt melts at 80°, gives off oxygen at about 200°, and, when strongly heated, leaves a residue of sodium dimolybdate.

Magnesium permolybdate, $Mg(MoO_4)_2 + 10H_2O$, is obtained in a similar way, and crystallises in slender needles very soluble in water.

Barium permolybdate is obtained in a similar way, or by the action of ammonium permolybdate on barium chloride. It crystallises in microscopic, yellow octahedra of the composition $Ba(MoO_4)_2 + 2H_2O$.

Permolybdates of the heavy metals are obtained by double decomposition with ammonium permolybdate. The copper salt is greenish-yellow, and has the composition $Cu(MoO_4)_2 + H_2O$; it is soluble in ammonia and in hydrochloric and nitric acids. The silver salt, $AgMoO_4$, forms yellow, microscopic octahedra. The mercurous salt is orange, and can be used in analysis for the separation of permolybdic acid from alkaline bases. C. H. B.

Complex Inorganic Acids: Phosphotungstic Acids. By F. Kehrmann and M. Freinkel (*Ber.*, **25**, 1966—1973).—When barium chloride is added to a solution of the ammonium salt of the acid $22WO_3,P_2O_5,7H_2O$ (Abstr., 1891, 1159), a double *barium ammonium salt* is obtained, and when a slight excess of silver nitrate is added to a solution of the latter, the *salt* $22WO_3,P_2O_5,4BaO,3Ag_2O + 34H_2O$ separates in lustrous prisms. The *salt* $22WO_3,P_2O_5,7K_2O + 31H_2O$ is prepared by adding an excess of potassium chloride to a solution of phosphoduodecatungstate (*loc. cit.*), suspending the washed precipitate in boiling water, and adding thereto a dilute solution of potassium carbonate until only a small portion remains undissolved; on evaporating the filtrate, the salt separates in colourless, translucent pyramids. It is readily soluble in hot and cold water, but insoluble in alcohol, and crystalline double salts are obtained when salts of the

heavy metals are added to its concentrated aqueous solution. Thus, the salt $22WO_3,P_2O_5,2K_2O,5BaO + 48H_2O$ separates in colourless octahedra on the addition of barium chloride.

When the salt $22WO_3,P_2O_5,7K_2O + 31H_2O$, is dissolved in a little water, and, after adding an excess of dilute hydrochloric acid, the solution is boiled and filtered from potassium phosphoduodecatungstate, a potassium salt separates slowly from the filtrate; this is converted into the ammonium salt, the latter mixed into a paste with concentrated hydrochloric acid (3 parts) and nitric acid (1 part), and the mixture heated to boiling, when the salt decomposes with the evolution of nitrogen, a solution being thus obtained from which the acid $21WO_3,P_2O_5,3H_2O + 30Aq$ separates on cooling. The potassium and ammonium salts are described. The authors have studied the decomposition of the salt $22WO_3,P_2O_5,7K_2O + 31H_2O$ quantitatively, but reserve the discussion of their results until more exact data are obtained. A. R. L.

Mineralogical Chemistry.

Fluorine in Recent and Fossil Bones. By A. Carnot (*Compt. rend.*, **114**, 1189—1192).—Analyses of many human and animal bones show that the proportion of calcium fluoride varies from 0·35 to 0·63, and that of calcium chloride from 0·20 to 0·39. Elephants' tusks contain an unusually small proportion of calcium fluoride and an abnormally large proportion of magnesium phosphate.

Fossil bones from post-tertiary formations contained from 0·88 to 3·82 per cent. of calcium fluoride, the proportion of calcium chloride being practically the same as in recent bones.

Fossil bones from formations of various ages were found to contain more than 10 times as much fluorine as recent bones, the proportion of calcium fluoride reaching to as high as 6·21 per cent. This increase is doubtless due to metamorphism, the fluorine being derived either from solutions of alkaline fluorides or from slow replacement by fluorine minerals with which the bones have been in contact. Direct experiment shows that solutions of alkaline fluorides act on bones with formation of calcium fluoride. There seems to be a tendency towards the formation of a crystalline fluorophosphate containing the same proportion of fluorine as apatite, but the proportion may rise higher than in apatite by reason of the action of the alkaline fluoride on the calcium carbonate in the bone. C. H. B.

Artificial Reproduction of Leucite. By A. Dubois (*Compt. rend.*, **114**, 1361—1363).—Potassium hydrogen fluoride is slowly heated to distinct redness and alumina is added to the fused salt. Silica is then thrown in in successive small quantities until all the alumina has been dissolved. When the mass is cooled and treated

with water, crystals of leucite are obtained several millimetres in length.

Leucite is also obtained in large crystals by adding alumina to fused potassium silicofluoride, but a double fluoride of aluminium and potassium is formed at the same time, and must be removed by treatment with potassium hydroxide solution.

A third method for the preparation of leucite consists in adding silica to a fused mixture of potassium fluoride and aluminium fluoride, prepared either by heating together calcined alumina and potassium hydrogen fluoride, at first slowly and afterwards at a red heat, or by adding to fused potassium fluoride either the product of precipitating the wash waters of the previous methods by alum or the double fluoride of potassium and aluminium.

Aluminium potassium fluoride, $3KF,AlF_3$, is obtained in elongated, birefractive crystals by heating an intimate mixture of calcined alumina and potassium hydrogen fluoride, at first slowly and afterwards to complete fusion, and extracting the cooled product with water. It is only slightly soluble in boiling water, but dissolves in a moderately concentrated and warm potassium hydroxide solution.

C. H. B.

Preservation of Mineral Waters. By P. Parmentier (*Compt. rend.*, **114**, 1363—1366).—Mineral waters containing carbonic anhydride, especially if they contain iron salts also, can only be preserved unchanged by collecting them in vessels previously filled with pure carbonic anhydride. It is essential that no trace of air should remain in the collecting vessels and that the water should not come in contact with air while the vessels are being filled. C. H. B.

Organic Chemistry.

Action of Fatty Acids on Olefines. By Béhal and Desgrez (*Compt. rend.*, **114**, 676—677).—The acid residue unites with the olefine hydrocarbon having the fewest hydrogen atoms attached, whilst the acid hydrogen unites with the remaining ethylene carbon, an ethereal salt of a secondary alcohol thus being formed.

Secondary octyl acetate, $C_6H_{13}\cdot CHMe\cdot OAc$, is formed when hexyl ethylene boiling at 122°, and prepared by the action of zinc chloride on methyl hexyl carbinol, is heated with glacial acetic acid (3 vols.) in a sealed tube for 20 hours at 300°. The fraction of the product boiling above 120° is washed, dried, and redistilled, when a liquid of agreeable odour, resembling that of raspberries, passes over at 189—190°. It yields the alcohol when hydrolysed with alcoholic potash.

Secondary heptyl acetate, $C_5H_{11}\cdot CHMe\cdot OAc$, a liquid boiling at 171—173°, identical with the acetate prepared from methyl pentyl carbinol, and having a pleasant odour resembling that of myrrh,

is obtained in a similar way when the pentyl ethylene boiling at 95—96°, and prepared by heating primary heptyl iodide in a reflux apparatus with alcoholic potash, is heated with acetic acid. The heptyl iodide is conveniently prepared from the alcohol obtained by reducing œnanthaldehyde.

The diacetin of propylene glycol, $OAc{\cdot}CHMe{\cdot}CH_2{\cdot}OAc$, a liquid of agreeable odour boiling at 186—187°, is obtained when alkyl acetate is heated in a similar manner with glacial acetic acid for 25 hours at 275—285°. JN. W.

Trimethylene. By J. W. BRÜHL (*Ber.*, **25**, 1952—1956).—The author's previous work has shown that in the case of compounds containing ethylene or acetylene groups, the observed molecular refractions and dispersions are greater than the calculated, whereas the values exhibit close agreement in the case of closed ring compounds containing single bonds. Thomsen found that propylene and trimethylene have the same heats of combustion. The author concludes from his determinations of the molecular refraction and dispersion of Gustavson's dichlorotrimethylene (Abstr., 1891, 159), that trimethylene is not a homologue of the olefines, and that it contains no ethylenoïd bonds. The thermic constants of the dichlorotrimethylene are being determined by Berthelot for the sake of comparing them with the isomeric propylene derivatives. A. R. L.

Higher Homologues of Acetylene. By F. KRAFFT and L. REUTER (*Ber.*, **25**, 2243—2251; compare Krafft, Abstr., 1884, 1108). The authors' results are in general agreement with those of Favorsky (Abstr., 1888, 798 and 1168), and they show that the hitherto known higher homologues of acetylene, from dodecylidene upwards, are di-substitution derivatives. When hexadecylene bromide, $C_{16}H_{32}Br_2$, is heated with the necessary quantity of very dilute alcoholic potash at 40—50°, *bromhexadecylene*, $C_{16}H_{31}Br$, boiling at 198—200° (18 mm.), is obtained; on heating the latter with a slight excess of alcoholic potash at 200°, methyltridecylacetylene, $CMe{:}C{\cdot}C_{13}H_{27}$, is formed; it does not give a precipitate with alcoholic silver nitrate (Béhal's reagent; Abstr., 1888, 930). When the last-mentioned hydrocarbon is heated at 200—220° with one-tenth of its weight of sodium, and the sodium derivative is decomposed by alcohol, *tetradecylacetylene*, $CH{:}C{\cdot}C_{14}H_{29}$, which gives a precipitate of the compound $C_{16}H_{29}Ag_2NO_3$ on addition of alcoholic silver nitrate, is produced; the silver derivative yields the corresponding hydrocarbon when treated with dilute hydrochloric acid in the cold. Tetradecylacetylene is also obtained when hexadecylene bromide is heated under diminished pressure with potassium hydroxide; after rectification under diminished pressure, it solidifies on cooling; it melts at 15°, boils at 155° (15 mm.), and the liquid hydrocarbon has a sp. gr. at 15° = 0·7999. On heating tetradecylacetylene with alcoholic potash at 160—180°, methyltridecylacetylene is formed. Methylpentadecylacetylene, $CMe{:}C{\cdot}C_{15}H_{31}$, boiling at 180° (15 mm.), is obtained by the action of alcoholic potash on octadecylene bromide; whereas, if the same bromide is heated with potassium hydroxide, under dimin-

ished pressure, hexadecylacetylene, $CH{:}C{\cdot}C_{16}H_{33}$, melting at 26° and boiling at 180° (15 mm.) is produced; the last-mentioned hydrocarbon has a sp. gr. in the liquid state = 0·7983 at 26°, and gives a precipitate with alcoholic silver nitrate.

Methylundecylacetylene, $CMe{:}C{\cdot}C_{11}H_{23}$, melting at 6·5° and boiling at 134° (15 mm.), and *duodecylacetylene*, $CH{:}C{\cdot}C_{12}H_{25}$, boiling at 128° (15 mm.), are obtained from tetradecylene bromide in a similar manner to the above-described homologues, and exhibit analogous behaviour to them.

Methylnonylacetylene, $CMe{:}C{\cdot}C_9H_{19}$, melting at −9° and boiling at 105° (15 mm. pressure), and *decylacetylene*, $CH{:}C{\cdot}C_{10}H_{21}$, boiling at 95—97°, have also properties analogous to their homologues.

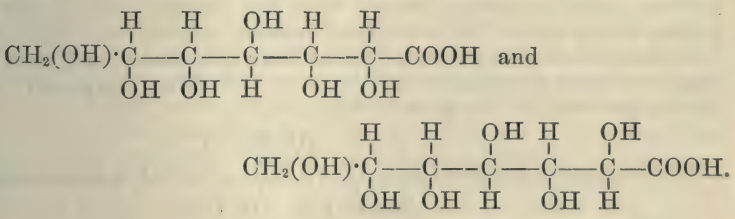
A. R. L.

Arsenic Cyanide. By E. Guenez (*Compt. rend.*, **114**, 1186—1189).—Very finely powdered arsenic is placed in a strong flask with a slight excess of dry cyanogen iodide, and about 10 parts of very carefully-dried carbon bisulphide is added. The reaction begins at the ordinary temperature, but the flask must be heated on the water-bath for some time before the change is complete. When all the arsenic has disappeared, the product is washed with carbon bisulphide until all arsenic iodide is removed, and the insoluble part is kept in sealed vessels filled with dry carbonic anhydride.

The arsenic cyanide thus obtained has the composition $AsCy_3$, and forms yellowish, microscopic crystals. It is rapidly attacked by atmospheric moisture, and is almost instantly decomposed by water with formation of arsenious and hydrocyanic acids. When heated, about one-third of the cyanogen is given off, and a residue of arsenic and paracyanogen is left. Concentrated sulphuric acid has very little action in the cold, but on heating, sulphurous anhydride and carbonic oxide are liberated and ammonium sulphate is formed. Iodine, even in the cold, forms arsenic iodide and cyanogen iodide; if heated, the change is practically instantaneous. When mixed with potassium chlorate, arsenic cyanide detonates violently if struck.

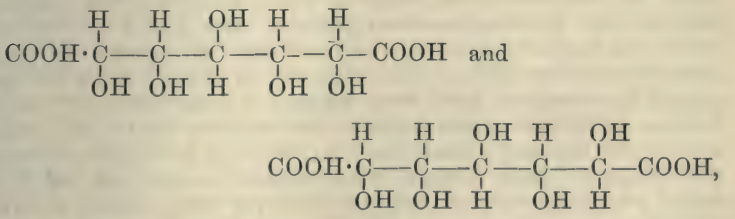
Phosphorous cyanide has been obtained by a similar reaction.

C. H. B.



Formation of Zinc Cyanide on Heating Organic Substances containing Nitrogen with Zinc-dust. By H. Aufschläger (*Monatsh.*, **13**, 268—275).—The author finds that a very large proportion of carbon compounds containing nitrogen yield zinc cyanide when they are exposed to the action of zinc-dust at a low red heat. Such substances are the amides of carbonic acid, carbamide, and its derivatives, proteïd substances, and similarly constituted compounds; and the reaction may be conveniently employed in showing their presence. A typical reaction is that between carbamide and zinc-dust, which is represented by the equation $2CO(NH_2)_2 + 3Zn = Zn(CN)_2 + 2ZnO + 2NH_3 + H_2$, the yield of zinc cyanide being about 50 per cent. of that required by theory.

G. T. M.



Sugars Richer in Carbon from Glucose (Dextrose). By E. Fischer and others (*Annalen*, **270**, 64—107).—In this paper experiments are described on the ascent of the glucose (dextrose) series of

sugars, the method employed being the same as used by Fischer and Passmore (Abstr., 1890, 1230) in the ascent of the mannose series. By this method two stereoisomeric glucoheptonic acids, which are provisionally designated the α- and β-compounds, are formed from glucose, thus corresponding with the case of mannose (Abstr., 1890, 1389). One of these acids, the α-compound, is identical with that obtained by Kiliani (Abstr., 1886, 526 and 687). In simpler cases, in which optically inactive materials have been dealt with, racemic compounds have invariably been produced; that is, the two stereoisomerides have been formed in equal amount. In the present case, however, the α-compound is always obtained in the larger quantity, and when the reaction is conducted at 20—25°, the quantity of the α-compound isolated in the pure state is about 73 per cent. of the theoretical, whereas the β-compound is almost absent from the product; the latter is obtained, however, to the extent of 13 per cent. when the operation is conducted at 40°, so that the course of the reaction is doubtless a function of the temperature.

Representing glucose by the configuration given by Fischer (Abstr., 1891, 1445), the two acids derived from it would have the configurations :—

Now, of the two dicarboxylic acids (pentahydroxypimelic acids) corresponding to them,

the first is optically inactive, and, as a matter of fact, it is found that the pentahydroxpimelic lactonic acid (Abstr., 1886, 936) which Kiliani obtained from his dextrosecarboxylic acid (α-glucoheptonic acid) yields an optically inactive pentahydroxypimelic lactonic acid on oxidation, whereas that obtained from β-glucoheptonic acid is optically active. It follows, therefore, that α- and β-glucoheptonic acids are represented by the configurations I and II respectively. α- and β-glucoheptose must be represented by corresponding formulæ; the synthesis having been carried further from the α-com-

pound, it is found that, as indicated by theory, two gluco-octonic acids are obtained from it; the configuration of these cannot be determined from the optical behaviour of the corresponding dicarboxylic acids, as both these are optically inactive, and, according to theory, the next possible optically active dicarboxylic acid would be derived from gluco-deconic acid, $C_{10}H_{20}O_9$.

Preparation of the Glucoheptonic Acids.—Anhydrous American grape sugar (5 kilos.) is dissolved in a large glass flask in 3 per cent. hydrogen cyanide solution (25 litres) and ordinary ammonia solution (10 c.c.) added. The mixture, after remaining at a temperature of 25° for six days, is boiled with a solution of barium hydroxide (6·7 kilos.) in water (20 litres), for several hours, until it no longer smells of ammonia; the hot filtrate is then acidified with sulphuric acid, the boiling repeated to remove the unaltered hydrogen cyanide, the sulphuric acid exactly precipitated with barium hydroxide, and the filtrate evaporated to a thick syrup in a flat dish heated by means of steam at a low tension. After remaining in the cold for several weeks, the greater portion of the α-heptonic lactone has separated; the mass is triturated with 80 per cent. alcohol, and the crystals (weighing about one-third that of the glucose employed) collected, a further quantity being obtained from the filtrate; whilst the last mother liquor yields the β-heptonic lactone (see below). The crude α-heptonic lactone is purified by dissolving it in water, and precipitating by means of alcohol, the yield of the pure compound being 30—35 per cent. of the glucose employed.

α-Glucoheptose, $CH_2(OH)\cdot\overset{OH}{\underset{H}{C}}\!-\!\overset{OH}{\underset{OH}{C}}\!-\!\overset{H}{\underset{OH}{C}}\!-\!\overset{OH}{\underset{H}{C}}\!-\!\overset{H}{\underset{OH}{C}}\cdot CHO$, is obtained when α-glucoheptonic lactone (50 grams) is dissolved in water (500 grams) and the solution cooled to its freezing point; dilute sulphuric acid (4 c.c.) and $2\frac{1}{2}$ per cent. sodium amalgam (250 grams) are now added with agitation, and, after a while, another small quantity of acid, so that the solution remains acid. The liquid is then again cooled to incipient freezing, and another 250 grams of sodium amalgam added as before. The operation is stopped when 750 grams of sodium amalgam have been added; it lasts about 50 minutes. Sodium hydroxide is now added to the solution until it still remains alkaline at the end of half an hour, when it is exactly neutralised with sulphuric acid, warmed with animal charcoal, the hot filtrate mixed with eight times its volume of 96 per cent. alcohol, allowed to remain at the temperature of the room for 12 hours, and then filtered from the greater portion of sodium sulphate and organic sodium salt. The alcohol is then distilled from the filtrate, and the residual solution concentrated on the water-bath to its point of crystallisation. The crystals are collected after some hours, and washed successively with 50 per cent., 80 per cent., and absolute alcohol; the dried product is then colourless, free from ash, and almost chemically pure, its amount being 32—38 per cent. of the weight of lactone employed. A considerable portion of the lactone is converted into the acid during the reaction, and may be recovered as sodium salt from the

alcoholic precipitate mentioned above. α-Glucoheptose separates from its aqueous solutions in rhombic crystals

$$a : b : c = 0{\cdot}8040 : 1 : 1{\cdot}7821,$$

which undergo no alteration at 100°; it melts at 180—190°, has a faintly sweet taste, and requires 10·5 parts of water at 14° for dissolution, being very readily soluble in hot water, and sparingly so in absolute alcohol. It exhibits birotation to a slight extent. 2·5 grams dissolved in 20 c.c. of warm water, cooled, and made up to 25 c.c. at 20°, gave the specific rotatory power $[\alpha]_{D20^\circ} = -19{\cdot}7$, and this was unaltered after 12 hours, whereas a portion dissolved in water at 20° gave, 15 minutes after preparation, $[\alpha]_{D20^\circ} = -25$; this value was reduced to the first, however, after some hours. The sugar is not fermentable with yeast, and reduces Fehling's solution somewhat less than glucose; a small quantity of furfuraldehyde is produced on heating it with dilute sulphuric or hydrochloric acid, but the chief product is humous substance. When a solution of α-glucoheptose in water (5 parts) is treated at 20° with bromine (2 parts), and at the end of three days the excess of bromine boiled off, and the hydrogen bromide precipitated with silver oxide, α-glucoheptonic acid may be isolated, the yield being 60 per cent. of the sugar.

α-Glucoheptose phenylhydrazone, $C_7H_{14}O_6{\cdot}N_2HPh$, is very readily soluble in water, and concentrated solutions must therefore be employed in its preparation; it resembles the hydrazones of the sugars already described, melts, when quickly heated, at 170° with decomposition, and is sparingly soluble in cold alcohol, and almost insoluble in ether. The *osazone*, $C_7H_{12}O_5(N_2HPh)_2$, is prepared by heating a solution of the sugar in water (10 parts) with phenylhydrazine (2 parts) and 50 per cent. acetic acid (1 part) on the water-bath for an hour, and isolating in the usual way. It forms yellow bunches of needles, and when quickly heated darkens at 190°, and melts at 195° with evolution of gas; it requires about 60 parts of boiling absolute alcohol for dissolution, and is almost insoluble in water and ether. It closely resembles glucosazone and yields a heptosone when treated with concentrated hydrochloric acid in the manner described under oxyglucose (glucosone) (Abstr., 1888, 1267; 1889, 484). When α-glucoheptose is treated in the manner described by Erwig and Königs for the preparation of pentacetyldextrose (Abstr., 1889, 952), it yields a *hexacetyl* derivative melting at 156°, and sparingly soluble in cold water; whilst, if the sugar is heated with an equal quantity of anhydrous sodium acetate and acetic anhydride (4 parts), in a reflux apparatus for 15 minutes, *decacetyldiglucoheptose*, $C_{34}H_{46}O_{23}$, is produced; after five recrystallisations from hot water, it melts at 131—132°.

α-Glucoheptitol, $C_7H_{16}O_7$, is obtained when α-glucoheptose (10 grams) is dissolved in water (100 grams) and treated with 20 per cent. sodium amalgam (500 grams in all); the solution is kept acid, and is well agitated during the addition of the amalgam, the reaction being complete in 2—3 hours, when it no longer reduces Fehling's solution. The compound is isolated in the usual manner, and purified by repeated recrystallisation from boiling methyl or ethyl alcohol.

It crystallises in delicate prisms, melts at 127—128°, is optically inactive, and readily soluble in water, but only sparingly in alcohol. The *heptacetyl* derivative, $C_7H_9(OAc)_7$, is prepared by boiling it in a reflux apparatus for an hour with acetic anhydride and zinc chloride. After being repeatedly recrystallised from water, it forms microscopic plates, and melts at 113—115°. *Benzalglucoheptitol*, $C_7H_{14}O_7{:}CHPh$, is formed when glucoheptitol (1 gram) is dissolved in 50 per cent. sulphuric acid (1·5 c.c.) and benzaldehyde (2 grams) added with vigorous shaking; it is heated for some minutes on the water-bath, and, after 24 hours, the compound is collected, washed with water, and later with ether. It is sparingly soluble in alcohol, crystallises therefrom in delicate, felted needles, and melts at 214°. It is noteworthy that mannitol forms a tribenzyl derivative (Abstr., 1888, 950), and sorbitol and perseïtol dibenzal derivatives (*Ann. Chim. Phys.* [6], **19**, 5), under the same circumstances.

β-Glucoheptonic acid, $CH_2(OH)\cdot\overset{OH}{\underset{H}{C}}-\overset{OH}{\underset{H}{C}}-\overset{OH}{\underset{H}{C}}-\overset{OH}{\underset{H}{C}}-\overset{OH}{\underset{H}{C}}\cdot COOH$, isolated from the last mother liquor, is obtained in the preparation of the α-acid (see above) as follows:—The syrup is boiled with an equal weight of brucine dissolved in hot water (15 parts), the solution treated with animal charcoal, and the filtrate evaporated to a syrup, the acid being in slight excess. The brucine salt separates after several hours; it is collected, washed with a little cold water, and finally recrystallised from alcohol, when it melts at 126°. To obtain the acid, the salt is dissolved in water and boiled with a slight excess of barium hydroxide; the precipitated brucine is filtered from the cool solution, the filtrate evaporated to a syrup, and triturated with cold alcohol. The barium salt is collected, dissolved in hot water, and the barium exactly precipitated with sulphuric acid; on evaporating the filtrate, the lactone principally separates, and is purified by crystallisation from hot absolute alcohol; it forms colourless delicate needles, melts at 151—152°, reduces Fehling's solution, and is very soluble in water. The values for specific rotatory power $[\alpha]_{D20°} = -67{\cdot}7$ and $-68{\cdot}6$ were found; birotation was not observed. The *calcium*, *barium*, and *cadmium* salts are all very soluble in water; the *phenylhydrazide*, $C_7H_{13}O_7(N_2H_2Ph)$, crystallises from alcohol in yellowish leaflets, and melts at 150—152°. When β-glucoheptonic lactone (4 grams) is heated with pyridine (4 grams) and water (20 grams) in a sealed tube for three hours, it is converted into α-glucoheptonic acid, which can be isolated and identified by means of its hydrazide.

β-Glucoheptose, $CH_2(OH)\cdot\overset{OH}{\underset{H}{C}}-\overset{OH}{\underset{H}{C}}-\overset{OH}{\underset{H}{C}}-\overset{OH}{\underset{H}{C}}-\overset{OH}{\underset{H}{C}}\cdot CHO$, is prepared by reducing the corresponding lactone in 10 per cent. aqueous solution with 2½ per cent. sodium amalgam (12 parts). It has not as yet been obtained in the crystalline condition. The *phenylhydrazone*, $C_7H_{14}O_6N_2HPh$, separates on mixing the syrupy sugar (2 parts) with phenylhydrazine (1·5 parts); it crystallises from alcohol in slender,

colourless needles, darkens when rapidly heated at 190°, and melts at 192° with the evolution of gas. The osazone exhibits the same form and solubility as that prepared from α-glucoheptose, a result which was to be expected. When β-glucoheptonic lactone is oxidised with nitric acid according to Kiliani's directions (Abstr., 1886, 936), the

pentahydroxypimelic acid, $COOH\cdot\overset{H}{\overset{|}{C}}-\overset{H}{\overset{|}{C}}-\overset{OH}{\overset{|}{C}}-\overset{H}{\overset{|}{C}}-\overset{OH}{\overset{|}{C}}\cdot COOH$, is obtained; it is isolated by means of its *calcium* salt, from which, on decomposition with the calculated quantity of oxalic acid, evaporation, and final recrystallisation from ethyl acetate, the *lactonic* acid, $C_7H_{10}O_8$, is prepared. When repeatedly recrystallised, the latter is obtained in long needles or prisms, melts at 177°, and has the specific rotatory power $[\alpha]_{D20°} = 68{\cdot}5$. The pentahydroxypimelic acid,

$COOH\cdot\overset{H}{\overset{|}{C}}-\overset{H}{\overset{|}{C}}-\overset{OH}{\overset{|}{C}}-\overset{H}{\overset{|}{C}}-\overset{H}{\overset{|}{C}}\cdot COOH$, derived from α-glucoheptonic acid,

has been described by Kiliani (*loc. cit.*); it is, as might be anticipated, optically inactive; the *phenylhydrazide* melts at 200° with decomposition, and is sparingly soluble both in alcohol and water.

Gluco-octonic Acids.—As already mentioned, two stereoisomeric octonic acids are produced by treating α-glucoheptose with hydrocyanic acid. The α-acid is always the chief product, and the amount of the β-acid formed varies with the temperature. For the preparation of the α-acid, glucoheptose (50 grams) is dissolved in water (350 grams) and anhydrous hydrogen cyanide (14 c.c.) added, the mixture being contained in a well-closed flask, and kept in an incubator at 25° for four days, after which it is boiled with barium hydroxide (50 grams) until the ammonia is expelled, diluted to redissolve the basic salt thus formed, and then treated with carbonic anhydride until neutral; the filtrate is evaporated, and the barium salt of the α-acid collected, that of the β-acid remaining in the mother liquor. α-Gluco-octonic acid is prepared from the barium salt in the usual manner; it yields the *lactone*, $C_8H_{14}O_8$, on evaporating its aqueous solution. The latter is very sparingly soluble in ethyl alcohol, somewhat more so in methyl alcohol, and very readily in water; it melts at 145—147°, and has a specific rotatory power $[\alpha]_{D20°} = 45{\cdot}9$. The *barium*, *calcium*, and *cadmium* salts are crystalline; the *phenylhydrazide* forms slender, colourless needles, and, when rapidly heated, melts at 215°.

α-Gluco-octose, $C_8H_{16}O_8 + 2H_2O$, is obtained by reducing α-gluco-octonic lactone (50 grams) with sodium amalgam (625 grams) in the manner described for the preparation of α-glucoheptose (see above); it crystallises in delicate, colourless needles, melts at 93°, loses its water of crystallisation partially when placed over concentrated sulphuric acid, but apparently not completely when heated for 48 hours at 75° under diminished pressure; it is only sparingly soluble in hot ethyl alcohol, but more readily in methyl alcohol. It exhibits birotation; the specific rotatory power calculated on the anhydrous sugar is $[\alpha]_{D20°} -50{\cdot}5$. The *phenylhydrazone*, $C_8H_{16}O_7(N_2HPh)$, is

sparingly soluble in cold water, and melts at 190° when rapidly heated. The *phenylosazone*, $C_8H_{14}O_6(N_2HPh)_2$, is almost insoluble in water, and melts at 210—212° when rapidly heated.

α-Gluco-octitol, $C_8H_{18}O_8$, is formed by reducing the last-described sugar with sodium amalgam; it forms slender, white needles, melts at 141°, and is readily soluble in water, very sparingly in ethyl alcohol, but somewhat more so in methyl alcohol. It has a specific rotatory power in 10 per cent. solution $[\alpha]_{D20°} = 2$, and when an equal weight of borax is dissolved in the solution the specific rotatory power is trebled.

β-Gluco-octonic acid is obtained from the mother liquor, after the separation of the α-acid in the preparation of α-gluco-octonic acid, when the same is conducted at a temperature of 40°; the yield amounts to about 15 per cent. of the heptose employed. The *lactone* is sparingly soluble in alcohol, and crystallises therefrom in colourless, slender needles, or from water in large, well-formed prisms, melts at about 186—188°, and has a specific rotatory power $[\alpha]_D = 23{\cdot}6$. The *phenylhydrazide* melts at 172°.

When α-gluco-octonic lactone is heated with pyridine and water in a sealed tube at 140°, it is partially converted into the β-compound.

Glucononic Acid.—When α-gluco-octose (30 grams) is dissolved in water (150 grams), and after the addition of anhydrous hydrogen cyanide (4·8 c.c.), the mixture kept at a temperature of 10—17° for 11 days, a small quantity of a substance separates, which is, perhaps, a nononic amide; the reaction is completed by keeping the mixture in an incubator at a temperature of 25° for two additional days. Two acids, probably stereoisomerides, are formed, that which is most readily isolated only being examined. When phenylhydrazine is added to a solution of the acid obtained from the crude barium salt, and the mixture heated on the water-bath for an hour, a hydrazide separates on cooling; this is described below; whilst a more soluble hydrazide, melting at 40° lower, may be obtained from the filtrate. The *lactone* obtained by evaporating a solution of the acid, prepared from the purified barium salt, is dextrorotatory, does not reduce Fehling's solution, and is very soluble in water, but only sparingly in alcohol; the *phenylhydrazide*, $C_9H_{19}O_9{,}N_2H_2Ph$, melts at 234°, and is sparingly soluble in hot water.

Glucononose, $C_9H_{18}O_9$, is prepared by reducing the last-described lactone in 10 per cent. solution with sodium amalgam at 0°; it was only obtained as a syrup. The *phenylhydrazone*, $C_9H_{18}O_8{:}N_2HPh$, is sparingly soluble in cold water and alcohol, and melts at 195—200°; the *phenylosazone*, $C_9H_{18}O_7(N_2HPh)_2$, is formed by heating the sugar with an excess of phenylhydrazine acetate, on the water-bath, for some hours; it is very sparingly soluble in hot water or alcohol, somewhat more readily so in dilute alcohol, and melts at 220—223°. Unlike mannononose (Abstr., 1890, 1233), glucononose does not ferment with yeast.

Glucononitol, $C_9H_{20}O_9$, is prepared by reducing crude, syrupy glucononose in the same manner as already described for the reduction of glucoheptose (see above). It is separated from sodium salts by taking advantage of its slight solubility in strong alcohol. It crys-

tallises from hot water in elongated tables or prisms, commences to sinter at 190°, and melts at 194°; it is readily soluble in hot water, very sparingly soluble in alcohol, and does not reduce Fehling's solution. A. R. L.

β-Galactan. By E. Schulze (*Ber.*, **25**, 2213—2218).—β-Galactan is a carbohydrate obtained from lupine seeds which, when boiled with dilute sulphuric acid, yields galactose. It has been described by E. Steiger (*Ber.*, **19**, 827), who, on analysing specimens dried at 115°, obtained numbers agreeing with the formula $C_6H_{10}O_5$.

The author has prepared β-galactan from lupine seeds, and confirms Steiger's results as to its properties. It yields the largest quantity of glucose when boiled for 1½ hours with one-fifth normal hydrochloric acid. The yield, however, is only 80 per cent. of that required by theory; the loss is due to some of the fruit sugar which is formed being decomposed. The product of the inversion consists of galactose, fruit sugar, and another sugar, which the author has not yet examined. Mannose and pentose could not be detected.

The author has analysed specimens of β-galactan dried at 100°, and obtained numbers agreeing with the formula $C_{12}H_{22}O_{11}$, or a multiple of the same. The specific rotation of the product, when dried at 100° in 5 per cent. aqueous solution at 22°, is $[\alpha]_D = +138°$. When dried at 110—115° $[\alpha]_D = +150°$. Three other preparations gave $[\alpha]_D =$ 148·7°, 149·8°, and 147·2°.

The author proposes to substitute the name *lupeose* for β-galactan. E. C. R.

Iodide of Starch. By G. Rouvier (*Compt. rend.*, **114**, 1366—1367).—In order to determine the composition of iodide of starch prepared in presence of excess of starch, a quantity of starch solution was mixed with a definite volume of a standard iodine solution, and a volume of a saturated solution of ammonium chloride, equal to the starch solution, was added. The precipitate was washed with ammonium chloride solution, and the carbon and iodine determined. The proportion of iodine varied from 8·57 to 9·12 per cent., whilst the proportion calculated for the formula $(C_6H_{10}O_5)_8I$ is 8·92 per cent. According to the author this result agrees with that of Mylius, who found (Abstr., 1887, 568) that the product of the action of an excess of iodine on starch is $(C_6H_{10}O_5)_4I$. C. H. B.

Product of the Oxidation of Starch. By P. Petit (*Compt. rend.*, **114**, 1375—1377).—When 4 parts of starch, containing 20 per cent. of water, is mixed with 5 parts of pure ordinary nitric acid, a gummy mass is obtained, which, when heated at 40° for several days, swells up, becomes green, and finally yields a very bulky, white, porous product, equal in weight to the original starch.

When this product, which contains 6 per cent. of nitric acid, is heated at 100°, it becomes reddish-yellow, and then gives off reddish vapours. When treated with water carbonic anhydride and nitrogen oxides are evolved, the evolution of gas being very abundant on heating, whilst dissolution is practically complete. In presence of alcohol there is less evolution of gas, and solution is much less complete in the cold;

but on heating there is a violent evolution of gas, and about half of the solid matter dissolves.

The addition of ether to a cold alcoholic solution precipitates a white, gummy substance, which gradually becomes less soluble in alcohol. When purified by solution in water, and reprecipitation by alcohol, it has the composition $C_5H_6O_5$. It dissolves very readily in water, and the acid solution is strongly dextrogyrate; it reduces ammoniacal silver nitrate and Fehling's solution in the cold. Its specific rotatory power is $\alpha_j = +152{\cdot}8$, and its reducing power is equal to 24·2 per cent. of that of glucose. The acid is monobasic with phenolphthaleïn as indicator, and with barium hydroxide gives the salt $(C_5H_5O_5)_2Ba$, but if this is left in contact with the mother liquor it partially redissolves, and about half as much more alkali is required to produce a coloration with the phenolphthaleïn.

When thrown into a concentrated solution of phenylhydrazine acetate, the acid yields a hydrazone, $C_5H_6O_4{\cdot}N_2HPh$, crystallising from boiling water in rudimentary needles that melt with decomposition at about 100°.

The acid is insoluble in cold alcohol, but if boiled for a long time with water, or for a shorter time with dilute inorganic acids, it is converted into a new acid, $C_5H_8O_6$, which is readily soluble. The ammonium salt of the latter, $C_5H_7O_6{\cdot}NH_4$, is sometimes obtained as a deliquescent amorphous product by the action of ammonia gas on the cold alcoholic solution of the original product. The corresponding hydrazone, $C_5H_8O_5{\cdot}N_2HPh$, forms readily at 60—70°, and in a dry vacuum it loses water and changes into the hydrazone of the acid $C_5H_6O_5$.

The acid $C_5H_8O_6$ is monobasic, and its potassium and cadmium salts are amorphous. C. H. B.

Chlorine Derivatives of Isobutylamines. By A. Berg (*Compt. rend.*, **114**, 1379—1382).—The chlorine derivatives of the isobutylamines were prepared by the method previously used for the corresponding derivatives of the amylamines, namely, the action of sodium hypochlorite on the hydrochlorides of the bases (Abstr., 1890, 952).

Monochlorisobutylamine, $NHCl{\cdot}C_4H_9$, is a colourless, oily liquid, with a very pungent odour and taste; sp. gr. at $0° = 0{\cdot}986$. It is only slightly stable, and changes to a crystalline mass after some hours. It is, however, more stable than the corresponding amyl compound, and can be boiled without immediate decomposition. Sulphuric acid of 25 per cent. converts it into dichlorisobutylamine and isobutylamine, whilst with hydrogen chloride, in presence of ether, it yields diisobutylamine hydrochloride, chlorine gas being evolved.

Dichlorisobutylamine, $NCl_2{\cdot}C_4H_9$, is obtained by distilling isobutylamine hydrochloride with 10 times its weight of bleaching powder. It is found in the first part of the distillate, and is treated with sodium thiosulphate solution, then with 25 per cent. sulphuric acid, and, finally, with 50 per cent. acid, in order to remove all traces of the monochloro-derivative, which would reduce its stability. Dichlorisobutylamine is a golden-yellow liquid, with a strong, irritating, chlorinous odour; it boils without decomposition at 37° under a pressure of

24 mm.; sp. gr. at 0° = 1·093. With hydrochloric acid, in presence of ether, it yields chlorine and isobutylamine hydrochloride.

Chlorodiisobutylamine, $NCl(C_4H_9)_2$, is a colourless, oily liquid, with a feeble disagreeable odour; sp. gr. at 0° = 0·891. It does not solidify at −40°; it boils at 61° without decomposition under a pressure of 19 mm., and with decomposition at about 163° under the ordinary pressure. At the ordinary temperature it slowly decomposes with deposition of crystals. Hydrochloric acid converts it into diisobutylamine hydrochloride, with liberation of chlorine.

Isobutylisobutylideneamine, $C_4H_9{\cdot}N{:}C_4H_8$, is obtained by the action of alcoholic soda on monochlorodiisobutylamine. It boils at 130—131° under a pressure of 760 mm. When distilled with excess of hydrochloric acid, it yields isobutylyamine and isobutaldehyde, and it can be formed, with development of heat and liberation of water, by mixing these two compounds in molecular proportion.

Diisobutylcyanamide, $NCy(C_4H_9)_2$, is obtained by the prolonged boiling of an alcoholic solution of chlorodiisobutylamine with a very concentrated aqueous solution of potassium cyanide. It is an oily liquid, which boils at 116—117° in a vacuum. It has a feeble aromatic odour and feeble basic properties, is insoluble in water, and dissolves in hydrochloric acid, but is precipitated from the latter on dilution. When heated with hydrochloric acid at 130°, it yields carbonic anhydride, ammonia, and diisobutylamine. C. H. B.

Hexamethyleneamine. By L. Hartung (*J. pr. Chem.* [2], **46**, 1—20).—*Hexamethylene benzochloride*, $C_6H_{12}N_4ClBz$, is a white, amorphous substance, which separates from a hot solution of hexamethyleneamine in benzene on the addition of an excess of benzoic chloride; it decomposes at 60°, is somewhat soluble in hot alcohol, insoluble in ether and benzene, and partially soluble in water, with separation of benzoic acid. The precipitate obtained by substituting acetic chloride for benzoic chloride was not analysed.

When hexamethyleneamine is heated with an excess of ethyl chloracetate at 110°, 2 mols. of it react with 1 of the chloracetate with elimination of alcohol and formation of the *compound* $C_{14}H_{25}ClN_8O$. This is white, decomposes at 50°, is easily soluble in water and alcohol, but insoluble in ether and benzene; the *platinochloride*, $C_{14}H_{25}ClN_8O,HCl,PtCl_4 + H_2O$, is an amorphous, red precipitate. The *hydrochloride* forms aggregates of needles, and is obtained when hexamethyleneamine is heated with an excess of ethyl chloracetate in absolute alcohol in a reflux apparatus.

In studying the action of sulphurous anhydride on hexamethyleneamine, it was found that when the gas is passed through a hot solution of the base in alcohol, isobutyl alcohol, or isopropyl alcohol, a white *compound*, $C_5H_{11}N_3SO_3$, is obtained; this is freely soluble in water but insoluble in the usual organic solvents; when titrated with decinormal iodine solution, only half of its sulphur is completely oxidised thereby; when it is oxidised by potassium permanganate, aldehyde is evolved. Another *compound*, $C_6H_{22}N_4S_2O_{10}$, is formed when methyl alcohol is the solvent; this is reddish in colour but possesses properties similar to those of the white compound; only

half of its sulphur is oxidised by iodine. When benzene is the solvent, a molecular *compound* of the hexamethyleneamine and sulphurous anhydride, of the formula $C_6H_{12}N_4,SO_2$, is produced; it is colourless and crystalline, dissolves easily in water, but only sparingly in alcohol, and decomposes at 60°.

Methylamine is the most noticeable and constant product of the action of acids on hexamethyleneamine. Ammonia and methyleneaniline are produced when hexamethyleneamine and aniline are heated together. A. G. B.

Configuration of Aldoximes. By W. Dollfus (*Ber.*, **25**, 1908—1926).—The author's experiments show that aliphatic aldoximes are only stable in one form, for, whilst they can be converted into hydrochlorides in a manner similar to the aromatic aldoximes when treated with hydrogen chloride in ethereal solution, these, on decomposition with alkali, give the original aldoxime. Lach has shown (Abstr., 1884, 1154) that when certain aliphatic aldoximes are heated with acetic anhydride, nitriles are formed. The author finds that when acetaldoxime is mixed with a slight excess of acetic anhydride with cooling, the mixture placed aside for a day, and carefully neutralised with potash, ether extracts acetonitrile; propionaldoxime, isobutyraldoxime, isovaleraldoxime, and œnanthaldoxime are converted into nitriles in the same way. The reaction proceeds quantitatively in each case, and it would seem to be the best method of converting aldehydes into nitriles. It shows, moreover, that these aldoximes may be represented by the general configuration $\begin{matrix}R\cdot C\cdot H\\ \|\\ N\cdot OH\end{matrix}$ (synaldoximes, see this vol., p. 312). The same applies to the aldoximes mentioned below. Phenylacetaldehyde is obtained according to Cannizzaro's directions (*Annalen*, **119**, 223) by distilling calcium phenylacetate; when regenerated from its hydrogen sulphite compound, it is fractionated and passes over at 193—195°. The *oxime*, $CH_2Ph\cdot CH{:}NOH$, melts at 97—99°, and when treated with acetic anhydride as above described, yields an oil, from which, after boiling with soda and acidifying, phenylacetic acid is obtained by extraction with ether. Hydrocinnamaldoxime (b. p. 208°), when treated with acetic anhydride, gives hydrocinnamonitrile; cinnamaldoxime gives the *acetyl* derivative, $CHPh{:}CH\cdot CH{:}NOAc$, melting at 69—70°, which, however, readily decomposes into cinnamonitrile and acetic acid on treatment with water; whilst when crotonaldoxime is dissolved in ether (10 parts) and an excess of acetic anhydride added, crotononitrile is formed (compare Schindler, this vol., p. 580).

Ortho-substituted aromatic aldoximes appear, in accordance with the observations of others, to be only capable of existence in one modification, which must, however, be represented by the anti-configuration, $\begin{matrix}R\cdot C\cdot H\\ \|\\ OH\cdot N\end{matrix}$ (*loc. cit.*), since they yield, on treatment with acetic anhydride, acetyl derivatives which give the original oxime but no nitrile on decomposition with water or alkali; the cases examined by the author are orthomethylbenzaldoxime, orthochloro-

benzaldoxime, and orthomethoxybenzaldoxime; the same is true of metahydroxybenzaldoxime, and of the corresponding parahydroxy-derivative, although parachloro-, nitro-, and methoxy-benzaldoxime are each known to exist in two modifications. A. R. L.

Relations between Constitution, Configuration, and Chemical Behaviour of Oximes. By A. Hantzsch (*Ber.*, **25**, 2164—2185).—A theoretical paper dealing with the subject from the point of view of the well-known theory of Hantzsch and Werner. The facts cited have all appeared in this journal. The matter is discussed under two headings, viz.:—I. *Influence of the constitution of asymmetrical oximes on the stability or existence of the two configurations* $\begin{matrix}X\cdot C\cdot Y\\ \|\\ HON\end{matrix}$ and $\begin{matrix}X\cdot C\cdot Y\\ \|\\ NOH\end{matrix}$. II. *Influence of configuration (and consequently of constitution) on the intramolecular reactions of asymmetrical oximes.*

A. R. L.

Stereoisomeric Dioximes from Ethyl Acetoacetate and Benzoylacetate. By G. Nussberger (*Ber.*, **25**, 2142—2164).—This investigation was undertaken in view of the fact that stereoisomerism has only heretofore been observed in mono- and di-carboxy-derivatives of aliphatic dioximes.

The two compounds described by Cérésole and Köckert (Abstr., 1884, 1120) as ethyl $\alpha\beta$-diisonitrosobutyrate and its anhydride are now shown to be *ethyl methylsynglyoximecarboxylate*,

$$\begin{matrix}Me\cdot C\text{----------}C\cdot COOEt\\ \|\qquad\qquad\|\\ N\cdot OH\quad HO\cdot N\end{matrix},$$

and *hydroximidomethylsynoxazolone*, $\begin{matrix}Me\cdot C\cdot C(NOH)\cdot CO,*\\ \|\qquad\quad|\\ N\text{----------}O\end{matrix}$ respectively, and are thus obtained:—

Crude, oily ethyl hydroximidoacetoacetate prepared by the action of nitrous acid at 0° on ethyl acetoacetate is treated with somewhat more than the molecular proportion of hydroxylamine hydrochloride in dilute alcoholic solution. The product is extracted with ether, and the ethereal solution shaken with soda solution, which extracts the above-mentioned oxazolone, whilst ethyl methylsynglyoximecarboxylate remains dissolved. Ethyl methylsynglyoximecarboxylate crystallises from ether in white, concentrically-grouped needles, darkens at 115°, and melts at 142° with evolution of gas; it is soluble in alcohol, ether, and hot water, and dissolves in alkalis forming a colourless solution, from which it is precipitated unchanged on acidification, but is absolutely insoluble in acids; a green precipitate is produced on adding copper sulphate to its neutral solution.

The diacetyl derivative, $\begin{matrix}Me\cdot C\text{----------}C\cdot COOEt\\ \|\qquad\qquad\|\\ N\cdot OAc\quad AcO\cdot N\end{matrix}$, is obtained by

* That this compound has not the alternative formula $\begin{matrix}CMe\cdot C\cdot COOH\\ \|\qquad\quad\|\\ N\cdot O\cdot N\end{matrix}$ is shown by its bad electrical conductivity, and its very small dissociation constant.

dissolving the oxime in acetic anhydride and allowing the solution to evaporate over sulphuric acid and soda in a vacuum; it crystallises in white needles, melts at 50°, is readily soluble in ether, less so in alcohol and chloroform, and almost insoluble in cold water, but can be crystallised from hot water without decomposition; it dissolves in alkalis without coloration, and ethyl methylsynglyoximecarboxylate separates on adding an acid; if, however, the alkaline solution has been kept a long time, the corresponding acid (see below) is obtained on acidification, whilst, if the same solution is boiled, it becomes red after a while, and on the addition of acid yields hydroximidomethylsynoxazolone.

Methylsynglyoximecarboxylic acid, $\begin{matrix}Me\cdot C & \text{———} & C\cdot COOH\\ \| & & \|\\ N\cdot OH & & HO\cdot N\end{matrix}$, is formed when the ethyl salt is allowed to remain for a day with an excess of concentrated sodium hydroxide solution, the unchanged ethyl salt extracted with ether, and after cautiously acidifying the solution, extracting the acid with ether. On crystallisation from ether, it is obtained in white cubes containing 2 mols. H_2O; it loses $1\frac{1}{2}$ mols. H_2O in the desiccator, but the remaining $\frac{1}{2}$ mol. is not removed below the temperature at which it undergoes decomposition. It is readily soluble in water, alcohol, and ether, sparingly so in chloroform, and insoluble in light petroleum, and melts at 120—121°; it dissolves in alkalis without coloration, and is precipitated unchanged by acids; in aqueous or neutral solution it gives, with silver and mercurous nitrates, white precipitates, and with copper acetate a yellowish-brown precipitate, with ferric chloride a brown coloration, but with lead acetate neither precipitate nor coloration.

Ethyl methylamphiglyoximecarboxylate, $\begin{matrix}Me\cdot C & \text{——} & CCOOEt\\ \| & & \|\\ N\cdot OH & & N\cdot OH\end{matrix}$, is obtained by passing dry hydrogen chloride through an ethereal solution of the syn-compound; it crystallises in white, ramified needles, melts at 132°, and is readily soluble in ether, alcohol, and chloroform, but insoluble in water, and gives neither a precipitate nor a coloration with copper acetate. The compound dissolves in alkali carbonates, and is precipitated unchanged on acidification, but if it is dissolved in alkali hydroxides, ethyl methylsyngloximecarboxylate separates on the addition of acid; the protracted action of alkali hydroxides, however, gives rise to the acid corresponding with the last-named salt.

The *diacetyl* derivative, $\begin{matrix}Me\cdot C & \text{———} & C\cdot COOEt\\ \| & & \|\\ N\cdot OAc & & N\cdot OAc\end{matrix}$, is prepared from the last-described compound by the method given above for the preparation of the stereoisomeride; it is also formed when ethyl methylsynglyoximecarboxylate is treated in ethereal solution with acetic chloride. It is a micro-crystalline powder, melts at 119—120°, is readily soluble in ether and alcohol, sparingly so in cold water, and is converted into ethyl methylamphiglyoximecarboxylate when boiled with water. The diacetyl derivative, moreover, dissolves in alkalis with a reddish colour, from which acids precipitate ethyl methylsynglyoximecarboxylate.

Hydroximidosynoxazolone (see above) is obtained when methylsynglyoximecarboxylic acid is treated at the ordinary temperature with hydrogen chloride, mere exposure of the latter to the acid vapours of the laboratory being sufficient to bring about the change; it crystallises in leaflets of the formula $C_4H_4N_2O_3 + \frac{1}{2}H_2O$, loses its water of crystallisation at 100°, melts at 132°, and is readily soluble in water, alcohol, and ether, very sparingly so in benzene. Its aqueous solutions have an acid reaction, and it forms salts with alkalis and ammonia, the solutions of which are red; the neutral solution of the ammonium salt gives, with copper acetate, a brown, and with lead acetate a red, coloration, with silver nitrate a brick-red precipitate, but no alteration with either mercuric nitrate or ferric chloride. Acetic anhydride, at the ordinary temperature, acetic chloride, and hydrochloric acid have no action on it. Hydroximidosynoxazolone may be regarded as the inner anhydride of methylamphiglyoximecarboxylic acid, $\begin{matrix}Me\cdot C & \text{——} & C\cdot COOH\\ \| & & \|\\ N\cdot OH & & N\cdot OH\end{matrix}$, which cannot be isolated in the free state; for example:—When the first-named compound is treated with an excess of alkali, the red colour at first formed quickly vanishes, and the neutralised solution gives, with mercurous nitrate, a white precipitate, and with ferric chloride a brown coloration; also a dark green coloration with copper acetate, a yellow precipitate with silver nitrate, and a white precipitate with lead acetate. As these reactions taken together differ from those exhibited by solutions of either the syn-acid or hydroximidosynoxazolone, they may be taken as indicative of the presence of the amphi-acid. When, however, the above-mentioned, colourless, alkaline solution is ever so carefully neutralised, under all circumstances, hydroximidosynoxazolone is obtained on extraction with ether.

When methylsyngloximecarboxylic acid is dissolved in acetic anhydride, a white, monacetyl derivative is formed; this dissolves in alkalis with a rose colour, undergoing hydrolysis, and melts at 150°; its configuration and constitution were not determined.

Hydroximidophenylsynoxazolone, $\begin{matrix}Ph\cdot C & \cdot C(NOH)\cdot CO\\ \| & \quad\quad\quad\quad |\\ N & \text{————} \quad O\end{matrix}$, has been prepared by Claisen and Zedel (Abstr., 1891, 468) and by Hantzsch (*ibid.*, 740), and described in each case as phenylisoxazolone.

Phenylamphiglyoximecarboxylic acid, $\begin{matrix}Ph\cdot C & \text{——} & C\cdot COOH\\ \| & & \|\\ N\cdot OH & & N\cdot OH\end{matrix}$ (?), is a labile compound, but the existence of its salts is indicated as follows:—When hydroximidophenylsynoxazolone is dissolved in an excess of aqueous sodium hydroxide and the solution allowed to remain and carefully neutralised, a colourless solution is obtained, that of the oxazolone salt being red; this solution gives, with copper acetate, a blackish-brown coloration, with lead acetate a white precipitate, and undergoes no alteration on addition of mercuric chloride. On acidification and extraction with ether, the acid is obtained, but soon undergoes conversion into hydroximidophenylsynoxazolone.

Phenylsynglyoximecarboxylic acid, $\begin{matrix}Ph\cdot C & \text{————} & C\cdot COOH\\ \| & & \|\\ N\cdot OH & & HO\cdot N\end{matrix}$ (?).—

The following evidence of the existence of this acid was obtained:—When hydroximidophenylsynoxazolone is dissolved in boiling aqueous sodium carbonate, the solution, on neutralisation, gives, with lead acetate, a white precipitate, with copper acetate a bright green coloration, and with mercuric chloride neither precipitate nor coloration. On acidifying the solution and extracting it with ether, *phenylazoxazolecarboxylic acid*, $\begin{matrix}C\cdot Ph\cdot C\cdot COOH\\ \|\quad\quad\|\\ N\text{–}O\text{–}N\end{matrix}$, is isolated. It crystallises in white, rhombic tables, melts at 110°, and is readily soluble in water, alcohol, and ether, but almost insoluble in benzene. It has all the properties of a carboxylic acid, forms colourless salts, gives no noticeable reactions with copper and lead acetates, but with silver nitrate and mercuric chloride, white precipitates; the *methyl* salt melts at 35°. A. R. L.

Action of Magnesium Acetate on Magnesium Oxide and on Lead Oxide. By Kubel (*Arch. Pharm.*, **230**, 173—182).—More than one deodoriser consists of a mixture of magnesium acetate solution with magnesium oxide, but the quantity of the oxide which actually dissolves in the solution is very small, and whether a basic magnesium acetate is formed is undecided. Lead oxide readily dissolves in a solution of magnesium acetate, tribasic lead acetate, $2PbO,Pb(C_2H_3O_2)_2$, being thereby formed. The solution is readily precipitated by carbonic anhydride, with the production of white lead. Silver nitrate gives a yellow precipitate with the solution; potassium iodide gives a white precipitate, which becomes yellow after a time; chlorine-water gives, after a time, a brown precipitate of lead peroxide. According to the author, ordinary basic lead acetate solution contains only bibasic lead acetate, together with the normal salt. When a 10 per cent. solution of magnesium acetate is boiled with 7 per cent. of lead oxide, and set aside for some hours until the excess of tribasic lead acetate has separated, the liquid still contains 4 per cent. of lead oxide; this forms a ready method of preparing a solution of such strength. A. G. B.

Constitution of Ethyl Sodacetoacetate. By A. Michael (*J. pr. Chem.* [2], **45**, 580—590).—Nef (this vol., p. 145) says that the action of ethyl sodacetoacetate on ethyl chlorocarbonate gives rise to the formation of ethyl acetylcarbintricarboxylate, together with ethyl acetomalonate, and regenerated ethyl acetoacetate. This reaction has already been studied by the author (Abstr., 1888, 1054), who found that the product is almost entirely ethyl carbethoxacetoacetate, only a little ethyl acetomalonate being formed at the same time. With phenylhydrazine acetate, ethyl carbethoxacetoacetate yields phenylmethylpyrazolone and a substance which melts at 80—81°; with free phenylhydrazine, no water or ethyl acetoacetate was formed, as Nef (*loc. cit.*) states to be the case with his compound, but the substance which melts at 80—81° and two oils, one acid and the other neutral, were isolated.

The action of ethyl chlorocarbonate on ethyl sodethylacetoacetate yields, as the main product, *ethyl carbethoxethylacetoacetate*,

$$COOEt{\cdot}O{\cdot}CMe{:}CEt{\cdot}COOEt;$$

this boils at 146° (20 mm.), and is converted by solid sodium ethoxide into ethyl acetoacetate, ethyl carbonate, and sodium carbonate; with phenylhydrazine it yields the substance which melts at 80—81° (see above). A *compound*, $COMe{\cdot}CEt(COOEt)_2$, isomeric with the one just described, is obtained by the action of acetic chloride on ethyl sodethylmalonate; it boils at 137° (20 mm.), and is converted by sodium ethoxide into ethyl ethylmalonate, ethyl acetate, and sodium acetate; with phenylhydrazine, it forms the compound $N_2H_2Ph{\cdot}COMe$; with phenylhydrazine acetate in dilute alcohol, the hydrazone, $N_2HPh{:}CMe{\cdot}CEt(COOEt)_2$ (m. p. 43—44°), is formed. The *methyl* derivatives, corresponding to the two above-mentioned ethyl derivatives, boil at 137° and 131—131·5° (20 mm.) respectively, and are prepared in a similar manner.

Some remarks on the formation of pyrazolones follow, involving the citation of experiments, the details of which are shortly to appear. The author points out that Nef's statements that ethyl ethylacetoacetate in ethereal solution is not reduced by sodium and that the calculated amount of hydrogen is evolved are incorrect, only some five-sevenths of the calculated hydrogen being actually obtained. Nef also states that ethyl malonate which has been dried by silicon chloride is not attacked by sodium; the fact being that both a silicon derivative and also hydrogen chloride are produced, and the latter attacks the sodium. A. G. B.

Action of Iodic Acid on Lævulinic Acid. By A. Angeli and A. Chiussi (*Ber.*, **25**, 2205—2208).—The authors have obtained an acid which they believe to be diiodacetoacrylic acid.

Diiodacetoacrylic acid, $C_5H_4I_2O_3$, is obtained by adding pure lævulinic acid (9 grams) to a boiling solution of iodic acid (7 grams) in water (30 c.c.); a vigorous reaction takes place, and, on cooling, the product separates as a bright yellow, crystalline compound. It crystallises from boiling acetic acid in large, yellow scales, decomposes at 150—160° with evolution of iodine, is insoluble in water, ether, benzene, and chloroform, easily soluble in alcohol, ethyl acetate, and acetic acid, and decomposes in solution in the light, or on heating, with evolution of iodine. When treated with an alkaline carbonate, it yields iodoform and a new acid which has not been further examined. When treated with hydriodic acid, it is decomposed and yields acetoacrylic acid, $CHAc{:}CH{\cdot}COOH$.

The *oxime* of *moniodacetoacrylic acid*, $C_5H_5IO_2{:}NOH$, is obtained when the above diiodo-acid, dissolved in alcohol, is warmed on the water-bath with twice the quantity of hydroxylamine hydrochloride. It melts at 155° with decomposition, and, by the further action of hydroxylamine, yields acetoacrylic oxime.

Acetoacrylic oxime, $C_5H_7NO_3$, is best obtained by adding the diiodo-acid to a boiling, aqueous solution of hydroxylamine hydrochloride; iodine is evolved, and, on decolorising the mixture with sulphurous acid

and extracting with ether, a solid, colourless product is obtained. It melts at 189°, with evolution of gas, has acid properties, is easily soluble in alcohol and warm water, less so in cold water, ethyl acetate, benzene, and chloroform, and reduces Fehling's solution. The *monacetate*, $C_5H_6NO_3Ac$, melts at 143°. This acetoacrylic oxime is not identical with the oxime prepared directly from acrylic acid by Wolff. The latter melts at 206°, and its acetate at 155°. The oxime melting at 189° is converted by boiling with water into the higher melting isomeride. The authors put forward the following formulæ for these two compounds :—

$$\underset{\text{OH·N}}{\overset{\text{Me·C·CH:CH·COOH}}{\|}} \quad \text{and} \quad \underset{\text{N·OH}}{\overset{\text{Me·C·CH:CH·COOH}}{\|}}$$

M. p. 189°. M. p. 206°.

E. C. R.

So-called Isoarabinic Acid. By C. Scheibler and H. Mittelmeier (*Ber.*, **25**, 1964—1966).—The authors have repeated Ballo's experiments (Abstr., 1889, 693), and arrive at the conclusion that the so-called "isoarabinic acid" there described is not a compound related to the carbohydrates. The acid, prepared according to Ballo's directions by the action of ferrous sulphate on tartaric acid, was converted into the calcium salt, and thence into the potassium salt. A determination of potassium in the latter gave K = 18·38 per cent., whereas Ballo found K = 19·15—19·5 per cent. To prepare the free acid, a solution of the potassium salt was treated with lead acetate, and the precipitate collected; the filtrate gave a further precipitate on the addition of basic lead acetate. Both precipitates were suspended in water, and decomposed by a current of hydrogen sulphide, the filtrates being concentrated, when, instead of an amorphous acid, in both cases crystalline substances separated, which proved to be tartaric acid. The authors find, moreover, that when potassium "isoarabinate" is dissolved in water, and heated on the water-bath with potassium hydroxide, ordinary potassium tartrate separates on allowing the solution to remain. Ballo's work can neither be regarded as a contribution to the part played by the iron present in chlorophyll, nor as a support to Liebig's theory of the formation of sugar in plants. Since the so-called "isoarabinic acid" bears not the slightest resemblance to arabic acid, it is desirable to rename it. A. R. L.

Derivatives of Sebacic Acid. By R. D. Phookan and F. Krafft (*Ber.*, **25**, 2252—2255).—*Sebacamide*,

$$CONH_2\cdot[CH_2]_8\cdot CONH_2,$$

is obtained when pure pulverised sebacic acid is mixed with phosphoric chloride (2 mol. props.) at the ordinary temperature, and the oily product slowly added to well cooled aqueous ammonia. It is insoluble in water, and only sparingly soluble in alcohol; it crystallises from isobutyl alcohol in minute crystals melting at 208°. On distilling the amide (100 parts) with phosphoric chloride (208 parts), sebaconitrile $C_8H_{16}(CN)_2$, a liquid having a faint fluorescence, a

characteristic penetrating odour, and boiling at 199—200° (15 mm.), is produced. When the nitrile (100 grams) is dissolved in absolute alcohol (2 kilos.), and sodium (350 grams) added, *decamethylene-diamine*, $C_8H_{16}(CH_2{\cdot}NH_2)_2$, is formed; the product is acidified with hydrochloric acid, and, after concentrating, the precipitated sodium chloride is removed, the filtrate evaporated to dryness, the residue dissolved in alcohol, and the *hydrochloride* precipitated with ether. The base is obtained by heating the hydrochloride with concentrated alkali; it melts at 61·5°, and boils at 140° (12 mm.). When the hydrochloride is heated at a high temperature, or sublimed under diminished pressure, it decomposes into ammonium chloride and *decamethyleneimine hydrochloride*. The free *base*, $C_{10}H_{20}NH$, of the latter is a liquid of a faint, ammoniacal odour boiling at 104—105° (16·5 mm.); it forms a nitroso-compound which boils at about 160° (15 mm.), and gives Liebermann's reaction. A. R. L.

Ethyl Dioxosuccinate. By R. Anschütz and E. Parlato (*Ber.*, **25**, 1975—1980).—The authors having found, on analysing the so-called ethyl dihydroxytartrate (Abstr., 1891, 725), that it has the formula COOEt·CO·CO·COOEt, propose to name it ethyl dioxosuccinate; it is an orange-yellow liquid of a not unpleasant odour, having a sp. gr. $d\ 20°/4° = 1·1873$, and boiling without decomposition at 115—117° under a pressure of 12 mm., or at 233—234° with slight decomposition at the ordinary pressure, the distillation being usually conducted in a current of hydrogen. A bye-product, boiling at 208—212° (12 mm.), was separated during the rectification. When treated with water (2 mols.), ethyl dioxosuccinate is converted into a colourless liquid, which is perhaps ethyl tetrahydroxysuccinate; after drying over calcium chloride and distilling under a pressure of 12 mm., it gives off water at 70—75°, and is reconverted into ethyl oxosuccinate. A compound, $C_{18}H_{16}N_4O_3$, melting at 154°, and identical with that described by Wislicenus and Scheidt (this vol., p. 458), is obtained when ethyl dioxosuccinate is heated on the water-bath with phenylhydrazine and water. It is also produced when the dihydrazone (m. p. 120°; *loc. cit.*) is boiled with glacial acetic acid.

A. R. L.

Action of Ethyl Salts of Unsaturated Acids on Ethyl Sodiocyanacetate. By P. T. Muller (*Compt. rend.*, **114**, 1204—1207).—When ethyl fumarate and ethyl sodiocyanacetate, in molecular proportion, are heated in presence of excess of alcohol, *ethyl sodiocyanotricarballylate*, COOEt·CH(CHNa·COOEt)·CH(CN)·COOEt, is obtained as a colourless oil which boils at 180—190° under a pressure of 15—20 mm.

When this is treated with dilute sulphuric acid, it yields a liquid, *ethyl cyanotricarballylate*, COOEt·CH(CH_2·COOEt)·CH(CN)·COOEt, which, when boiled for several hours with hydrochloric acid, is decomposed, yielding carbonic anhydride, tricarballylic acid, alcohol, and ammonium chloride. It is the α-derivative, and is isomeric with the β-derivative obtained by Haller and Barthe by the action of ethyl monochloracetate on ethyl cyanosuccinate.

Citraconic acid under similar conditions yields *ethyl methyl-α-cyanotricarballylate*, $COOEt{\cdot}CMe(CH_2{\cdot}COOEt){\cdot}CH(CN){\cdot}COOEt$, which boils at about 190° under a pressure of 15 mm. When saponified with hydrochloric acid, it yields β-methyltricarballylic acid. Like its homologue, β-methyl-α-cyanotricarballylic acid is soluble in alkalis.

Naphthenes and their Derivatives in the General System of Organic Compounds. By V. Markovnikoff (*J. pr. Chem.* [2], **45**, 561—580).—The first part of a review of our knowledge of the naphthene and naphthylene hydrocarbons. Inasmuch as they differ in many respects both from the aliphatic and aromatic hydrocarbons, the author regards them and their derivatives as constituting a third general class of organic compounds (compare Abstr., 1884, 1276; 1887, 922).

A. G. B.

Tribromonitrobenzene. By C. L. Jackson and W. B. Bentley (*Amer. Chem. J.*, **14**, 363—366).—Tribromonitrobenzene (5 grams) was dissolved in benzene, mixed with an alcoholic solution of sodium ethoxide (1 gram of sodium), heated on the water-bath for some time, and then left at a temperature a little above the ordinary for several hours; the liquid was filtered, water and dilute sulphuric acid were added, and the benzene separated; the aqueous portion was then washed with ether, and the residue from the evaporation of this was mixed with that from the benzene, and crystallised from alcohol. Analysis proved this substance to be *dibromonitrophenetoïl*, $NO_2{\cdot}C_6H_2Br_2{\cdot}OEt$; it crystallises in bundles of white prisms, turns brown in air, and melts at 91°; it is very slightly soluble in water, light petroleum, cold glacial acetic acid, and cold alcohol, and freely soluble in benzene, chloroform, acetone, carbon bisulphide, ether, hot alcohol, and hot glacial acetic acid; it distils with steam. The reaction between tribromonitrobenzene and sodium methoxide appears to yield dibromonitranisoïl.

Tribromonitrobenzene is more stable than tribromodinitrobenzene and tribromotrinitrobenzene, the former of which reacts with sodium ethoxide in the cold to produce bromodinitroresorcinol ethyl ether, whilst with the latter a more deep-seated reaction occurs. Aniline, which readily forms anilido-derivatives with the dinitro- and trinitro-derivatives, is without action on tribromonitrobenzene.

Synthesis of Dihydroparaxylene. By A. v. Baeyer (*Ber.*, **25**, 2122—2123; compare this vol., pp. 833 and 1074).—When ethyl sodiosuccinosuccinate is treated with methyl iodide, an oil, insoluble in dilute alkalis, and boiling at about 192° (14 mm.), is obtained; the distillate solidifies, forming crystals which melt at 72·5° and have the composition of an *ethyl dimethylsuccinosuccinate*. Inasmuch, however, as this compound gives a phenylhydrazone (m. p. 207°), it may be regarded as ethyl dimethyldiketohexamethylenedicarboxylate,

$$COOEt{\cdot}CMe<\begin{matrix}CH_2{\cdot}CO\\CO{\cdot}CH_2\end{matrix}>CMe{\cdot}COOEt.$$

The compound, when treated with dilute sulphuric acid, behaves in a manner analogous to ethyl succinosuccinate, already described (*loc. cit.*, p. 833), a *dimethyldiketohexamethylene* melting at 93° being formed; this, on reduction, yields a *dihydroxy-compound* (*dimethylquinitol*) in the form of a syrup. The *dibromide*,

$$CHMe<\begin{matrix}CH_2\cdot CHBr\\CHBr\cdot CH_2\end{matrix}>CHMe,$$

obtained from the latter, if heated with quinoline, gives a *dihydroxylene* which is in all probability represented by the formula $CMe<\begin{matrix}CH\cdot CH_2\\CH_2\cdot CH\end{matrix}>CMe$. This boils at about 133—134° under a pressure of 720 mm., has the odour of oil of turpentine, changes the colour of permanganate to brown, gives a crystalline bromo-additive product when treated with bromine water, and decolorises a solution of bromine in chloroform, with evolution of hydrogen bromide. It solidifies in crystals after a while, and gives a yellowish-red colour with alcoholic sulphuric acid; a crystalline nitrosite could not be obtained. It is not possible to decide from these properties whether the dihydroxylene is identical with one of the known terpenes, but, since it behaves as a terpene, the synthesis of the members of the limonene series is to be regarded as a solved problem. The preparation of terpenes derived from cymene can be accomplished by introducing methyl and isopropyl groups into ethyl succinosuccinate.

The author is now studying the action of ethylene bromide and methylene iodide on ethyl sodiosuccinosuccinate. Cantharene is probably a derivative of orthoxylene. A. R. L.

Mechanism of the Formation of Tricyanides from Nitriles and Acid Chlorides in the presence of Aluminium Chloride. By P. Eitner and F. Krafft (*Ber.*, **25**, 2263—2269).—When a mixture of benzoic chloride and aluminium chloride (1 part of each) and benzonitrile (2 parts) is heated for eight hours and then triturated with chloroform, lustrous, prismatic crystals of the *compound* $COPh\cdot N{:}CPh\cdot N{:}CPhCl,AlCl_3$ rise to the surface of the liquid. The compound is very hygroscopic, and dissolves in alcohol with the formation of imidodibenzamide (m. p. 104°) and ethyl benzoate; when, however, the solution is treated with ammonia, a small quantity of kyaphenine (triphenyl tricyanide) is obtained. The latter fact led to the discovery of the following method of preparing kyaphenine:—

Benzonitrile (15 parts), benzoic chloride (8 parts), and well-dried, pulverised ammonium chloride (9 parts) are mixed, and coarsely pulverised aluminium chloride (8·5 parts) added to the mixture at 0° with agitation; after 1—2 hours, the aluminium chloride dissolves, the liquid is heated in an oil-bath for 24 hours at a temperature gradually increasing from 90° to 140°, and finally maintained at 140—150° for a time; hydrogen chloride is evolved, and the product, which solidifies on cooling, is poured into ice-cold water, collected, washed successively with hydrochloric acid, water, and ether, and

subsequently with sodium hydroxide, water, and cold alcohol, when kyaphenine, to the extent of 60 per cent. of the theoretical amount, remains.

In the formation of tricyanides from nitriles, acid chlorides, and aluminium chloride in the absence of ammonium chloride, the nitrile probably undergoes conversion into the amide or ammonium salt by means of the water present in the crude reagents, and this view finds support in the fact that when pure materials are employed, very little tricyanide is produced, whereas a large yield is obtained when a small quantity of water vapour is passed into the mixture.

In the preparation of methyl diphenyl tricyanide (Abstr., 1890, 1252), a yellow, crystalline bye-product is obtained, which yields the tricyanide, and not, as in the above-mentioned case, a dicyanide, on treatment with water. This compound appears not to be an intermediate one in the reaction, and it is formed when aluminium chloride (1 part) is dissolved in acetic chloride (15 parts) at 0° and methyl diphenyl tricyanide added.

The question of the formation of methyl diphenyl tricyanide is still an open one. The authors do not regard the explanation offered by Pinner (this vol., p. 1110) as impossible, but they point out that the benzoylbenzamidine obtained by the latter cannot be an intermediate product of the synthesis, but must result from the decomposition of an intermediate product. A. R. L.

Monosodium Catechol. By DE FORCRAND (*Compt. rend.*, **114**, 1195—1197).—Sodium (1 equivalent) is dissolved in a cold alcoholic solution of catechol (1 equivalent) in an atmosphere of hydrogen. When solution is complete, the alcohol is dissolved off, and the residue is heated at 120—125° in an atmosphere of hydrogen until quite dry. The monosodium catechol thus obtained is white and crystalline, but rapidly becomes grey when exposed to air, and by prolonged exposure to air or oxygen becomes black.

Heat of dissolution at 15—20° = +1·29; heat of dissolution of catechol −3·46 Cal.

$C_6H_6O_2 + \frac{1}{2}Na_2O$	develops	+ 5·96 Cal.
$C_6H_6O_2$ sol. + Na sol. = H gas + $C_6H_5NaO_2$ sol.	„	+44·29 „
$C_6H_6O_2$ sol. + NaOH sol. = H_2O sol. + $C_6H_5NaO_2$ sol.	„	+12·42 „

These numbers are higher than the corresponding values for phenol, and it would seem that in the case of the polyhydric phenols there is an exaggeration of the apparent value of the first phenolic function, similar to that already observed in the case of the polyhydric alcohols. Moreover the difference between the value of the first function in the case of methyl alcohol and glycol (5·81 Cal.) is practically the same as the corresponding difference between phenol and catechol (5·19 Cal.). C. H. B.

Sodium Resorcinol and Sodium Quinol. By DE FORCRAND (*Compt. rend.*, **114**, 1370—1373).—The method employed for the

preparation of the sodium compounds of resorcinol and quinol was similar to that adopted in the case of the corresponding compound of catechol (preceding abstract). They are more soluble in alcohol than the catechol compound, and are more rapidly affected by exposure to air. They also retain alcohol more tenaciously, and the resorcinol compound is very hygroscopic.

Heats of dissolution of the two phenols at 20°, resorcinol −3·79 Cal., quinol −4·42 Cal.; heats of dissolution of the sodium compounds, resorcinol +8·82 Cal., quinol +7·01 Cal.; heats of neutralisation by sodium hydroxide in dilute solution, resorcinol +8·23 Cal., quinol +7·50 Cal. It follows that—

$C_6H_6O_2$ sol. + Na sol. = H gas + $C_6H_5NaO_2$ sol.	develops	resorcinol	+38·70 Cal.
		quinol	+39·15 „
$C_6H_6O_2$ sol. + NaOH sol. = H_2O sol. + $C_6H_5NaO_2$ sol. .	„	resorcinol	+ 6·83 „
		quinol	+ 7·28 „

These numbers are practically identical for the two isomerides, and agree with the corresponding numbers for phenol. Combining these results with those obtained in the case of catechol (*loc. cit.*), it is evident that when the two hydroxyl groups are in the meta- or para-positions, the first phenolic function has practically the same value as in ordinary phenol, but when the hydroxyl groups are in the ortho-position there is an apparent exaggeration of the thermal value of the first phenolic function analogous to that observed in the case of glycol.

It is noteworthy that catechol gives the highest number for the heat of neutralisation in the solid state, but the lowest number when the compounds are in dilute solution. This difference may be due to the greater energy with which the sodium salts of resorcinol and quinol combine with the water. C. H. B.

Bimetallic Derivatives of Dihydric Phenols. By DE FORCRAND (*Compt. rend.*, **114**, 1434—1437).—The bimetallic derivatives were prepared in the same way as the mono-derivatives, using, of course, two equivalents of sodium (preceding abstracts).

Disodium catechol is colourless in hydrogen, but when exposed to air becomes first grey, then black, and deliquesces. The resorcinol compound becomes brown, and deliquesces very rapidly in moist air. The quinol compound is slightly coloured, even in hydrogen, and when exposed to air becomes dark blue, and finally black. Heat of dissolution at 20°, catechol compound +12·09 Cal., resorcinol compound +20·51 Cal., quinol compound +20·70 Cal.

		Catechol.	Resorcinol.	Quinol.
NaOH diss. + $C_6H_5NaO_2$ diss.	develops	+ 1·48	+ 7·10	+ 6·18 Cal.
Na_2 sol. + $C_6H_6O_2$ sol...	„	+78·05	+77·19	+74·72 „
Na sol. + $C_6H_5NaO_2$ sol.	„	+33·76	+38·49	+35·57 „

In the case of catechol the total value is 78·05 Cal., and the mean value +39·025 Cal., which is identical with the value for ordinary phenol. The relation between phenol and catechol is, therefore, the

same as between methyl alcohol and glycol. There is an exaggeration of the apparent thermal value of the first phenolic function, and a corresponding reduction of the value of the second function, due to intramolecular combination between the free second function and that in which the substitution of the metal has already taken place. In the case of catechol this combination develops +5·26 Cal., and in the case of glycol +5·67 Cal. when liquid, and 4·34 Cal. when solid.

The thermal values of the two functions of resorcinol are practically identical, but each value, as well as the mean +38·6, is distinctly lower than +39, and the difference is greater than the error of experiment. It follows that the separation of the two C·OH groups by a CH group not only reduces the energy of intramolecular combination, but also reduces the mean energy of the phenolic function.

Quinol behaves partly like catechol and partly like resorcinol. The difference between the apparent values of the two functions +39·15 Cal., +35·57 Cal., indicates intramolecular combination, resulting in a development of +1·79. The mean value of the phenolic function +37·36 Cal. is even lower than in the case of resorcinol.

The value of the phenolic function is only constant when the two OH groups are contiguous, and it diminishes as the separation of the OH groups by hydrocarbon groups becomes greater and greater.

Colson has shown that the heats of neutralisation of the three phthalic acids are as follows: ortho- +53·99 × 2, meta- +52·23 × 2, para- +51·68 × 2; and Massol has shown that similar and greater differences are observed in the case of bibasic organic acids derived from paraffin. C. H. B.

Action of Chlorine on Phenols. By T. Zincke (*Ber.*, **25**, 2219—2236).—A continuation of the study of the products obtained from the so-called heptachlororesorcinol (Abstr., 1891, 691).

The acid $C_6H_2Cl_8O_2$ (*loc. cit.*) is conveniently prepared by adding a dilute solution of bleaching powder to one of the heptachlororesorcinol in a little glacial acetic acid, and subsequently dilute hydrochloric acid, when it separates. The following experiment shows that it is trichloracetopentachlorobutyric acid. When the acid is dissolved in an excess of cold, aqueous soda, and the solution, after a time, acidified with hydrochloric acid, chloroform separates, and *pentachloroglutaric acid*, $CHCl(CCl_2{\cdot}COOH)_2$, is obtained on extracting the aqueous portion with ether. The latter crystallises in small, white needles, containing 1 mol. H_2O, is readily soluble in water, alcohol, and ether, but only sparingly so in light petroleum; when dried at 100°, it melts at 165°. The *methyl salt* melts at 61—62°. The acid $C_6H_2Cl_7BrO_3$, when treated in an analogous manner, yields dichlorobromomethane and pentachloroglutaric acid.

When tetrachlorodiketopentamethylene (*loc. cit.*) is treated in a fused condition with dry chlorine at 200° for 2—3 hours, and the product distilled, *perchloro-β-acetoacrylic chloride*,

$$CCl_3{\cdot}CO{\cdot}CCl{:}CCl{\cdot}COCl,$$

passes over at 149—150° under a pressure of 17—20 mm. The corresponding acid, $CCl_3{\cdot}CO{\cdot}CCl{:}CCl{\cdot}COOH$, is obtained when the chloride

is heated with dilute hydrochloric acid at 130—140°; it is also formed when the tetrachlorodiketopentamethylene is heated in a sealed tube at 150—160° for some hours with finely-powdered manganese peroxide (1 mol. prop.) and the calculated quantity of hydrochloric acid. It crystallises from light petroleum in small, white needles or leaflets, melts at 83—84°, and is readily soluble in alcohol, ether, and benzene; it also crystallises from hot water with $1\frac{1}{2}$ mols. H_2O. Both the acid and the chloride dissolve in sodium hydroxide solution, with the formation of chloroform and dichloromaleïc acid (m. p. 118—119°). The *amide*, $C_5Cl_5O_2{\cdot}NH_2$, formed when the chloride is carefully treated in the cold with concentrated aqueous ammonia, avoiding excess, crystallises from hot water in colourless, translucent tablets melting at 85—86°, or from benzene in prisms which effloresce on exposure, and then melt at 143°. The *anilide*, $C_5Cl_5O_2{\cdot}NHPh$, obtained when aniline (2 mols.) is added to a solution of the chloride in glacial acetic acid, crystallises from dilute alcohol in white, silky needles, melts at 182—183°, and dissolves in sodium hydroxide solution with decomposition. The corresponding *paratoluidide* melts at 192—193°. When the above-described acid chloride is dissolved in glacial acetic acid, and the solution heated on the water-bath with an excess of aniline, a *compound* separates, which crystallises from benzene in red needles, and melts at 229°; whilst on adding water to the filtrate a *compound* is obtained crystallising from alcohol in the form of yellow nodules melting at 146—147°. These substances are, perhaps, represented by the formulæ

$$\begin{array}{l} NHPh{\cdot}C{\cdot}CO{\cdot}NPh \\ NHPh{\cdot}C{\cdot}CO{\cdot}CO \end{array} \quad \text{and} \quad \begin{array}{l} NHPh{\cdot}C{\cdot}CO{\cdot}NPh \\ NHPh{\cdot}C{\cdot}CO{\cdot}C{:}NPh \end{array}$$

respectively. Two similar compounds, melting at 196° and 152°, are obtained from the chloride and paratoluidine.

On dissolving the amide, $C_5Cl_5O_2{\cdot}NH_2$ (see above), in alcohol, and boiling the solution with aniline, the chief product is a compound which crystallises from alcohol in orange, rhombic leaflets, and melts at 221°; its constitution is possibly $\begin{array}{l} NHPh{\cdot}C{\cdot}CO{\cdot}NH \\ NHPh{\cdot}C{\cdot}CO{\cdot}C{\cdot}NPh \end{array}$.

The compound $C_5Cl_8O_2$, previously described (*loc. cit.*), is obtained when the acid chloride $C_5Cl_6O_2$ (see above) is heated for 8—10 hours in a sealed tube at 200° with phosphorus pentachloride. It is a colourless, highly-refracting oil, boils at 153—154° (12—15 mm.), and is extremely stable, being only attacked by alcoholic potash on boiling with it for a day, when it yields dichloromaleïc acid. As already stated (*loc. cit.*), the compound is decomposed by the continued action of phosphorus pentachloride into hexachlorethane and an oil, C_3Cl_4O; the latter appears, however, to be a solution of hexachlorethane in the unattacked substance. The above facts harmonise best with the constitution $CCl_3{<}\begin{array}{l} CCl{-}{-}CCl \\ O{\cdot}CCl_2{\cdot}CCl \end{array}$ for the compound. A. R. L.

Phenylene Oxide. By W. Vaubel (*J. pr. Chem.* [2], **46**, 51—53). —Märker (*Annalen*, **124**, 249) stated that he had obtained phenylene

oxide, C_6H_4O, by the destructive distillation of salicylosalicylic acid. Goldschmidt (*Jahresberichte*, 1883, 1137), however, failed to recognise it among the products, and the author has also failed to prepare it, not only by the method indicated, but also by heating the dibromobenzenes with zinc oxide, resorcinol with phosphoric anhydride, and hydroquinone with the same dehydrating agent.

Kekulé's formula for benzene will only admit of the existence of one phenylene oxide, for it can only be conceived of as being the anhydride of orthodihydroxybenzene, in which the hydroxyls are adjacent. According to the author's formula for benzene (Abstr., 1891, 1343) it is quite possible for a para- or meta-dihydroxybenzene to yield phenylene oxide. Nor would such a reaction be particularly out of the common, for it is known that pariodophenol yields resorcinol when melted with an alkali (Abstr., 1888, 262), and the same seems to be true of orthiodophenol above 200° (Schall, *Ber.*, **16**, 1897; Abstr., 1883, 1109). If mutual attraction and ability to shift their positions be allowed to the substituting groups in a benzene derivative, the formation of phenylene oxide as an intermediate product in these reactions is to be expected. A. G. B.

Oxidation of Bisecondary Pentethylphloroglucinol by means of Uncombined Oxygen. By B. C. Ulrich (*Monatsh.*, **13**, 245—251).—When pentethylphloroglucinol was allowed to remain for from four to six weeks in a flask containing uncombined oxygen and exposed to light, decomposition occurred (compare Herzig and Zeisel, Abstr., 1888, 247 and 966, and Spitzer, Abstr., 1890, 1110), with the formation of carbonic anhydride, propionic acid, tetrethylacetone, and a small quantity of diethylmalonic acid. When the oxidation was induced by alkaline permanganate, a volatile acid (in all probability propionic acid), was the chief product, but a small quantity of a heavy neutral oil of the formula $C_{15}H_{26}O_2$, boiling at 275—285°, was also formed. This oil must be regarded as the triketone

$$CHEt_2{\cdot}CO{\cdot}CEt_2{\cdot}CO{\cdot}COEt,$$

since, on further oxidation, it gave, as was expected, a mixture of tetrethylacetone and propionic acid. *Tetrethylacetone*, $C_{11}H_{22}O$, thus obtained, was volatile in a current of steam, boiled at 200—205° (uncorr.), had a characteristic but not unpleasant odour, and did not form a compound with hydrogen sodium sulphite. G. T. M.

Formation of Diphenylamine from Orthobromobenzoic Acid. By A. Heidenreich and V. Meyer (*Ber.*, **25**, 2188—2189).—It has been shown that the bromine is eliminated from orthobromobenzophenone by an alkaline solution of hydroxylamine, and that the oxime of this ketone gives up its bromine when treated with soda. The authors have found that the bromine of orthobromobenzoic acid can also be eliminated by alkalis.

When the bromobenzoic acid is heated with aqueous ammonia in a sealed tube, action takes place at 180°, and is easily completed at 200°. With alcoholic ammonia, the action takes place at 130°. The

product contains only a very small quantity of anthranilic acid, but somewhat notable quantities of salicylic acid and diphenylamine; the latter floats on the aqueous solution as an oil, and is easily separated by steam distillation. The authors believe that the diphenylamine is produced through a diphenylaminecarboxylic acid as represented by the equation $NH_3 + 2C_6H_4Br{\cdot}COOH = 2HBr + NH(C_6H_4{\cdot}COOH)_2 = 2CO_2 + NHPh_2$, and on examining the aqueous solution they obtained evidence of the presence of a diphenylaminecarboxylic acid.

Orthobromobenzoic acid is not so easily attacked by other bases as by ammonia, and when boiled for one hour with aniline, the bromine was not eliminated. E. C. R.

Schiff's Bases. By W. v. Miller, J. Plöchl, and others (*Ber.*, **25**, 2020—2071).—Schiff's bases, derived from aromatic aldehydes, have a similar constitution to benzylidenaniline, PhN:CHPh, which serves as the type of these compounds. Most of them are well characterised compounds, and very many have been prepared. Of the bases derived from the fatty aldehydes, a smaller number are known, and only a few of these are well characterised compounds. The authors have prepared Schiff's ethylidenaniline (*Annalen*, **210**, 118), the valeraldehydaniline of Lippmann and Strecker (*Ber.*, **12**, 74), and the anhydroformaldehydaniline (m. p. 140°) of Tollens (*Ber.*, **17**, 657) and Pratesi (*Gazzetta*, **14**, 351).

The molecular weight of these compounds is not yet determined with certainty. The authors, employing Raoult's method, obtained results pointing to the treble formula for anhydroformaldehydaniline, and to the double formula for anhydrovaleraldehydaniline and acetaldehydaniline. Whilst, however, anhydroformaldehydaniline and anhydrovaleraldehydaniline behave in their reactions like the simple base, and are easily split into the same, acetaldehydaniline and propylaldehydaniline behave in an entirely different manner; for they yield acetyl, benzoyl, and nitroso-compounds, and therefore contain an imido-group. Also they unite with bromine and are easily converted into quinoline derivatives. The authors assign to acetaldehydaniline the constitution $NPh{:}CH{\cdot}CH_2{\cdot}CHMe{\cdot}NHPh$, and to propylaldehydaniline the constitution $NPh{:}CH{\cdot}CHMe{\cdot}CHEt{\cdot}NHPh$. When heated with hydrochloric acid, aniline is eliminated, and the former yields quinaldine, the latter α-ethyl-β-methylquinoline.

A similar polymerisation of the simple base into a bimolecular form of a secondary character has only been observed in the case of the anilide of isobutaldehyde, and then only partially. In all other cases the polymerisation takes place without influencing the tertiary character of the bases. These bases are obtained in their unpolymerised form as oils when formed in the cold, but if allowed to remain for some time they polymerise and become solid. The authors were unable to obtain isomeric forms of the condensation product of aldehyde and aniline as described by Schiff (*Annalen*, Suppl., Bd. **3**, 346).

The authors have examined the behaviour of these compounds towards hydrogen sulphide, reducing agents, and hydrocyanic acid. An easy method of obtaining the nitriles is to dissolve the

amine in ether, add hydrocyanic acid, and then gradually add the aldehyde.

Most of Schiff's bases easily combine with hydrocyanic acid, many of them with avidity. The anilide of acetylcarboxylic acid is an exception, and the reaction takes place with difficulty in the case of the anilide of benzoïn. The authors have also examined the behaviour of hydrazones and oximes towards hydrocyanic acid, and find that the hydrazones and oximes of aldehydes and ketones of the fatty series react with hydrocyanic acid; those of the aromatic series do not.

Thus, as regards the capability of reacting with hydrocyanic acid, Schiff's bases correspond with oximes and hydrazones which contain aliphatic radicles, and the compounds of aniline, phenylhydrazine, and hydroxylamine with acetylcarboxylic acid correspond with hydrazones and oximes which contain aromatic radicles. The authors propose to explain the different behaviour of these similarly constituted compounds by means of space formulæ. The oximes and hydrazones of the fatty series which have exclusively alkyl or hydrogen combined to the carbon atom of the grouping =C=N- are not known to occur in stereomeric forms, nor are Schiff's bases as far as the authors' observations go. The hydrazones and oximes of the aromatic series, however, occur in stereomeric forms. The authors assume that those compounds capable of combining with hydrocyanic acid have a symmetrical configuration, so that the three bonds of the nitrogen atom lie in a plane, and that in those compounds which do not combine with hydrocyanic acid the third bond of the nitrogen atom is not in the same plane as the other two.

Anhydroformaldehydaniline is prepared by mixing aniline with the equivalent quantity of formaldehyde, taking care to keep the mixture cool, and, after some hours, washing the product with water. A mixture is obtained consisting of anhydroformaldehydaniline, which is extracted with benzene, and melts at 140°, and of a crystalline compound quite insoluble in benzene. A determination of the molecular weight of the compound melting at 140° gave numbers pointing to a polymerisation of three molecules of the simple formula PhN:CH_2. The second insoluble compound the authors regard as a higher polymeride, and it gives all the reactions of the less complex compound. When anhydroformaldehydaniline (50 grams) is added with cooling to dry hydrogen cyanide (50 grams), combination takes place slowly, and on remaining over night a crystalline *nitrile* is obtained. This crystallises from a mixture of petroleum and ether in large, white plates, melts at 43°, and is easily soluble in alcohol, ether, and benzene, very sparingly so in petroleum and water. When boiled with concentrated hydrochloric acid for a few minutes, it is converted into phenylglycocoll, $\text{NHPh·CH}_2\text{·COOH}$, which crystallises from water in small, white crystals, and melts at 126°.

Anhydroformaldehydaniline, when suspended in benzene and treated with hydrogen sulphide, yields a compound of the formula $\text{S(CH}_2\text{·NHPh)}_2$, melting at 93°, and also a well crystallised compound which contains sulphur, and melts at 112—117°.

When it is reduced with zinc-dust and concentrated hydrochloric acid, it yields methylaniline.

Condensation of Aniline with Acetaldehyde.—When the equivalent quantity of acetaldehyde is gradually added to aniline dissolved in an equal quantity of 90 per cent. alcohol, and the mixture cooled with ice, a dark yellow oil is precipitated, which soon solidifies. The compound is purified by precipitation with petroleum from its solution in ether. The authors put forward the following formulæ for this compound : $NPh{:}CH{\cdot}CH_2{\cdot}CHMe{\cdot}NHPh$ or $NHPh{\cdot}CHMe{\cdot}C_6H_4{\cdot}N{:}CHMe$. It crystallises from ether in large, hexagonal crystals, melts at 126°, boils at 300° without decomposition, and is sparingly soluble in alcohol and benzene, more so in ether. When heated with hydrochloric and acetic acids, it yields quinaldine; it does not combine with hydrocyanic acid or hydrogen sulphide, but yields an acetyl, benzoyl, and nitroso-compound. A determination of the molecular weight by Raoult's method gave numbers agreeing with the above formulæ. The *acetyl compound*, $C_{18}H_{20}N_2O$, crystallises from alcohol, melts at 188°, is soluble in hot alcohol and benzene, sparingly so in ether, and combines with bromine to yield a compound melting at 150—153°. The *benzoyl compound* crystallises in silky leaflets, melts at 218°, and is insoluble in boiling alcohol, ether, and benzene.

The base may also be prepared by adding acetaldehyde to a solution of aniline (21 grams) in water (1000 grams). On allowing the milky liquid to stand for a few days, it deposits a white powder which consists of the above base mixed with the simple base $NPh{:}CHMe$, which is an oil, and reacts with hydrogen cyanide. The nitrile of the oily base is best prepared by adding acetaldehyde to a solution of aniline and hydrocyanic acid in ether. It crystallises from ether or benzene in monoclinic leaflets, melts at 92°, and, when hydrolysed with concentrated sulphuric acid, yields an amide melting at 140°, and then an acid melting at 163°.

Condensation of Propaldehyde with Aniline.—Propaldehyde and aniline, when cautiously mixed, taking care to cool well, yield an oil which solidifies after a time. The solid compound, to which the authors assign the formula $NPh{:}CH{\cdot}CHMe{\cdot}CH(NHPh){\cdot}CH_2Me$ or $NHPh{\cdot}CHEt{\cdot}C_6H_4N{:}CHEt$, melts at 103—104°, is insoluble in water, sparingly soluble in cold alcohol, easily so in ether, benzene, and hot alcohol, and crystallises in white needles. With hydrochloric acid, it yields a sparingly soluble salt. When heated with hydrochloric acid, it is converted into α-ethyl-β-methylquinoline. It does not combine with hydrocyanic acid. The *benzoyl compound* melts at 144—145°, is insoluble in water, and sparingly soluble in petroleum and cold alcohol, easily so in benzene, ether, and hot alcohol.

The simple Schiff's base, propylidenaniline, is obtained by adding the aldehyde to aniline dissolved in ether with cooling. When hydrocyanic acid is added to the ethereal solution thus obtained, the *nitrile* is formed; it is, however, more conveniently obtained by adding the aldehyde to an ethereal solution of aniline and hydrogen cyanide. It crystallises in needles, melts at 39°, is easily soluble in alcohol, ether, and benzene, sparingly in petroleum, and insoluble

in water. When the nitrile is cautiously hydrolysed with sulphuric acid, and the solution diluted with water and saturated with ammonia, α-anilidobutyramide is obtained; this crystallises from alcohol in iridescent scales, melts at 122—123°, is soluble in benzene and ether, somewhat so in hot water, and when treated with hydrochloric acid on the water-bath is converted into α-anilidobutyric acid (m. p. 140—141°).

The *hydrazone*, NHPh·N:CHEt, is prepared by adding propaldehyde to an ethereal solution of phenylhydrazine. When hydrocyanic acid is added to the mixture, the *nitrile* is formed, and on evaporation of the ether and hydrocyanic acid is obtained crystalline. The nitrile is also obtained by adding the aldehyde to an ethereal solution of phenylhydrazine and hydrocyanic acid. It separates in large crystals from a mixture of ether and petroleum, melts at 37°, is insoluble in water, and easily soluble in ether, alcohol, benzene, and chloroform. When hydrolysed with fuming hydrochloric acid, it is converted into *α-phenylhydrazidobutyramide*. The latter crystallises from a mixture of ether and petroleum in slender needles, melts at 79°, is soluble in alcohol, ether, and benzene, reduces ammoniacal silver solution in the cold, and, when hydrolysed by boiling with 5 per cent. sodium hydroxide, is converted into the corresponding acid.

Butylidenaniline is obtained by mixing equivalent quantities of aniline and normal butaldehyde, and cooling the mixture with ice. It is a viscid oil which was not obtained crystalline, and readily reacts with hydrocyanic acid to yield an oily nitrile. The nitrile is, however, more easily obtained by adding butaldehyde to an ethereal solution of aniline and hydrogen cyanide. It solidifies after some time, crystallises from light petroleum in nacreous leaflets, and melts at 51°. Both the crystalline and oily nitrile, when hydrolysed with concentrated sulphuric acid, yield α-anilido-*n*-valeramide (m. p. 99°), and then α-anilido-*n*-valeric acid (m. p. 147—148°).

Isobutaldehyde and aniline yield an oily condensation product which crystallises after a time. The freshly prepared oil combines with hydrogen cyanide to yield a nitrile. The solid base crystallises from petroleum and benzene in white needles, melts at 140°, is easily soluble in ether, alcohol, and benzene, sparingly so in petroleum, insoluble in water, and yields a sparingly soluble salt with hydrochloric acid, and an *acetyl compound* when treated with acetic anhydride. The oily base, when reduced in alcoholic solution with sodium, yields aniline and aldehyde; isobutylaniline could not be detected in the reduction product. The *nitrile*, prepared in the same way as the nitriles mentioned above, crystallises in white needles, melts at 54°, is easily soluble in alcohol, ether, benzene, and hot petroleum, and evolves hydrogen cyanide when warmed with water. When hydrolysed with concentrated sulphuric acid, *α-anilidoisovaleramide* is obtained; this crystallises from benzene in white leaflets, melts at 102—103°, is easily soluble in alcohol, benzene, and ether, sparingly so in petroleum and warm water, and, when melted with aqueous sodium hydroxide, is converted into α-anilidoisovaleric acid melting at 135°.

Anhydrovaleraldehydaniline, $(NPh{:}CH{\cdot}CH_2{\cdot}CHMe_2)_2$, is obtained as described by Lippmann and Strecker (*Ber.*, **12**, 72). When purified by washing with absolute alcohol, it forms a white, crystalline powder, melts at 97°, is very easily soluble in ether, benzene, and chloroform, easily so in toluene, acetone, and hot petroleum, sparingly in cold petroleum and hot alcohol, and insoluble in cold absolute alcohol. It boils at 227°, can be distilled without noticeable decomposition, and is volatile with steam. It does not yield either an acetyl or benzoyl derivative when treated with the usual agents, but is decomposed with formation of acetanilide and benzanilide. When treated with concentrated hydrochloric acid or with zinc chloride, it is converted into α-isobutyl-β-isopropylquinoline. When reduced in amyl alcoholic solution with sodium, it yields isoamylaniline. When reduced in ethyl alcoholic solution with sodium, it yields a compound of the formula $C_2H_2(NHPh)_2(CH_2{\cdot}CHMe_2)_2$; this is a viscid oil, distils at 300—315° without decomposition, and yields a crystalline hydrochloride which is very sparingly soluble in water. The *acetyl derivative* crystallises from light petroleum in large, colourless prisms, and melts at 132°. The *benzoyl derivative* crystallises from light petroleum in colourless tablets, melts at 132—134°, and with sodium nitrite yields a nitroso-compound melting at 118°. The *nitroso-compound* crystallises from light petroleum in concentric needles, and melts at 83—84°.

Anhydrovaleraldehydaniline does not yield additive compounds with hydrogen sulphide or carbon bisulphide; the former converts it into thioaldehyde and aniline, the latter into thiocarbanilide. It is energetically attacked by bromine and iodine in chloroform solution, but the products evolve halogen hydride, and are quickly converted into resin. Neither could any definite compound be obtained by the action of ethyl iodide.

When treated with excess of dry hydrogen cyanide, the *nitrile*, $NHPh{\cdot}CH(CN){:}CH_2{\cdot}CHMe_2$, is obtained; this crystallises from benzene in long, thin prisms, melts at 67°, is volatile with steam, and distils at 210—230° without decomposition. When hydrolysed with concentrated sulphuric acid, it is converted into the corresponding *acid amide*, which melts at 106—107°, and, when boiled with concentrated hydrochloric acid, yields the acid

$$NHPh{\cdot}CH(COOH){\cdot}CH_2{\cdot}CHMe_2.$$

This crystallises in quadratic tablets, melts at 168—170°, and is easily soluble in ether, alcohol, chloroform, and hot benzene.

When treated with 40 per cent. aqueous hydrocyanic acid, it is converted into the *nitrile* of the bimolecular compound of the formula $C_{23}H_{31}N_3$, together with a small quantity of the preceding nitrile. This nitrile forms white, strongly refractive crystals, melts at 136°, is not volatile with steam, and, when distilled at 200—230°, is split into the normal nitrile (m. p. 67°) and the simple base, the latter decomposing.

The unpolymerised base, $NPh{:}CH{\cdot}CH_2{\cdot}CHMe_2$, is obtained by adding the aldehyde to a well cooled solution of aniline in two parts of ether. It remains liquid for some days, and, with

aqueous hydrocyanic acid, gives a very good yield of the normal nitrile.

Isovalerylidenetoluidine is obtained by shaking an ethereal solution of paratoluidine with isovaleraldehyde. It separates from hot alcohol in colourless crystals, and melts at 99°. The *nitrile* is obtained from the crystalline base only by employing a large excess of concentrated hydrocyanic acid, but is easily obtained by the indirect method previously described, and melts at 62—63°. The corresponding *acid amide* melts at 131°; the *acid* at 192°.

Condensation of Œnanthaldehyde with Aniline.—The condensation product of œnanthaldehyde and aniline is a yellow oil having a characteristic odour; it soon polymerises, and cannot be obtained in a solid state. When treated with hydrocyanic acid, large quantities of resin are formed, and the nitrile could not be obtained. The *nitrile* is easily obtained by adding œnanthaldehyde to an ethereal solution of aniline and hydrogen cyanide. It crystallises from alcohol, and melts at 39·8°. The *acid amide* obtained from it crystallises from alcohol in minute, white needles, melts at 105·3°, and when boiled with dilute hydrochloric acid is converted into the corresponding *acid*. The latter is a white, crystalline powder, melts at 147·3°, and when damp is easily decomposed.

Œnanthaldehydehydrazone, when dissolved in ether and treated with excess of concentrated hydrocyanic acid and allowed to remain eight days, yields a very small quantity of nitrile. The *nitrile* is, however, easily obtained by adding œnanthaldehyde to an ethereal solution of phenylhydrazine and hydrogen cyanide, allowing the mixture to remain 24 hours in a closed flask, and distilling off the ether and hydrocyanic acid. After four days the nitrile solidifies. It crystallises from a mixture of alcohol and ether in large, colourless leaflets, and melts at 50·8°.

Phenyl-α-anilidocrotonitrile, NHPh·CH:CH·CHPh·CN, is obtained by gradually adding cinnamanilide to well-cooled hydrocyanic acid. It crystallises from alcohol or benzene in colourless needles, melts at 131°, is easily soluble in alcohol, less so in benzene, insoluble in water and light petroleum, and when boiled with concentrated hydrochloric acid, is converted into phenyl-α-anilidocrotonic acid.

Benzylideneparanitraniline is obtained by heating paranitraniline with twice the theoretical quantity of benzaldehyde for 4—5 hours at 120—130°. It crystallises from acetone in yellowish prisms, melts at 117—118°, and is easily soluble in warm alcohol, acetone, and benzene, more sparingly in the cold solvents, somewhat sparingly in ether and light petroleum. When boiled with dilute acids, it is decomposed with formation of benzaldehyde. It remains unaltered when heated at 120—130° for 48 hours. The *nitrile*, easily obtained by treating it with hydrocyanic acid, melts at 129°, and is easily soluble in warm alcohol and benzene, and in acetone and chloroform, less so in ether, and only sparingly in petroleum. By boiling with water it is slowly decomposed, and very quickly by alkalis, but it is not decomposed by dilute acids.

An additive product of paranitraniline and benzaldehyde is obtained if the nitraniline is dissolved in the benzaldehyde, and the filtered

solution allowed to remain, when it crystallises out as a yellow precipitate. When dried on a porous plate, it melts at 85—86°, is decomposed by washing with ether or other solvents, and cannot be recrystallised. The product is not pure, and contains small quantities of benzoic acid and the preceding anhydro-base.

Diphenylmethyleneaniline, obtained from benzophenone chloride and aniline, crystallises from absolute alcohol in yellow plates, and melts at 112—113°. The *nitrile* is easily obtained by allowing the base to remain with excess of dry hydrogen cyanide. It crystallises from alcohol in slender, radiating needles, melts at 146·5°, is easily soluble in ether, acetone, chloroform, and benzene, more sparingly in alcohol and light petroleum, is not appreciably decomposed when boiled for a short time with water or dilute acids, and dissolves in concentrated sulphuric acid with a beautiful carmine coloration, which disappears on the addition of water with separation of white flocks.

Anhydrocinnamaldehydanisidine is obtained by heating paranisidine hydrochloride and cinnamaldehyde with concentrated hydrochloric acid. It crystallises in yellow leaflets, and melts at 122°. The *nitrile* is easily formed, crystallises in small, white leaflets, melts at 126—127°, is easily soluble in acetone and chloroform, less so in alcohol and benzene, and sparingly so in ether and light petroleum. When boiled with water or dilute acids, it yields cinnamaldehyde, and gives a dark-red coloration with concentrated sulphuric acid.

Anhydrometanitrocinnamaldehydanisidine is obtained in a similar way to the preceding compound. It crystallises in yellow plates, and melts at 127°. The *nitrile* crystallises in yellow leaflets, and melts at 106°.

Action of Hydrogen Cyanide on Hydrazones.—Those hydrazones which do not combine with hydrogen cyanide at the ordinary temperature do not combine with it even when heated at 70—80°. The following hydrazones were found not to combine with hydrogen cyanide, benzaldehydephenylhydrazone, acetylbenzaldehydephenylhydrazone, cinnamaldehydephenylhydrazone, dihydrobenzaldehydephenylhydrazone, benzophenonephenylhydrazone, acetophenonephenylhydrazone, the two forms of the phenylhydrazone of orthonitrophenylglyoxylic acid, and the hydrazone of acetylcarboxylic acid. The following hydrazones combine with hydrogen cyanide: ethylidenephenylhydrazone, ethylidenediphenylhydrazone, propylidenephenylhydrazone, and acetonephenylhydrazone.

The *nitrile of phenylhydrazidopropionic acid*, NHPh·NH·CHMe·CN, is obtained by allowing a mixture of ethylidenephenylhydrazone and excess of hydrocyanic acid to remain at the ordinary temperature; or by gradually adding acetaldehyde to a solution of phenylhydrazine in excess of hydrocyanic acid, and allowing the mixture to remain. It is purified by drying on porous plates, crystallises from a mixture of petroleum and ether in aggregates of colourless needles, melts at 58—59°, and is very easily soluble in alcohol, ether, chloroform, and acetone, easily so in benzene, but only sparingly in light petroleum. It is insoluble in cold water, but dissolves in hot water, and is deposited on cooling in oily drops. It dissolves in dilute hydrochloric and

sulphuric acids, and is precipitated unchanged on adding an alkali. When boiled with dilute acids, hydrogen cyanide is evolved. It reduces Fehling's solution slowly in the cold, and very quickly when boiled with it.

The corresponding *acid amide* is easily obtained by treating the nitrile with fuming hydrochloric acid. It separates from hot water in spear-like crystals, melts at 124—125°, is easily soluble in alcohol, acetone, and hot water, moderately so in chloroform, sparingly in benzene and ether, and insoluble in petroleum. When hydrolysed with dilute sodium hydroxide (sp. gr. = 1·26) it yields phenylhydrazidopropionic acid, NHPh·NH·CHMe·COOH; this crystallises from methyl alcohol in nodular aggregates of very small needles, and melts between 169° and 172°: when heated quickly, it melts at 174°. It reduces Fehling's solution in the cold; when oxidised with ammoniacal copper sulphate solution, it is converted into phenylhydrazineacetylcarboxylic acid.

Ethylidenediphenylhydrazone is obtained by adding an excess of acetaldehyde to a solution of diphenylhydrazine in ether, and allowing the mixture to remain. It crystallises from light petroleum in thick, colourless tablets or short prisms, melts at 60—61°, and is easily soluble in the ordinary solvents, with the exception of water. It does not dissolve in dilute hydrochloric or sulphuric acid, but when boiled with somewhat concentrated hydrochloric acid, it dissolves with a yellow coloration; in concentrated sulphuric acid it dissolves with a yellow coloration, which quickly changes to yellowish-green, green, bluish-green, and finally pure blue. When treated with hydrocyanic acid, it yields a *nitrile;* this crystallises in thin, colourless tablets, melts at 65°, and is easily soluble in the ordinary solvents, with the exception of water and light petroleum.

The nitrile of phenylhydrazidopropionic acid agrees in its properties with the compound obtained by Reissert (*Ber.*, **17**, 1453) from ethylidenecyanhydrin and phenylhydrazine, and on comparing these products they were found to be identical.

Ethyl anilacetoacetate, when treated with hydrocyanic acid, yields a thick yellow oil, which on being hydrolysed gave the corresponding acid amide. The latter crystallises from alcohol in white, lustrous leaflets, and melts at 163°.

Anilbenzoïn and hydrocyanic acid yield an oily nitrile, which on hydrolysis gives an acid amide. The latter crystallises from dilute alcohol, and melts at 166°.

Ethylmethylketoxime gives a yellow, oily nitrile, which on hydrolysis yields a crystalline compound melting at 57°.

The oxime of acetaldehyde combines with hydrogen cyanide to yield an oily *nitrile*, which soon solidifies; it crystallises from a mixture of ether and petroleum, melts at 97°, and is easily soluble in alcohol, acetone, and water, more sparingly in ether and benzene, and insoluble in petroleum.

Acetoxime yields a nitrile of the formula $C_4H_8N_2O$, which crystallises from ether in large, monoclinic tablets, and melts at 98·5°.

Ethylphenylhydrazine acetoacetate yields a *nitrile*, which crystallises from benzene in needles, and melts at 110°. E. C. R.

Diacetylorthodiamines. By A. Bistrzycki and F. Ulffers (*Ber.*, **25**, 1991—1995; compare Abstr., 1890, 1115).—*Dinitrodiacetyldiamidotoluene*, $C_6HMe(NO_2)_2(NHAc)_2$, is prepared by treating a mixture of diacetylorthodiamidotoluene [$Me : (NHAc)_2 = 1 : 3 : 4$] (2 grams) and carbamide nitrate (0·4 gram) at 0° with the strongest colourless nitric acid, then heating the mixture at 40° for 25 minutes, and, after cooling, pouring it into water. The precipitated compound is fractionally crystallised from alcohol, the least soluble portion being the dinitro-derivative, which when pure forms white, silky needles, melts at 251—252°, and is more readily soluble in glacial acetic acid than in alcohol, but insoluble in water. It forms metallic derivatives which are orange-red or yellow; these are stable towards water, but are decomposed by acids, even by carbonic acid.

Ethenyldinitrotoluyleneamidine, $C_6HMe(NO_2)_2<\overset{-N}{NH}>CMe$, is formed by dissolving the last-described compound in 70 per cent. sulphuric acid at 90°, diluting, and neutralising, when the compound separates; it crystallises from benzene in long, lemon-yellow prisms, melts at 219°, and is insoluble in water; it dissolves, moreover, in both acids and alkalis, in the latter case forming metallic derivatives.

Nitrodiacetylorthodiamidotoluene is obtained when a solution of diacetyldiamidotoluene [$Me : (NHAc)_2 = 1 : 3 : 4$] in glacial acetic acid ($7\frac{1}{2}$ parts) is mixed in the cold with concentrated sulphuric acid (10 parts), and potassium nitrate (0·5 part) is dropped by degrees into the mixture heated to 45°. The compound, precipitated by pouring the solution into water, is crystallised from dilute acetic acid; it forms long, yellowish-white needles, melts at 239°, is insoluble in water, and more readily soluble in alcohol than in glacial acetic acid. Its compounds with metallic bases are of various shades of yellow.

Ethenylnitrotoluyleneamidine, $C_6H_2Me(NO_2)<\overset{-N}{NH}>CMe$, is prepared from the last-described compound by the method already given under the corresponding dinitro-derivative; it crystallises from water with 1 mol. H_2O, and has the properties already ascribed to it by Niementowski (Abstr., 1886, 545); it, moreover, forms salts with acids and metallic bases, the latter having a red or yellow colour.

Nitrodibenzoylorthodiamidotoluene, $C_6H_2Me(NO_2)(NHBz)_2$, is obtained by heating the dibenzoyldiamidotoluene [$Me : (NHBz)_2 = 1 : 3 : 4$] with a mixture of glacial acetic acid and nitric acid at 45°; it crystallises from glacial acetic acid in white needles, melts at 246°, is insoluble in water, and only slightly soluble in alcohol.

Benzenylnitrotoluyleneamidine, $C_6H_2Me(NO_2)<\overset{-N}{NH}>CPh$, is formed when the compound just described is heated in a sealed tube for six hours with alcoholic potash at 110—130°; it crystallises from dilute alcohol in small, brownish-yellow tufts of needles containing water of crystallisation (about $1\frac{1}{2}$ mols.), melts at 222—223°, and is insoluble in water, sparingly soluble in benzene, but readily in alcohol and glacial acetic acid. It behaves towards acids and alkalis like the ethenyl derivative (see above). A. R. L.

Reduction of Symmetrical Triamidotrinitrobenzene. By A. W. Palmer (*Amer. Chem. J.*, **14**, 377—380).—The reduction of triamidotrinitrobenzene results in the replacement of at least one amido-group or one nitro-group by hydrogen (compare Nietzki, Abstr., 1887, 476, 929). Pentamidobenzene trihydrochloride was the only product which could be identified (Abstr., 1888, 1276; 1890, 247).

A. G. B.

Dinitrosoazobenzene. By F. Kehrmann (*J. pr. Chem.* [2], **46**, 53—56).—Kehrmann defends himself against Willgerodt's animadversions (this vol., p. 1079). A. G. B.

New Synthesis by means of Diazo-compounds. By R. Hirsch (*Ber.*, **25**, 1973—1975; compare Abstr., 1891, 437).—Aniline (50 grams) is dissolved in 30 per cent. hydrochloric acid (150 grams), and diluted to 400 c.c., the ice-cold solution being then diazotised with sodium nitrite (39 grams), dissolved in water (100 c.c.), and subsequently mixed with aniline (950 grams); on rendering the solution alkaline, drying the oil which separates with calcium chloride, and heating it at 150°, nitrogen is evolved, and by carefully raising the temperature to 190°, the greater portion of the aniline distils over; when the boiling point is 200°, the distillation is stopped, and the residue boiled with water (10 parts) and neutralised with hydrochloric acid. Sodium hydroxide is now cautiously added, and the oil which floats on the surface of the liquid, and consists of amidoazobenzene dissolved in diphenylamine, is removed with bibulous paper; on adding sodium sulphate, paramidodiphenyl sulphate is precipitated and can be collected; the filtrate from this is rendered strongly alkaline, and the oil which separates fractionated, the portion passing over at 275° being almost pure orthamidodiphenyl. When the above-given quantities are employed, the yield is about 45 grams of amidodiphenyl, 900 grams of aniline being recovered. Heussler (Abstr., 1891, 555) has likewise observed the formation of amidodiphenyl by the decomposition of diazoamidobenzene. Amidoazobenzene is formed in not inconsiderable quantity when a solution of diazobenzene is heated with quinoline, but the mechanism of the reaction is not clear.

A. R. L.

Parahydroxyalkyl Derivatives of Phenylhydrazine, &c. By J. Altschul (*Ber.*, **25**, 2185).—Groll claims to have described (*Inaug. Diss., Basel*, 1888) sodium paraethoxydiazobenzenesulphonate and paraethoxyphenylhydrazinesulphonate, which have been lately obtained by the author (this vol., p. 1080). Groll's observation (*loc. cit.*) that these salts cannot be obtained in the anhydrous condition is incorrect. A. R. L.

Action of Nitrous Acid on certain Unsaturated Aromatic Compounds. By A. Angeli (*Ber.*, **25**, 1956—1963).—The *compound* (m. p. 124°) obtained from isosafrole (this vol., p. 44) is probably a dioxime peroxide, $\begin{matrix}O\cdot N:C\cdot C_6H_3:O_2:CH_2\\ |\qquad\qquad |\\ O\cdot N:CMe\end{matrix}$; it is insoluble in alkalis, and, when heated at 210° with acetic anhydride, is converted into a colourless modification which melts at the same temperature; as

both substances give the same nitro-derivative, it is difficult to decide whether they are different compounds. The dioxime peroxide, on oxidation with potassium permanganate, gives piperonylic acid and other products; and on reduction with tin and hydrochloric acid, it gives a compound which crystallises from alcohol in white needles and melts at 86°; it probably has the constitution

$$O<\begin{matrix}N:C\cdot C_6H_3:O_2:CH_2\\ |\\ N:C\cdot Me\end{matrix};$$

on reduction with zinc and acetic acid, on the other hand, two compounds are obtained, one, probably $CH_2:O_2:C_6H_3\cdot CH_2\cdot COMe$, crystallises in white needles and melts at 38°, the other, $C_{20}H_{18}N_2O_4$, melts at 180°. The keto-compound (m. p. 38°) forms a phenylhydrazone melting at 97°. When the dioxime peroxide is dissolved in alcohol, and carefully reduced with zinc-dust and dilute acetic acid, the dioxime (?), $CH_2:O_2:C_6H_3\cdot C(NOH)\cdot CMe:NOH$, is produced; it crystallises from benzene in colourless prisms and melts at 159°. It is soluble in alkalis, forms a *diacetyl* derivative melting at 138°, and is reconverted into the peroxide on oxidation with potassium ferricyanide in dilute alkaline solution. On treatment with nitrous acid, isobutenylbenzene yields a *nitrosite*, $C_{10}H_{12}N_2O_3$, melting at 112°. When isosafrole dioxime peroxide (see above) is treated with alcoholic potash, an *isomeride* is obtained melting at 185° with decomposition; it dissolves in alkali hydroxides, but not in carbonates, forms an acetyl derivative melting at 129°, a *benzoyl* derivative melting at 146°, and, on oxidation with potassium permanganate, yields piperonylic acid and its nitrile, together with piperonylcarboxylic acid.

A. R. L.

Orthochlorobenzaldoximes. By R. Behrend and D. Nissen (*Annalen*, **269**, 390—403).—Although anti-benzaldoxime, and all those of its meta- and para-substitution products which have been investigated, are converted into the corresponding syn-oximes by hydrogen chloride, it has not hitherto been found possible to bring about such an intramolecular change in the case of the ortho-substitution products of benzaldoxime; the authors have now succeeded in preparing the two modifications of orthochlorobenzaldoxime by the method previously employed by Behrend and König in the case of paranitrobenzaldoxime (compare Abstr., 1891, 1032).

β-Dichlorobenzylhydroxylamine, $OH\cdot N(CH_2\cdot C_6H_4Cl)_2$, is formed when orthochlorobenzyl chloride (2 mols.) is boiled with an alcoholic solution of hydroxylamine; it separates from alcohol in colourless, granular crystals, and melts at 116—117°. The *hydrochloride* crystallises in needles, melts at 135—155°, and is only very sparingly soluble.

Orthochlorobenzylisoorthochlorobenzaldoxime,

$$C_6H_4Cl\cdot CH_2\cdot N<\begin{matrix}O\\ \\ \end{matrix}>CH\cdot C_6H_4Cl,$$

can be obtained by oxidising the preceding compound with potassium dichromate and acetic acid; it crystallises from a mixture of ether and light petroleum in long needles, melts at 98—99°, and is decom-

posed by hydrochloric acid into chlorobenzaldehyde and β-chlorobenzylhydroxylamine hydrochloride.

β-Chlorobenzylhydroxylamine, $C_6H_4Cl\cdot CH_2\cdot NH\cdot OH$, prepared by decomposing the hydrochloride with sodium carbonate, crystallises from a mixture of ether and light petroleum in lustrous, rectangular plates, melts at 72—74·5°, and reduces Fehling's solution. The *hydrochloride*, C_7H_8ClNO,HCl, separates from alcoholic ether in prismatic crystals, melts at 153—158°, and is very readily soluble in alcohol and water. The *nitroso*-derivative, $C_6H_4Cl\cdot CH_2\cdot N(NO)\cdot OH$, is obtained when β-chlorobenzylhydroxylamine hydrochloride is treated with sodium nitrite in ice-cold solution; it separates from ethereal light petroleum in long prisms, melts at 48—49°, and gives Liebermann's reaction.

Dinitrosylorthochlorobenzyl, $C_{14}H_{12}Cl_2N_2O_2$, is formed, with evolution of nitrogen, when the nitroso-compound just described is dissolved in a mixture of ether and glacial acetic acid, and a trace of fuming nitric acid added to the solution; it crystallises from a mixture of chloroform and ether in needles, melts at 115·5—117°, and is only sparingly soluble in ether and alcohol; it gives Liebermann's reaction.

When dinitrosylorthochlorobenzyl is treated with 10 per cent. soda, and the mixture kept for several days, it is partially converted into approximately equal quantities of syn- and anti-orthochlorobenzaldoxime; on largely diluting the filtered solution and then passing a stream of carbonic anhydride, the more sparingly soluble syn-oxime is deposited, whilst the anti-oxime (m. p. 75—76°) remains in solution.

Synorthochlorobenzaldoxime, C_7H_6ClNO, melts at 98—102°, and in appearance is not to be distinguished from the anti-oxime; both compounds crystallise in small, slender needles, and dissolve freely in the ordinary organic solvents, except light petroleum; they are both decomposed by sulphuric acid into hydroxylamine and chlorobenzaldehyde. The syn-oxime is very readily converted into the anti-modification, not only by hydrogen chloride, but also by dilute acids. When the syn-oxime is dissolved in acetic anhydride, it yields an unstable *acetyl* derivative which, on treatment with sodium carbonate, even in the cold, is quickly converted into chlorobenzonitrile; the acetyl derivative of the anti-oxime melts at 84—88°, and is not acted on by sodium carbonate. F. S. K.

Aromatic Alkyl Ketoximes containing a Halogen Atom in the Ortho-position relatively to the Ketoxime Group. By A. Claus (*J. pr. Chem.* [2], **46**, 20—50; compare this vol., p. 985; Abstr., 1890, 769, 979; 1891, 199, 564, 1222).—*Parabromometatolyl methyl ketone* [Me : COMe : Br = 1 : 3 : 4] is a colourless, mobile, refractive liquid of aromatic odour; it boils at 262° (corr.), is slightly volatile with steam, is still liquid at −20°, and dissolves in the usual organic solvents, but hardly at all in water. The *ketonic acid*, obtained by oxidising it with alkaline potassium permanganate, melts at 54°. The acid obtained by its further oxidation melts at 154—155° (uncorr.), and is undoubtedly bromomethylbenzoic acid

[Me : COOH : Br = 1 : 3 : 4]

(compare Beilstein, 2nd Edition, **2**, 858; the barium salt crystallises with 4 mols. H_2O), for it is converted by still further oxidation into 4-bromisophthalic acid [$(COOH)_2 : Br = 1 : 3 : 4$] (m. p. 287°, uncorr.; Abstr., 1891, 1222).

The conversion of brominated ketones, in which the bromine is in the meta- or para-position relatively to the ketone group, into oximes, takes place in the absence of alkalis, the ketone being merely heated with hydroxylamine hydrochloride in dilute alcohol; it is otherwise when the bromine is in the ortho-position relatively to the ketone group, the presence of alkalis being then necessary, and the product less pure.

Parabromometatolyl methyl ketoxime [Me : CMe : N·OH : Br = 1 : 3 : 4] crystallises in brilliant, large, transparent, rectangular tables when its alcoholic solution is gradually evaporated, and in needles and quadratic prisms when the hot solution is cooled; it melts at 109° (uncorr.). By treatment with sulphuric acid, it is converted into the isomeric *parabromometacetotoluidide* [Me : HN·COMe : Br = 1 : 3 : 4], which melts at 164° (uncorr.), and therefore differs from Neville and Winther's compound (*Ber.*, **13**, 972). By saponification with alkali and distillation with steam, the toluidide yields parabromometatoluidine [Me : NH_2 : Br = 1 : 3 : 4]; this is characterised by its intense odour of naphthalene, and, with this exception, is identical with Neville and Winther's bromotoluidine (*loc. cit.*).

Parachlorometatolyl methyl ketone [Me : COMe : Cl = 1 : 3 : 4] is a colourless, aromatic, refractive oil boiling at 239—240° (uncorr.), and soluble in the usual organic solvents. By oxidation with aqueous potassium permanganate, it yields *parachlorometatoluic acid*

[Me : CO_2H : Cl = 1 : 3 : 4],

which crystallises in colourless needles, sublimes easily, and melts at 167° (uncorr.). By further oxidation this is converted into *parachlorisophthalic acid* [Cl : $(CO_2H)_2$ = 4 : 1 : 3], which crystallises in colourless needles, melts at 286° (uncorr.), and sublimes; it dissolves easily in hot water, and is not volatile with steam. This chlorisophthalic acid is identical with that described by Claus and Neukranz, who, however, asserted that it does not melt below 340°.

Parachlorometatolyl methyl ketoxime [Me : CMe : N·OH : Cl = 1 : 3 : 4] crystallises in brilliant, quadratic tables and prisms, when its alcoholic solution is slowly evaporated, and in colourless needles when the hot solution is cooled; it melts at 94° (uncorr.), and is not attacked by hot alkalis.

Parachlorometacetotoluidide [Me : HNCOMe : Cl = 1 : 3 : 4] is obtained by the action of sulphuric acid on the ketoxime; it forms colourless needles or columns, and melts at 124° (uncorr.); when deacetylised, it is converted into *parachlorometatoluidine* [Me : NH_2 : Cl = 1 : 3 : 4], which is a colourless oil boiling at 230° (uncorr.), and solidifying to a crystalline mass which melts about 32°; it is characterised by its naphthalene-like odour.

Parachlorometa-1 : 2-xylyl methyl ketone [Me_2 : COMe : Cl = 1 : 6 : 3 : 4] is easily obtained by acetylising 4-chloro-1 : 2-xylene

(Abstr., 1885, 1053) with a considerable excess of the usual reagents (aluminium chloride, 3 parts; acetic chloride, 2 parts; chloroxylene, 1 part); it is a colourless, aromatic oil, boils at 275—276° (uncorr.), dissolves in the usual solvents, and soon becomes coloured in light and air. The corresponding *ketoxime* [Me_2 : CMe : N·OH : Cl = 1 : 6 : 3 : 4] crystallises in colourless columns and needles; it melts at 134° (uncorr.), and is somewhat soluble in hot water; it is not attacked by hot alkalis. The corresponding *acetoxylide*

[Me_2 : HNCOMe : Cl = 1 : 6 : 3 : 4],

easily obtained by heating the ketoxime with sulphuric acid, crystallises in colourless, slender prisms, melts at 154° (uncorr.), and dissolves sparingly in hot water; on saponification, it yields *chlororthoxylidine* [Me_2 : NH_2 : Cl = 1 : 6 : 3 : 4] which crystallises in white laminæ, melts at 86° (uncorr.), sublimes, and dissolves easily in the usual organic solvents.

The corresponding compounds from 3-chloro-1 : 2-xylene, namely, the *methyl ketone* (m. p. 278—279°, uncorr.), the *ketoxime* (m. p. 126°, uncorr.), the *acetoxylide* (m. p. 186°, uncorr.), and the *chlororthoxylidine* (m. p. 73°, uncorr.), are here briefly mentioned; they will be further discussed.

The fact that the oximes here described do not lose hydrogen halide when heated with alkalis, proves that the halogen atom is directly united to the benzene nucleus, and is not associated in any way with the oxime hydrogen atom. This observation is contrary to that of Cathcart and V. Meyer (this vol., p. 992), who found that the oxime of orthobromobenzophenone is easily decomposed by alkalis, with elimination of hydrogen bromide. On this peg the author hangs a discussion of the structure of oximes, questioning some of Cathcart and Meyer's theories. An appendix contains a reply to a recent article by Hantzsch on these matters (this vol., p. 1083).

A. G. B.

Configuration of γ-Ketoximic Acids. By W. Dollfus (*Ber.*, **25**, 1926—1936).—γ-Ketoximic acids appear to exist in one stable modification only; as an example, levulinic oxime (Abstr., 1884, 1129) may be cited. This oxime is probably represented by the configuration $\begin{matrix} Me\cdot C\cdot CH_2\cdot CH_2\cdot COOH \\ \| \\ N\cdot OH \end{matrix}$ (methylsynketoximepropionic acid); when hydrogen chloride is passed into its ethereal solution, it forms a hydrochloride, which decomposes on treatment with soda, yielding the original oxime. The *acetyl* derivative, $COOH\cdot CH_2\cdot CH_2\cdot CMe{:}NOAc$, is obtained by adding the calculated quantity of acetic anhydride to the oxime; it melts at 74—75°, and also yields the original oxime when decomposed with soda. The formation of methylsuccinimide observed by Bredt and Böddinghaus (Abstr., 1889, 1061) is probably preceded by intramolecular change.

Benzoylpropionic acid is prepared according to Burker's directions (*Ann. Chim. Phys.* [5], **26**, 435) by the condensation of benzene with succinic anhydride in the presence of aluminium chloride. The *oxime*,

$COOH{\cdot}CH_2{\cdot}CH_2{\cdot}CPh{:}NOH$, is obtained when the acid is dissolved in dilute sodium hydroxide solution, and treated with hydroxylamine hydrochloride ($1\frac{1}{2}$ parts); it crystallises from hot water in long, spear-shaped needles, melts at 129°, and behaves similarly to levulinic oxime. The *acetyl* derivative melts at 99°, and may be crystallised from hot water or dilute alcohol without decomposition; it decomposes into the oxime when boiled with water or soda. When the oxime (m. p. 129°) is allowed to remain in contact with concentrated sulphuric acid for about two days, it slowly dissolves; on now diluting the solution with ice water in such a manner that the temperature does not rise much above 0°, an isomeric *oxime*, melting at 95—96°, is precipitated. It is probably phenylantiketoximepropionic acid,

$$\begin{matrix} Ph{\cdot}C{\cdot}CH_2{\cdot}CH_2{\cdot}COOH \\ \| \\ HO{\cdot}N \end{matrix},$$

and when exposed to the air it changes into the stable modification (m. p. 129°).

Trichloracetylacrylic acid (Kekulé and Strecker, Abstr., 1884, 1122) is decomposed by alkalis, and cannot, therefore, be converted into its oxime in alkaline solution. If an alcoholic solution of hydroxylamine hydrochloride (12 grams) is converted into the base by means of sodium ethoxide, ether added, trichloracetoacrylic acid (10 grams) dissolved in the filtrate, and the solution then placed in a vacuum, crystals separate which are insoluble in water, alcohol, and ether, and are successively washed with these liquids; they darken at 115° and melt at about 140°, but are found on analysis to be neither the oxime nor its anhydride. The compound is being further investigated. A. R. L.

Amidotolylurethane. By H. Schiff (*Ber.*, **25**, 2210—2212).—The author has already described a method of preparing amidotolylurethane from paranitrotoluidine. He finds that it is more easily prepared from acetyltoluylenediamine, $C_6H_3Me(NH_2){\cdot}NHAc$ [1 : 2 : 4].

The acetyl compound (20—30 grams) is suspended in 8—10 times the quantity of dry ether and 3 c.c. of ethyl chloroformate added to the mixture for every 10 grams of the acetyl compound. In $1\frac{1}{2}$—2 hours a crystalline magma is obtained which contains acetamidotolylurethane and acetyltoluylenediamine hydrochloride. The ether is distilled off and the hydrochloride washed out with very dilute hydrochloric acid. *Acetamidotolylurethane* crystallises in long, colourless, lustrous needles, melts at 181°, and is easily soluble in alcohol, sparingly so in hot water. Amidotolylurethane is obtained by gradually adding it to boiling hydrochloric acid and precipitating the solution with sodium carbonate. Amidotolylurethane is volatile with steam, and melts at 95°, and not at 91° as previously stated. E. C. R.

Mandelamide. By G. Pulvermacher (*Ber.*, **25**, 2212—2213).—By the action of fuming hydrochloric acid on the nitrile of mandelic acid, the author has obtained the condensation product

$OH{\cdot}CHPh{\cdot}CO{\cdot}N{:}CHPh$,

already described by Michael and Jeanprêtre (this vol., p. 1088), which melts at 194°, and has been described as mandelamide by Tiemann and Friedländer (*Ber.*, **14**, 1967). A small quantity of mandelamide is found in the mother liquors of the above compound. Mandelamide melts at 132°. Biedermann has described it as melting at 190°, but on preparing the amide according to Biedermann's directions by the action of alcoholic ammonia on the α-lactone of mandelic acid, the author obtained a product melting at 132°. E. C. R.

Modes of Formation of Substituted Imides. By A. Haller (*Compt. rend.*, **114**, 1326—1329).—When a mixture of phthalic acid (1 mol.) and phenyl isocyanate (2 mols.) is gradually heated, carbonic anhydride is evolved and the mixture melts entirely at about 200°. As soon as the evolution of gas ceases the product is allowed to cool, and is crystallised from alcohol; phenylphthalimide is thus obtained in slender, white, silky needles melting at 209°.

Succinic acid, under similar conditions, yields phenylsuccinimide in small, white needles melting at about 154°.

The formation of substituted phenylimides under these conditions would seem to be due to the formation of an anhydride and symmetrical diphenylurea, which afterwards interact with production of the substituted imide, aniline, and carbonic anhydride.

This view is supported by the fact that phthalic anhydride or succinic anhydride, when heated with symmetrical diphenylurea in molecular proportion, yields phenylphthalimide or phenylsuccinimide, as the case may be. The reaction is quantitative, and only traces of secondary products are formed.

Symmetrical orthoditolylurea reacts in a similar way with phthalic anhydride at 200°, and yields orthotolylphthalimide, which crystallises from alcohol in small, white crystals, melts at 174°, and is only slightly soluble in cold alcohol or cold ether.

Attempts to obtain tetra-substituted imides by an analogous reaction gave negative results. Tetraphenylurea and phthalic anhydride remain unchanged when heated together at 150°, 180°, 200°, and even 350°.

Methyl hydrogen phthalate and methyl hydrogen succinate, when heated with phenyl isocyanate in molecular proportion, yield phenylphthalimide and phenylsuccinimide respectively.

Methyl hydrogen phthalate is easily obtained by dissolving phthalic anhydride in absolute methyl alcohol and distilling off the excess of alcohol. It crystallises in white plates, melts at 85°, and dissolves in most solvents except water. The ease with which the salt can be obtained in a state of purity, and the equally great facility with which the phthalic acid, separated by saponification, can be reconverted into phthalic anhydride, make methyl hydrogen phthalate an excellent compound from which to prepare pure methyl alcohol.

Methyl hydrogen succinate is obtained in a precisely similar manner. It crystallises in transparent, rectangular tables, very soluble in ether or alcohol. C. H. B.

Metallic Compounds of Aromatic Ketones. By E. Louise and Perrier (*Compt. rend.*, **114**, 1377—1379).—Ketones unite with anhydrous metallic chlorides to form coloured, solid compounds, sometimes amorphous, but more frequently crystalline.

A solution of the ketone in carbon bisulphide is heated at about 40° in a vessel furnished with a reflux condenser, and anhydrous ferric or aluminium chloride in molecular proportion is gradually added. On cooling, the solid products separate; they alter rapidly in moist air. As a rule, the compounds form most readily when the ketones are in the nascent state, and are being produced at a low temperature, by the method of Friedel and Crafts, in presence of carbon bisulphide. The compound of benzoylmesitylene and aluminium chloride, for example, is most readily obtained in crystals by the addition of aluminium chloride to a solution of mesitylene and benzoic chloride in carbon bisulphide.

The formation of crystalline compounds with aluminium chloride under these conditions makes it possible to isolate ketones readily, and to separate those that are formed in different stages of the reaction. In this way, new ketones formed by the action of acid chlorides on anthracene, phenanthrene, acenaphthene, fluorene, stilbene, diphenylnaphthalene, mesitylene, &c., have been isolated.

Benzoyl-retene is obtained by prolonged boiling of a carbon bisulphide solution of benzoic chloride and retene in molecular proportion to which aluminium chloride has been added gradually. The metallic compound is decomposed by water, and the benzoyl-retene crystallised from light petroleum; it melts at 114°. C. H. B.

Dibromobenzoic Acids. By A. Claus and A. Weil (*Annalen*, **269**, 216—224).—The authors have prepared and characterised four of the dibromobenzoic acids.

Nitrodibromacetanilide [NHAc : Br_2 : NO_2 = 1 : 3 : 5 : 4] is formed, together with a much larger quantity of the corresponding 1 : 3 : 5 : 2-derivative, when dibromacetanilide (m. p. 215°) is nitrated with ice-cold acid of sp. gr. 1·5; it sublimes in small, lustrous plates, melts at 270—271°, and crystallises from alcohol in hexagonal plates, but is insoluble in water.

Nitrodibromaniline [NH_2 : Br_2 : NO_2 = 1 : 3 : 5 : 4], prepared by heating the acetyl derivative with moderately concentrated sulphuric acid at 120—125°, sublimes in lustrous, yellow needles, and melts at 186°; when treated with sodium nitrite and concentrated sulphuric acid in ice-cold alcoholic solution, and the mixture then heated on the water-bath, it is converted into dibromonitrobenzene (m. p. 84°), from which, by reducing with stannous chloride and hydrochloric acid in alcoholic solution, dibromaniline (m. p. 81°), identical with the compound (m. p. 83—84°) prepared by Heinichen (Abstr., 1890, 165), can be obtained.

Dibromobenzonitrile [Br_2 : CN = 3 : 5 : 4], prepared from dibromaniline (m. p. 81°), crystallises in colourless needles, melts at 151°, and is volatile with steam. The corresponding *acid*, obtained by hydrolysing the nitrile with moderately concentrated sulphuric acid at 170°, crystallises and sublimes in small, lustrous needles, melts at

189°, and is readily soluble in alcohol, ether, chloroform, and hot water, but almost insoluble in cold water. The *barium* salt crystallises in slender needles containing 3 mols. H_2O, and is readily soluble in water.

Dibromobenzonitrile [CN : Br_2 = 1 : 2 : 4], prepared from the corresponding dibromaniline, crystallises from alcohol in long, colourless needles melting at 79—80°; on hydrolysis with sulphuric acid, it yields dibromobenzoic acid (m. p. 166·5°), the *barium* salt of which crystallises in needles containing 3 mols. H_2O, and is very readily soluble in water.

Dibromobenzonitrile [CN : Br_2 = 1 : 2 : 5], prepared from the corresponding dibromaniline, crystallises from alcohol and hot water in long, yellowish needles, and melts at 132°. The corresponding acid crystallises in flat, colourless needles melting at 153°; its barium salt crystallises from 90 per cent. alcohol in small plates containing $1\frac{1}{2}$ mols. H_2O, and from water in needles containing 6 mols. H_2O, or in small plates containing $2\frac{1}{2}$ mols. H_2O.

Dibromobenzonitrile [CN : Br_2 = 1 : 3 : 5] crystallises from alcohol in lustrous, colourless needles, melts at 89°, and is readily volatile with steam. The corresponding *acid* crystallises from boiling water in flat, colourless needles, melts at 209°, and sublimes readily; its *barium* salt is not very readily soluble in water and crystallises in small, colourless needles containing 4 mols. H_2O. F. S. K.

Dichlorobenzoic Acids. By A. Claus and A. Stavenhagen (*Annalen*, **269**, 224—231).—*Dichlorobenzonitrile* [CN : Cl_2 = 1 : 3 : 5] prepared from the corresponding dichloraniline, separates from solvents and sublimes in long colourless needles, melts at 65°, and is very readily soluble in alcohol, ether, and chloroform, but insoluble in cold water; it is moderately easily volatile with steam. When hydrolysed with moderately concentrated sulphuric acid, it is converted into dichlorobenzoic acid (m. p. 182°) identical with the compound obtained by Lellmann and Klotz (*Annalen*, **231**, 324) by the oxidation of dichlorotoluene; the *barium* salt of this acid crystallises in short prisms containing $3\frac{1}{2}$ mols. H_2O.

Dichlorobenzonitrile [CN : Cl_2 = 1 : 2 : 6], obtained in like manner, crystallises from alcohol in small, colourless needles, melts at 49°, sublimes readily, and dissolves freely in alcohol, ether, chloroform, and carbon bisulphide, but is more sparingly soluble in glacial acetic acid, light petroleum, and benzene, and insoluble in water. The corresponding *dichlorobenzoic acid* prepared from the nitrile sublimes in colourless needles, melts at 132—133°, and is moderately easily soluble in boiling water, from which it separates in small prisms; its *barium* salt is very readily soluble in water, moderately easily in hot alcohol, and crystallises with $3\frac{1}{2}$ mols. H_2O. This dichlorobenzoic acid is more conveniently prepared from orthochlorotoluene; the last-named compound is first chlorinated, using iron as the halogen carrier, and the mixture of the two isomerides obtained in this way is carefully oxidised with potassium permanganate. The two dichlorobenzoic acids thus produced are partially separated by fractional decomposition of their potassium salts with hydrochloric acid, when the

pure 2:4-dichloro-compound (m. p. 151°) is first precipitated; the later fractions contain both acids, which are separated by the fractional crystallisation of their barium salts. F. S. K.

Nitration and Bromination of Parabromorthotoluic Acid. By A. Claus and L. Beck (*Annalen*, **269**, 207—216; compare Claus and Herbabny, this vol., p. 174).—*Nitrobromorthotoluic acid* [COOH : Me : Br : NO_2 = 1 : 2 : 4 : 5] is obtained, together with a smaller quantity of the isomeride melting at 220°, when finely-divided parabromorthotoluic acid is gradually added to nitric acid of sp. gr. 1·52, heated at about 50°; the two compounds can be separated by means of their magnesium salts. It crystallises in colourless needles, melts at 200°, and sublimes without decomposition, but is not volatile with steam; it is only sparingly soluble in water, but dissolves freely in alcohol, ether, and chloroform. The *potassium* salt, $C_8H_5NO_4BrK + H_2O$, is readily soluble in water and crystallises in lustrous needles. The *sodium* salt crystallises in large nacreous plates with 4 mols. H_2O, and is very readily soluble in water. The *barium* salt crystallises with 4 mols. H_2O in long, lance-shaped needles, and is only moderately easily soluble. The *magnesium* salt forms large, lustrous needles containing 7 mols. H_2O, and is rather more readily soluble than the barium salt.

Nitrobromorthotoluic acid [COOH : Me : NO_2 : Br = 1 : 2 : 3 : 4] crystallises in small, colourless needles, melts at 220°, and is readily soluble in alcohol, ether, and chloroform, but only moderately easily in boiling water; it sublimes unchanged, but is not volatile with steam. The *barium* salt forms nodular aggregates containing 1 mol. H_2O, and is much more readily soluble in water than the corresponding salt of the isomeride just described. The *magnesium* salt is so readily soluble that it does not crystallise from its aqueous solution.

Nitrobromacetotoluidide [NHAc : Me : Br : NO_2 = 1 : 2 : 4 : 6] crystallises in large, colourless, rhombic prisms, and melts at 206°. The corresponding *nitrile*, prepared from nitrobromorthotoluidine by Sandmeyer's method, crystallises from alcohol in broad, yellow needles, melts at 106—107°, and is readily soluble in alcohol and ether, but only very sparingly in hot water; it sublimes in needles, but is only slightly volatile with steam. The corresponding *amide*, $NO_2 \cdot C_6H_2MeBr \cdot CO \cdot NH_2$, is best obtained by heating the nitrile with moderately concentrated sulphuric acid; it crystallises in small, lustrous needles, melts at 235°, and is soluble in alcohol, ether, and boiling water.

Nitrobromorthotoluic acid [COOH : Me : Br : NO_2 = 1 : 2 : 4 : 6], prepared by heating the amide with concentrated hydrochloric acid at 230—250°, crystallises from dilute alcohol in slender needles, melts at 226°, sublimes undecomposed, and is readily soluble in alcohol, ether, light petroleum, and boiling water, but only sparingly in cold water.

Dibromorthotoluic acid [COOH : Me : Br_2 = 1 : 2 : 4 : 5] is formed when parabromorthotoluic acid is heated with bromine and water at 120° for 3 hours; it crystallises in small, lustrous, needles, melts at

210°, and dissolves freely in alcohol, ether, chloroform, and boiling water, but is only sparingly soluble in cold water. The *barium* salt crystallises in needles containing 6 mols. H_2O, and is moderately easily soluble.

Dibromorthotoluonitrile [CN : Me : Br_2 = 1 : 2 : 4 : 6], prepared from dibromorthotoluidine, crystallises in colourless, lustrous needles, sublimes without decomposition, and is moderately easily volatile with steam; it melts at 86°, and is soluble in alcohol, ether, chloroform, and boiling water. The corresponding *amide* crystallises in colourless needles and prisms, melts at 198°, and is readily soluble in alcohol, but only sparingly in hot water. The corresponding *acid*

[COOH : Me : Br_2 = 1 : 2 : 4 : 6]

is formed when the amide is hydrolysed with concentrated hydrochloric acid at 250°; it crystallises in small needles, melts at 157°, and is readily soluble in alcohol, ether, chloroform, and hot water, but only sparingly in cold water. The *barium* salt is readily soluble in water, and crystallises with 1 mol. H_2O. F. S. K.

Amido- and Urethano-tolyloxamic Acids. By H. Schiff and A. Vanni (*Annalen*, **268**, 305—349).—In this paper, the authors give a somewhat fuller account of the experiments which have already been described (Abstr., 1890, 1124; 1891, 702, 833, and 907); there is practically nothing new in the paper except a systematic arrangement of the compounds that have been prepared.

Ethyl amidotolyloxamate, $NH_2 \cdot C_6H_3Me \cdot NH \cdot C_2O_2 \cdot OEt$, can be obtained by heating toluylenediamine with ethyl oxalate, or ethyl oxamate, in concentrated alcoholic solution; it crystallises from hot alcohol in colourless plates, and melts at 168—170°. The *acetyl* derivative, $NHAc \cdot C_6H_3Me \cdot NH \cdot C_2O_2 \cdot OEt$, crystallises from boiling alcohol in colourless plates, melts at 192°, and is almost insoluble in cold alcohol.

Toluyleneoxamide, $C_9H_8N_2O_2$, is formed when ethyl amidotolyloxamate is heated for some time at 180°; it is a yellow substance, melts at 235—260°, and is almost insoluble in all ordinary solvents. F. S. K.

Action of Heat on Salicylic Acid. By C. Graebe and A. Eichengrün (*Annalen*, **269**, 323—325).—When salicylic acid is heated at 195—220°, it is to a great extent converted into phenyl salicylate; if the product is now distilled, a considerable quantity of xanthone is formed.

When parahydroxybenzoic acid (10 grams) is heated in an open vessel at 200°, phenol and carbonic anhydride pass off, and after 18 hours time there remains only a small quantity (0·6 gram) of some compound of high melting point.

Metahydroxybenzoic acid undergoes very little change even on prolonged heating at 210°. F. S. K.

Methyl Salts of Abnormal Structure. By R. Wegscheider (*Monatsh.*, **13**, 252—267).—On methylation, opianic acid can give rise, according to circumstances, to two distinct compounds, which

have the same empirical formula and molecular weight. Of these, one is to be regarded as the true methyl salt; the other, as a pseudo-methyl salt, which, although it behaves in some respects as an ordinary methyl salt, must yet have a dissimilar constitution.

Normal methyl opianate, $COH{\cdot}C_6H_2(OMe)_2{\cdot}COOMe$, is prepared, according to the method previously described by the author (*Monatsh.*, **3**, 356), from silver opianate, methyl iodide, and methyl alcohol, all of which substances must be quite free from acid. It forms crystals, which melt at 82—84°, and, under a reduced pressure of 51—52 mm., boils at 232—234° (uncorr.). This salt can also be obtained from opianyl chloride and methyl alcohol. It is readily hydrolysed on warming with very dilute hydrochloric acid, and is completely volatile in a current of steam.

Pseudo-methyl opianate is formed according to the method of Liebermann and Kleemann (Abstr., 1887, 584), on heating together opianic acid and methyl alcohol, or by saturating a solution of opianic acid in methyl alcohol with sulphurous anhydride, and also, under certain conditions, by the reaction between opianyl chloride and wood spirit. It forms monosymmetric crystals,

$$a : b : c = 0{\cdot}5714 : 1 : 0{\cdot}2792,$$

quite distinct from the crystals of the true methyl salt, from which it is also sharply distinguished by its relatively slight solubility in methyl alcohol. It melts at 103—103·5°, boils at 238—239°, (uncorr.), under a reduced pressure of 51—52 mm., is readily hydrolysed on warming with water, and has, in all probability, the constitution $C_6H_2(OMe)_2{<}\overset{CO\text{———}}{CH(OMe)}{>}$. This accords with the supposition of Liebermann, who states (*Ber.*, **19**, 765 and 2288) that opianic acid is a tautomeric substance, and sometimes reacts as though it had the constitution $C_6H_2(OMe)_2{<}\overset{CO\text{———}}{CH(OH)}{>}O$.

G. T. M.

Bromopianic Acid. By K. Tust (*Ber.*, **25**, 1995—2002).—Bromopianic acid was first prepared by Prinz (Abstr., 1882, 404); the author confirms Wegscheider's value, 204°, for the melting point of the acid. The *calcium* salt is sparingly soluble in hot water, and the *ethyl* salt forms slender, white needles, and melts at 78°. The *trichloride*, $CHCl_2{\cdot}C_6HBr(OMe)_2{\cdot}COCl$, is formed by mixing bromopianic acid and phosphorus pentachloride in the cold and completing the reaction by heating; the product, after well washing with ice water, is dried, dissolved in benzene, and reprecipitated by light petroleum; it crystallises in needles, melts at 100—101°, and is sparingly soluble in water, readily in ether. The *amide*,

$$COH{\cdot}C_6HBr(OMe)_2{\cdot}CO{\cdot}NH_2,$$

formed by dissolving the trichloride in concentrated aqueous ammonia, separates, on cooling, in white needles, and, when recrystallised from water, melts at 180°; it is readily soluble in hot water and alcohol, sparingly so in benzene.

Anilidobromopianic acid, $CH{:}NPh{\cdot}C_6HBr(OMe)_2{\cdot}COOH$, is obtained

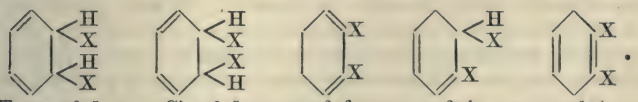
by boiling a solution of equal weights of bromopianic acid and aniline in glacial acetic acid (3—4 parts); it melts at 191°, and is insoluble in water and in light petroleum, fairly soluble in hot alcohol, and readily so in hot glacial acetic acid; it is hydrolysed when boiled with concentrated aqueous potash.

Bromopianoximic anhydride, $C_6HBr(OMe)_2<\begin{matrix}CO\\CO\end{matrix}>NH$, is produced when opianic acid and hydroxylamine hydrochloride (equal weights) are heated on the water-bath with 80 per cent. alcohol; the needles which separate from the solution on cooling are collected and recrystallised from benzene; the compound melts at 163—165°, resolidifies above this, and finally melts at 220°; it is readily soluble in hot benzene and chloroform and fairly so in alcohol. By the prolonged boiling of its alcoholic solution, it yields *bromohemipinimide*, $C_6HBr(OMe)_2<\begin{matrix}CO\cdot O\\CH{:}N\end{matrix}$, which crystallises from benzene in slender, felted needles, melts at 221—222°, and is readily soluble in alcohol, benzene, and chloroform (compare opianoximic anhydride, Liebermann, Abstr., 1887, 46; Perkin, Trans., 1890, 1070).

Bromopianic phenylhydrazide, $C_6HBr(OMe)_2<\begin{matrix}CO\\CH\end{matrix}>N_2Ph$, is prepared by mixing boiling aqueous solutions containing molecular proportions of the acid and phenylhydrazine and boiling for some minutes; it separates on cooling, and, when crystallised from alcohol or benzene, forms stout, white crystals, melts at 160°, and is insoluble in alkalis. Bromopianic acid behaves with phenylhydrazine, therefore, in a manner analogous to opianic acid (see Liebermann, Abstr., 1886, 550). *Bromopianic methylphenylhydrazone*,

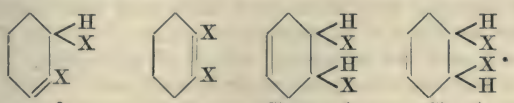
$$N_2MePh{:}CH{:}C_6HBr(OMe)_2{\cdot}COOH,$$

is obtained from the acid and asymmetrical methylphenylhydrazine; it crystallises from dilute acetic acid in yellowish-green crystals, melts at 291°, and is insoluble in water, but dissolves in alkalis.



Diphenylhydrazine and hydrazobenzene react with bromopianic acid as with opianic acid (Abstr., 1888, 1209). *Diphenylhydrazonopianic acid*, $N_2Ph_2{:}CH{\cdot}C_6HBr(OMe)_2{\cdot}COOH$, formed by boiling an alcoholic solution of diphenylhydrazine and bromopianic acid (equal mols.), separates from glacial acetic acid in yellow crystals and melts at 230°, whilst *bromopianic hydrazobenzene*, obtained in a similar manner from bromopianic acid and hydrazobenzene, crystallises from benzene in coloured plates, melts at 211°, and is insoluble in alkalis.

Benzidylbromopianic acid, $C_{32}H_{26}Br_2N_2O_8$, is formed when concentrated aqueous solutions of bromopianic acid (2 mols.) and benzidine (1 mol.) are boiled together; the white needles which separate out are dissolved in ammonia and reprecipitated with acid. The compound does not melt at 300°, and is very sparingly soluble in solvents. It is to be noted that bromopianic acid does not give a condensation derivative with carbamide, as does opianic acid (Abstr., 1888, 1210), whilst its behaviour with orthodiamines has been investigated by Bistrzycki and Cybulski (this vol., p. 1248). Attempts to nitrate



bromopianic acid led to negative results, as the acid is thereby decomposed. A. R. L.

α-Phenylhydrocinnamic Acid. By W. v. Miller and G. Rohde (*Ber.*, **25**, 2017—2020).—The authors have observed that α-phenylhydrocinnamic acid occurs in three modifications which melt respectively at 82°, 88—89°, and 95—96°. α-Phenylhydrocinnamic acid is obtained by reducing α-phenylcinnamic acid (m.p. 172·5°) with 3 per cent. sodium amalgam. When it is dissolved in cold chloroform, and the solution allowed to evaporate slowly, it crystallises in small, colourless prisms which melt at 88—89°. The high melting modification is obtained by heating it at 94° with constant stirring; this modification when cautiously heated melts at 95—96°, but when dissolved in chloroform and allowed to crystallise slowly, it is converted into the low melting modification. The latter melts at 82°, and crystallises in thin plates which are crystallographically distinct from the modification melting at 88—89°. The low melting modification is also obtained by quickly cooling the melted acid. The low melting modification has a sp. gr. = 1·1430, the intermediate modification a sp. gr. = 1·1481, and the high melting modification a sp. gr. = 1·1495. The authors were unable to detect any difference in chemical behaviour between the three modifications. E. C. R.

Reduction Products of Phthalic Acid. Constitution of Benzene. By A. v. Baeyer (*Annalen*, **269**, 145—206; compare Abstr., 1890, 1275).—The author has prepared four new dihydrophthalic acids, so that the following five isomerides are now known:—

Further investigation has shown that the acid previously described as the Δ^3-tetrahydrophthalic acid is the cis Δ^4-acid, and since no new tetrahydro-acid has been prepared there are at present the following four compounds known:—

Including the two forms of the hexahydro-acid, 11 of the 15 theoretically possible hydrophthalic acids have now been obtained and their constitutions determined; there yet remain to be prepared the cis Δ^3- and the trans Δ^3-tetrahydro-acids, the $\Delta^{2:5}$- and the $\Delta^{1:3}$-dihydro-acids; it is probable, however, that the first three compounds are either very unstable or incapable of existence. Attempts to prepare the $\Delta^{1:3}$-acid were unsuccessful.

When phthalic acid is reduced with sodium amalgam in the manner described below, it is converted into the trans $\Delta^{3:5}$-dihydro-acid; the constitution of the reduction product is deduced from the following considerations:—Only two of the theoretically possible dihydro-acids stand in the relation to one another of a fumaroïd to a maleïnoïd acid, namely, the two $\Delta^{3:5}$-compounds; if, therefore, the primary reduction product is a $\Delta^{3:5}$-acid, it must either consist of the two geometrical forms or it must be capable of being converted into a geometrical isomeride. As a matter of fact, the primary reduction product gives an anhydride from which a new, more readily soluble acid is obtained on treatment with water; since this new acid is readily reconverted into the anhydride, and has, moreover, the same chemical properties as the primary reduction product, the latter must be the fumaroïd, the former the maleïnoïd, modification of the $\Delta^{3:5}$-dihydrophthalic acid. These two $\Delta^{3:5}$-dihydrophthalic acids resemble the $\Delta^{2:5}$-dihydroterephthalic acid, the primary reduction product of terephthalic acid, in their behaviour with silver and copper salts (see later). When $\Delta^{2:5}$-dihydroterephthalic acid is warmed with a solution of copper acetate, carbonic anhydride is evolved, and a white precipitate of a cuprous salt is produced; on adding an acid and warming, this precipitate dissolves with separation of cuprous oxide, and the solution then contains benzoic acid and traces of terephthalic acid. The other hydroterephthalic and hydrophthalic acids are not oxidised by copper acetate, and are either not acted on or only slowly oxidised by silver salts.

The reduction of phthalic acid, as is the case with terephthalic acid, takes a different course under different conditions. In acetic acid solution, the trans $\Delta^{3:5}$-dihydro-acid is produced, whereas in alkaline solution, the $\Delta^{2:6}$-dihydro-acid is formed. When reduction takes place in carbonic acid solution, the sole products are sticky, ill-defined acids, probably because under these conditions the carboxyl group also undergoes reduction. When finely-divided phthalic acid is rubbed to a paste with water, the mixture treated with sodium amalgam until solution is complete, and then dilute sulphuric acid added in excess, there is formed a colourless, crystalline precipitate which is insoluble in sodium carbonate but soluble in warm soda; this product melts at 253—255°, and is probably a lactone similar to, or identical with, the compound (hydrodiphthalyl) obtained by Wislicenus (*Ber.*, **17**, 2180) by treating phthalic anhydride with zinc-dust and acetic acid; the solution also contains a considerable quantity of the $\Delta^{3:5}$-dihydrophthalic acid, and has a strong odour of phthalide. This curious difference in behaviour between phthalic acid and its sodium hydrogen salt, on reduction, may possibly be accounted for by assuming, as Anschütz does, that phthalic acid is really the hydrate of the anhydride, but that even in its acid salts it is transformed into the form containing two carboxyl groups.

The author then proceeds to discuss the constitution of the other acids described in the experimental part of the paper; it would, however, be difficult to reproduce his arguments unless they were given in full.

Of the 11 known hydrophthalic acids, all have been converted

into the corresponding anhydride except the trans $\Delta^{3:5}$-dihydro-acid, which gives the anhydride of the cis modification. These anhydrides are all crystalline compounds, and are reconverted into the acids more or less readily by boiling water. The anhydride of the cis modification invariably melts at a lower temperature than that of the trans form, but no other simple relation between melting point and constitution is observable.

The electrical conductivity of eight of the hydrophthalic acids, as determined by Ostwald, is given in the following table:—

Hexahydro-acid (trans)	$K = 0{\cdot}0062$
„ „ (cis)	$K = 0{\cdot}0044$
Tetrahydro-acid, Δ^2	$K = 0{\cdot}0074$
„ „ trans Δ^4	$K = 0{\cdot}0118$
„ „ Δ^1	$K = 0{\cdot}059$
Dihydro-acid, $\Delta^{2:4}$	$K = 0{\cdot}0155$
„ „ $\Delta^{2:6}$	$K = 0{\cdot}0172$
„ „ trans $\Delta^{3:5}$	$K = 0{\cdot}0246$

It will be seen that, just as is the case with the hydronaphthoïc acids (this vol., p. 191), the conductivity of the labile acids is greater than that of the stable forms; speaking generally, the conductivity of the hydrophthalic acids is much lower than that of the alkyl derivatives of succinic acid, although in constitution and in properties the two classes of compounds are in many respects rather closely related.

As regards stability, the hexahydrophthalic acids come first, the dihydro-compounds last, the tetrahydro-acids standing between the two; the trans forms are more stable than the cis isomerides towards alkalis and acids.

The author then discusses at considerable length the behaviour of the hydroterephthalic and hydrophthalic acids on reduction and on oxidation; he shows that it is impossible to draw any conclusions regarding the constitution of benzene from the behaviour of a benzene derivative on reduction, but that it is possible to do so by studying the re-formation of true benzene derivatives from the reduced compounds. The conclusion arrived at is that, with the limitation that para-linkings exist only as long as the benzene nucleus remains intact, Claus' formula is the one which best explains the various reactions of the hydrophthalic and hydroterephthalic acids, and is in fact the only formula which can account for the formation of benzoic acid by the oxidation of the $\Delta^{2:6}$-dihydrophthalic acid. Fresh facts may, however, render it necessary to abandon this view; and in any case the question of the constitution of benzene cannot be considered as settled, because it is impossible as yet to form any representation of what the configuration of the benzene molecule may be; the solution of this problem will be immediately attempted, and in fact experiments on the reduction of isophthalic acid and of carboxy-derivatives of complex benzene derivatives have already been commenced with this object in view.

Although the author claims to have established the existence of a

para-linking in the molecule of phthalic acid, it would not be justifiable, considering the diversity in character of the benzene derivatives, to extend this conclusion generally; in the case of phloroglucinol, for example, it has been proved, with an equal degree of certainty, that the molecule contains three double linkings. It would seem, therefore, that the benzene nucleus exists in two forms, which may be regarded as tautomeric, in the sense that every single derivative has a definite constitution; this view best explains the facts, and gains in probability when it is considered that the ortho- and the para-linking in phenanthrene and anthracene respectively have almost identical properties, and are similar to the "breakable" linkings in the molecule of benzene.

Trans $\Delta^{3:5}$-*dihydrophthalic acid* is formed when 3 per cent. sodium amalgam (400 grams) and 50 per cent. acetic acid (60 c.c.) are added in small portions at a time with constant stirring to a well cooled solution of phthalic acid (20 grams) and sodium acetate (32·8 grams) in water (200 c.c.); when reduction is complete, the solution is mixed with 20 per cent. sulphuric acid (50 c.c.), kept until the separation of sodium sulphate is at an end, the acid then precipitated with 20 per cent. sulphuric acid (150 c.c.), and purified by recrystallisation from boiling water. The yield of the pure acid is 58 per cent. of the phthalic acid employed. It forms long, flat prisms, melts at 210°, is soluble in 610 parts of water at 10°, and in 15—17 parts of boiling water; it is not reduced by sodium amalgam in the cold. The *lead* salt crystallises in short, thick prisms, and is readily soluble in acetic acid. When the acid is boiled for a short time with soda, or for nine hours with water, it is completely converted into the $\Delta^{2:6}$-dihydro-acid. It is more readily oxidised than any of the position isomerides, and at once decolorises potassium permanganate; it immediately reduces ammoniacal silver nitrate solution on warming, and even silver nitrate is reduced after some time. When the acid is warmed with an aqueous solution of copper acetate, there is formed a green precipitate which undergoes decomposition with evolution of carbonic anhydride; if now a little acetic acid is added, and the mixture boiled, cuprous oxide is precipitated and benzoic acid remains in solution. This remarkable reaction is observed even more distinctly when the copper acetate is added drop by drop to a hot solution of the acid; the solution first becomes yellow, carbonic anhydride is evolved, and a white precipitate, probably cuprous benzoate, is produced; on adding acetic acid and heating, the white precipitate is converted into cuprous oxide. If the $\Delta^{2:6}$-dihydro-acid is present in solution, there is formed a colourless, very stable precipitate, which is the cuprous salt of the $\Delta^{2:6}$-acid. Trans $\Delta^{3:5}$-dihydrophthalic acid is decomposed on boiling it with copper sulphate, benzoic acid being formed and carbonic anhydride liberated. It combines directly with 4 atoms of bromine, yielding an oily *tetrabromide* which, on treatment with zinc-dust and acetic acid, is reconverted into the original dihydro-acid; it also combines readily with the halogen acids, giving, with hydrobromic acid, for example, a saturated *dihydrobromide*, which, however, could not be obtained in a crystalline form; this additive product is converted into hexahydro-

phthalic acid on reduction with sodium amalgam, but it does not give an unsaturated acid on treatment with zinc-dust and glacial acetic acid, a fact which shows that the two bromine atoms are not in the ortho-position relatively to one another. When the dihydrobromide is boiled with alcoholic potash, it yields an oil which contains bromine. The reason why the trans $\Delta^{3:5}$-dihydrophthalic acid combines with 4 atoms of bromine, whereas the $\Delta^{2:6}$- and the $\Delta^{2:4}$-dihydro-acids combine with 2 only, is, doubtless, because in the former the pair of double linkings do not join carbon atoms which are directly combined with a carboxyl group, but unite what may be called hydrocarbon groups; if this is really the cause of the great combining power of the acid with the halogens and halogen acids, it is evident that dihydrocymene, or a hydrocarbon of similar constitution, would possess the property in question to an even greater extent.

Cis $\Delta^{3:5}$-*dihydrophthalic acid* is prepared by boiling the trans $\Delta^{3:5}$-modification with acetic anhydride for seven minutes, adding to the cold solution an equal volume of water, and then warming until the decomposition of the anhydride is complete; it is purified by means of its lead salt, which, unlike the salt of the fumaroïd acid, is almost insoluble in acetic acid. It crystallises from hot water in large, flat, colourless prisms, melts at 173—175°, and is soluble in 93 parts of water at 10°. The *anhydride*, prepared by warming the acid with acetic anhydride, crystallises from a mixture of chloroform and ether in colourless needles, melts at 99—100°, and is slowly reconverted into the acid by boiling water. In chemical properties, the cis resembles the trans acid, than which, however, it is rather less stable; it is converted into the $\Delta^{2:6}$-isomeride even by cold 15 per cent. soda, whereas the fumaroïd acid is unchanged under these conditions.

$\Delta^{4:6}$-Dihydrophthalic acid has been previously described (*loc. cit.*), but, at the time, it was suggested that it might be the $\Delta^{2:4}$-acid; it is soluble in 506 parts of water at 10°, and in 322 parts at 25°. On prolonged warming with very concentrated aqueous or alcoholic potash, it is partially converted into the $\Delta^{2:4}$-isomeride. It is only very slowly reduced by sodium amalgam in the cold, but at a higher temperature, and in presence of carbonic acid, it yields the Δ^{2}-, and the two modifications of the Δ^{4}-tetrahydro-acid. On oxidation with potassium permanganate, it yields oxalic acid and phthalic acid, but not succinic acid; when boiled with an alkaline solution of potassium ferricyanide, it gives a large quantity of benzoic acid, this compound being also produced, with evolution of carbonic anhydride, when the acid is treated with freshly precipitated manganese dioxide and dilute sulphuric acid. The *anhydride* is obtained in large, rhombic plates or prisms, when the acid is boiled with acetic chloride for about two hours, and the solution then evaporated over soda-lime and sulphuric acid under reduced pressure; it melts at 83—84°, and dissolves freely in hot water, being reconverted into the original acid. It dissolves in sodium carbonate, yielding an orange-red solution, from which resinous products are precipitated on the addition of an acid; it also resinifies very readily when heated on the water-bath, and at the same time phthalic acid sublimes. When a small quantity of the anhydride is added to very dilute sodium carbonate containing a

little tincture of litmus, the blue colour disappears on shaking, owing to the reduction of the colouring matter, but reappears as soon as the whole of the anhydride has passed into solution.

Dibromotranshexahydrophthalic acid [$Br_2 = 2:6$, $(COOH)_2 = 1:2$], is formed, together with an oily acid, when $\Delta^{2:6}$-dihydrophthalic acid is treated with hydrobromic acid (*loc. cit.*); on treatment with sodium amalgam, it is converted into the transhexahydro-acid. Its *anhydride*, prepared by warming the acid with acetic chloride, crystallises from chloroform in plates, and melts at 157°. When the silver salt of the dibromo-acid is warmed with water, an odour of bromoform is observed, and the mixture turns brown; from the solution, the $\Delta^{2:6}$-dihydro-acid can be isolated.

$\Delta^{2:4}$-*Dihydrophthalic acid* is obtained when the dibromo-acid, just described, is warmed with methyl alcoholic potash (4 mols.) for 1½ hours; it is purified by converting it into the anhydride. It crystallises from warm water in short, concentrically-grouped prisms, melts at 179—180°, and is much more readily soluble in water than the $\Delta^{2:6}$-acid; when a not too concentrated solution of the acid is warmed with copper acetate, there is deposited a colourless, amorphous salt which redissolves on cooling. Its behaviour with oxidising agents is exactly the same as that of the $\Delta^{2:6}$-acid, into which it is converted when boiled with soda. The *anhydride*, prepared by treating the acid with acetic chloride at the ordinary temperature, crystallises from chloroform in colourless cubes, melts at 102—104°, and is readily soluble in warm water, being reconverted into the acid; it dissolves in sodium carbonate, yielding a colourless solution, but it bleaches litmus just like the anhydride of the $\Delta^{2:6}$-acid; when heated, it is converted into the anhydride of the $\Delta^{1:4}$-dihydro-acid. The $\Delta^{2:4}$-acid is the only known dihydrophthalic acid that is reduced by sodium amalgam in the cold.

Dibromotranshexahydrophthalic acid [$Br_2 = 2:4$], prepared by heating the preceding compound with a concentrated, glacial acetic acid solution of hydrogen bromide at 100° for 10 hours, crystallises from ether in rhombic plates, melts at 189—190°, and is very stable towards potassium permanganate; on treatment with sodium amalgam, it is converted into transhexahydrophthalic acid.

Cis Δ^4-*tetrahydrophthalic acid* is obtained when the $\Delta^{2:4}$-dihydro-acid is reduced with sodium amalgam in the cold, in carbonic acid solution; it crystallises from water in well-defined prisms, melts at 174°, and is soluble in 108·1 parts of water at 6°. When boiled with acetic anhydride, it is converted into the *anhydride*, which crystallises from ether in quadratic plates melting at 58—59°. Cis Δ^4-tetrahydrophthalic acid has been previously described (*loc. cit.*) as the Δ^3-tetrahydro-compound, and its formation from the anhydride of the trans Δ^4-tetrahydro-acid was accounted for by assuming that the position of the double linking had shifted; a more exact study has led the author to the conviction that such a shifting does not occur.

$\Delta^{1:4}$-*Dihydrophthalic acid* is obtained by boiling the $\Delta^{2:4}$-acid for six minutes with acetic anhydride, evaporating the solution at the ordinary temperature, and decomposing the purified crystalline an-

hydride prepared in this way with hot water; it separates from cold water in large, flat crystals, melts at 153°, and is partially reconverted into the anhydride when heated at 100°, or when its aqueous solution is concentrated on the water-bath; it is soluble in 59·7 parts of water at 6°. The *anhydride* crystallises in lustrous plates, melts at 134—135°, and sublimes very readily in voluminous, feathery plates. The *lead* salt and the *copper* salt are both sparingly soluble in acetic acid. The *silver* salt is not decomposed by boiling water, and crystallises in concentrically-grouped plates. The acid is not reduced by sodium amalgam, even on warming gently, but it decolorises potassium permanganate almost immediately; on oxidation with dilute sulphuric acid and freshly prepared manganese dioxide, or with a boiling alkaline solution of potassium ferricyanide, it is converted into phthalic acid. When boiled for half an hour with 10 per cent. soda, it is converted into a mixture of the $\Delta^{2:6}$- and the $\Delta^{2:4}$-dihydro-acids. F S. K.

Products of the Action of Nitric Acid on Ethyl Bromotrinitrophenylmalonate. By C. L. Jackson and W. B. Bentley (*Amer. Chem. J.*, **14**, 331—363).—Further slight improvements have been made in the method for producing tribromotrinitrobenzene (Abstr., 1890, 497).

Ethyl bromotrinitrophenylmalonate nitrite,

$$C_6HBr(NO_2)_3{\cdot}C(NO_2)(COOEt)_2,$$

is prepared by warming ethyl bromotrinitrophenylmalonate (*loc. cit.*, 3 grams) with nitric acid of sp. gr. 1·38 (10 grams) for three minutes on the water-bath; the solid which separates on cooling is again warmed with nitric acid, washed with water, dissolved in warm chloroform, and gradually separated from this solution by the addition of an equal volume of alcohol. It crystallises in short, thick, well-formed, lustrous, white prisms; when suddenly heated at 124—126°, it melts to a blood-red liquid which occupies many times the volume of the original solid, and contains gas bubbles. The change can be brought about more slowly at lower temperatures, the final product of the decomposition being ethyl bromotrinitrophenyltartronate (see below). The nitrite is very sparingly soluble in water, more soluble in alcohol, benzene, carbon bisulphide, and glacial acetic acid, and freely soluble in chloroform and acetone. Cold concentrated acids have no action on it, nor have aqueous alkalis, but alcoholic soda turns it red, forming sodium nitrite.

Ethyl anilidotrinitrophenylmalonate nitrite,

$$NHPh{\cdot}C_6H(NO_2)_3{\cdot}C(NO_2)(COOEt)_2,$$

is obtained by mixing ethyl bromotrinitrophenylmalonate with a slight excess of aniline in ether, by which the action is moderated. The liquid is washed with water containing a little hydrochloric acid, evaporated, and the residue recrystallised from chloroform. It forms red rhombohedra, melts at 119°, with slight decomposition, and decomposes violently at 120°. It is insoluble in water and light petroleum; only slightly soluble in alcohol, ether, and carbon bisulph-

ide; more soluble in methyl alcohol and glacial acetic acid, and freely soluble in chloroform, benzene, and acetone. Acids have little or no action on it; alkalis dissolve it pretty freely, showing that it has a distinctly acid bias, supposed by the authors to be due to the influence of the three nitro-groups on the anilido-hydrogen; to confirm this supposition they prepared *sodium anilidotrinitrotoluene*, $NPhNa{\cdot}C_6MeH(NO_2)_3$ (Abstr., 1890, 486), and found it to be a maroon-black powder which is decomposed by water and is soluble in alcohol, but insoluble in ether and benzene.

Ethyl bromotrinitrophenyltartronate,

$$C_6HBr(NO_2)_3{\cdot}C(OH)(COOEt)_2,$$

is formed when the action of nitric acid on ethyl bromotrinitrophenylmalonate is continued on the water-bath for three hours, after which it separates on cooling. It crystallises from alcohol in long, white prisms, melts at 156°, and is insoluble in light petroleum, nearly insoluble in water and carbon bisulphide, soluble in cold alcohol, ether, and chloroform, and freely so in benzene, glacial acetic acid, acetone, and hot alcohol. It shows strong acid tendencies. When mixed with aniline, it yields *ethyl anilidotrinitrophenyltartronate*, $NHPh{\cdot}C_6H(NO_2)_3{\cdot}C(OH)(COOEt)_2$, which exists in a red and a yellow modification. The *red modification* is best obtained by crystallising the crude product several times from alcohol, and then allowing a strong alcoholic solution of these crystals to evaporate slowly at 50—70°; it is thus obtained in well-formed, orange-red prisms, and melts at 143°; it is insoluble in cold water and light petroleum; slightly soluble in hot water, cold benzene, glacial acetic acid, and carbon bisulphide; soluble in cold alcohol, methyl alcohol, ether, and chloroform; freely soluble in hot alcohol, acetone, and hot benzene. From most of its solutions, it crystallises together with the *yellow modification*, which can be obtained pure by dissolving the mixture in warm glacial acetic acid and adding water after some hours. This modification crystallises in slender needles, united into spherical groups; when quickly heated to 122°, it melts and changes into the red modification, into which it is easily converted by slow crystallisation from alcohol; in solubility it resembles the red form, but is generally rather more soluble. Ethyl anilidotrinitrophenyltartronate has well marked acid properties, and the *monopotassium salt*, $NHPh{\cdot}C_6H(NO_2)_3{\cdot}C(OK)(COOEt)_2$, and *disodium salt*,

$$NPhNa{\cdot}C_6H(NO_2)_3{\cdot}C(ONa)(COOEt)_2,$$

were analysed and are described; a solution of the ammonium salt gives the following precipitates:—with a zinc salt, orange-brown; with a manganese salt, brown; with a cadmium salt, reddish-brown; with a copper salt, yellowish-brown; with a lead, mercuric, or silver salt, reddish-brown.

Ethyl anilidotrinitrophenylmalonate,

$$NHPh{\cdot}C_6H(NO_2)_3{\cdot}CH(COOEt)_2,$$

is easily obtained by adding aniline to ethyl bromotrinitrophenylmalonate, and crystallising the product from alcohol. It forms aggre-

gates of long, slender, sharp, yellow needles, and melts at 133°; it is insoluble in light petroleum and cold water, slightly soluble in hot water and carbon bisulphide, freely soluble in hot alcohol, chloroform, benzene, acetone, glacial acetic acid, and ether. It is acid in its behaviour to alkalis, and the solution of its sodium salt gives reddish-brown or yellowish-brown precipitates with most of the dyad metals, the calcium salt being the least, and barium salt the most soluble. Attempts to prepare the above described nitrite by the direct action of nitric acid on this compound failed.

Ethyl trinitrophenylenedimalonate nitrite,

$$CH(COOEt)_2{\cdot}C_6H(NO_2)_3{\cdot}C(NO_2)(COOEt)_2,$$

is prepared from ethyl trinitrophenylenedimalonate (Abstr., 1890, 498) similarly to ethyl bromotrinitrophenylmalonate nitrite. It crystallises in thick, lemon-yellow plates, and melts at 111°. It is insoluble in light petroleum and cold water; slightly soluble in cold alcohol, hot water, and carbon bisulphide; freely soluble in hot alcohol, chloroform, benzene, acetone, glacial acetic acid, and ether. It has acid properties, and a solution of the sodium salt gives yellow precipitates with salts of most of the dyad metals.

Ethyl bromodinitrophenylmalonate nitrite,

$$C_6H_2Br(NO_2)_2{\cdot}C(NO_2)(COOEt)_2,$$

similarly prepared, forms thick, white, rhombic crystals, and melts at 111°. It is nearly insoluble in light petroleum and cold water; soluble in ether, carbon bisulphide, and alcohol, and freely soluble in benzene, chloroform, acetone, and glacial acetic acid. It is decomposed by sodium hydroxide, and is very stable to nitric acid. When it is reduced with hydrochloric acid and tin, *amidohydroxyoxindole chloride*, $NH_3Cl{\cdot}C_6H_3{<}\begin{matrix}CH(OH)\\NH-CO\end{matrix}{>}$, is obtained; this crystallises in large, yellow plates.

The authors regard the above compounds as nitrites containing the NO_2 group in the side chain attached to the molecule by oxygen and not by nitrogen, first, because of their easy conversion by nitric acid and by heat into the corresponding tartronates, a reaction resembling the conversion of the nitrate of tartaric acid into tartronic acid; and secondly, because the reduction of ethyl bromodinitrophenylmalonate nitrite yields amidohydroxyoxindole chloride, and not diamidoxindole chloride. A. G. B.

Alkyl Salts of Sulphonic Acids. By F. Krafft and A. Roos (*Ber.*, **25**, 2255—2262).—Schiller and Otto have stated that ethyl benzenesulphonate is not formed by the action of ethyl alcohol on benzenesulphonic chloride, but the compound described by them as this salt (this Journal, 1877, i, 463), as also the compounds obtained by Hübner (Abstr., 1884, 1180), were not pure substances. The authors find, however, that methyl and ethyl benzenesulphonate are readily prepared by mixing benzenesulphonic chloride with the alcohol (3 parts), and allowing the mixture to remain for 4—5 days,

pouring the product into ice-cold water, taking up the precipitated oil with ether, and rectifying under diminished pressure.

Methyl benzenesulphonate, $C_6H_5{\cdot}SO_3Me$, is a colourless, almost tasteless oil, d 17°/4° = 1·273, boiling at 150° (15 mm.); whilst ethyl benzenesulphonate resembles it, d 17°/4° = 1·2192, and it boils at 156° (15 mm.). *Propyl benzenesulphonate* is prepared in the same manner, but the reaction requires 12—14 days for completion; it boils at 162—163° (15 mm.), d 17°/4° = 1·1804. Ethyl paratoluenesulphonate melts at 32—33° as stated by Jaworsky (*Zeit. f. Chem.*, 1865, 221), boils at 173° (15 mm.), and has a sp. gr. at 32° = 1·1736.

Methyl parachlorobenzenesulphonate, prepared from *parachlorobenzenesulphonic chloride* (m. p. 53°), melts at 50·5° and boils at 165—166° (15 mm.); whilst the *ethyl* salt melts at 25—26° and boils at 171—172°.

Methyl parabromobenzenesulphonate, prepared from *parabromobenzenesulphonic chloride* (m. p. 75°), melts at 60° and boils at 176° (15 mm.); whilst the *ethyl* salt melts at 39·5° and boils at 181—182° (15 mm.).

Methyl β-naphthalenesulphonate is obtained from *β-naphthalenesulphonic chloride* (m. p. 76—77°); it melts at 53—54° and boils at 224—225° (15 mm.); whilst the ethyl salt melts at 11—12°.

α-Naphthalenesulphonic chloride boils at 194—195° (13 mm.), and yields on treatment with methyl alcohol *methyl α-naphthalenesulphonate*, melting at about 75° and boiling at 214° (15 mm.). The investigation is proceeding. A. R. L.

Phenylhydrindone. By W. v. Miller and G. Rohde (*Ber.*, **25**, 2095—2102).—*Phenylhydrindone*, $C_6H_4{<}\overset{CH_2}{\underset{CO}{}}{>}CHPh$, is prepared by dropping dried pulverised α-phenylcinnamic acid (10 grams) into concentrated sulphuric acid (80 grams) at 140°, shaking, and after a few minutes, pouring the solution on to ice. The resulting milky liquid is shaken with ether, whereby the phenylhydrindone is extracted, and an oil, probably a sulphonic acid, separates in a layer between the aqueous and ethereal solutions. The ethereal solution is washed successively with soda and water, and the phenylhydrindone obtained from it repeatedly crystallised from boiling alcohol, and finally from cold ether, when it is obtained in well-formed white prisms, melts at 77—77·5°, is readily soluble in benzene, alcohol, and ether, sparingly so in light petroleum, and as good as insoluble in water; it distils at 344° with partial decomposition, is volatile with steam, and reduces ammoniacal silver and Fehling's solutions. Phthalic and benzoic acids are formed on oxidation with dilute nitric acid. The *phenylhydrindonehydrazone*, $C_{21}H_{18}N_2$, crystallises from benzene in almost white crystals, which become brownish on exposure to light; it melts at 137—138°, and dissolves in concentrated sulphuric acid with a yellow colour, becoming dark-violet on the addition of ferric chloride.

If an ethereal solution, containing 10 grams of phenylhydrindone, is shaken with seven successive portions of 10 per cent. sodium hydr-

oxide solution (50 grams) for 1—2 hours in each case, and after washing, the ether is distilled off, and the crystalline residue washed with a little ether, *hydroxyphenylhydrindone*, $C_6H_4<\begin{matrix}CH_2\\CO\end{matrix}>CPh\cdot OH$, or $C_6H_4<\begin{matrix}CH(OH)\\CO\text{———}\end{matrix}>CHPh$, is left. On slowly evaporating an ethereal solution, it separates in six-sided tablets, melting at 129°. The corresponding *hydrazone*, $C_{21}H_{18}N_2O$, forms yellow crystals, melts at 160°, and dissolves in concentrated sulphuric acid with a violet colour, becoming blue on the addition of ferric chloride; when, however, its solution in sulphuric acid is placed aside, it becomes claret coloured, and passes into bluish-green on the addition of ferric chloride. The *acetyl* derivative melts at 167°.

β-Deoxybenzoïnorthocarboxylic acid, melting at 169—170°, and identical with that obtained by Gabriel (Abstr., 1885, 1231), separates on acidifying the sodium hydroxide solution, which has been shaken with an ethereal solution of phenylhydrindonephenylhydrazone, as above described.

When phenylhydrindone is oxidised with alkaline potassium permanganate, besides phthalic and benzoic acids, traces of hydroxyphenylhydrindone (m. p. 129°) and other compounds are formed. The investigation is still in progress. A. R. L.

Condensation of the Three Isomeric Methylhydrocinnamic Acids to the Corresponding Methylhydrindones. By Young (*Ber.*, **25**, 2102—2109).—The yield of orthomethylcinnamic acid obtained by Perkin's reaction is poor (see Kröber, Abstr., 1890, 969). Claisen's method (Abstr., 1890, 891), however, gives better results. Orthotolualdehyde (10 grams) is gradually dropped into a well-cooled mixture of sodium (2 grams) in excess of ethyl acetate; after a while the calculated quantity of glacial acetic acid is added to the mixture, which is then diluted with water, and extracted with ether. The acid has the properties already ascribed to it by Kröber (*loc. cit.*).

Orthomethylhydrocinnamic acid is prepared by reducing the last-mentioned acid with sodium amalgam, the solution being kept neutral by means of a current of carbonic anhydride; it is readily soluble in hot water and other ordinary solvents, and separates in elongated, monoclinic prisms.

Orthomethylhydrindone, $C_6H_3Me<\begin{matrix}CO\\CH_2\end{matrix}>CH_2$, is formed when the methylhydrocinnamic acid (10 grams) is dropped into hot concentrated sulphuric acid (15 grams) at a temperature of 180—190°, and the mixture poured on to ice; the hydrindone is driven over in a current of steam, and, subsequently, crystallised from light petroleum, from which it separates in white needles melting at 95°. The *phenylhydrazone*, $C_{10}H_{10}:N_2HPh$, crystallises from dilute alcohol in slender, white needles, melting at 133° with decomposition. When orthomethylhydrindone is oxidised with nitric acid, *methylphthalic acid*, [Me : $(COOH)_2$ = 1 : 2 : 3], melting at 144°, and giving an *anhydride* melting at 109—110°, is formed. The corresponding *methylphthalimide*

is obtained when the acid is treated with ammonium thiocyanate by Aschan's method (Abstr., 1886, 704); it forms nodular groups of needles, and melts at 183—184°.

When meta- or para-methylhydrindone is oxidised with nitric acid, methylphthalic acid [Me : $(COOH)_2 = 1 : 3 : 4$], melting at 124°, is obtained. The methylphthalic acid described by Niementowski (this vol., p. 607) is probably a mixture of two isomerides. A. R. L.

The Formation of Hydrindone Derivatives from Halogen Cinnamic Acids. By W. Miersch (*Ber.*, **25**, 2109—2116; compare Abstr., 1890, 1139).—Orthobromocinnamic acid is prepared by reducing technical orthonitrocinnamic acid by Fischer and Kuzel's method (*Annalen*, **221**, 266), and displacing the amido-group in the product thus obtained by bromine, according to Gattermann's method (Abstr., 1890, 971); it is reduced to the corresponding hydro-acid by hydriodic acid and phosphorus.

Orthobromhydrindone, $C_6H_3Br<\begin{matrix}CO\\CH_2\end{matrix}>CH_2$, is formed by treating orthobromhydrocinnamic acid with concentrated sulphuric acid at 180—190°, the yield being 10 per cent. of the bromo-acid employed; it crystallises from alcohol in colourless needles, and melts at 95·5—96·5°. The *phenylhydrazone* melts at 146—147·5°; whilst parabromhydrindonephenylhydrazone melts at 158—159·5°.

Parachlorhydrocinnamic acid is prepared by reducing paramidocinnamic acid either with sodium amalgam or with hydriodic acid and phosphorus (details being given in the paper), and replacing the NH_2 group by chlorine, by Gattermann's method; it melts at 122°.

Parachlorhydrindone, $C_6H_3Cl<\begin{matrix}CO\\CH_2\end{matrix}>CH_2$, obtained by heating the last-mentioned acid with concentrated sulphuric acid at 180°, melts at 79—80°, and gives a *phenylhydrazone* melting at 136·5—137·5°.

A compound melting at 126—127° was obtained from paraiodohydrocinnamic acid; it is probably paraiodohydrindone.

Meta- and ortho-bromhydrindone, when heated on the water-bath with 25 per cent. nitric acid, give consecutive bromophthalic acid (m. p. 183°); whilst parachlorhydrindone gives, on similar treatment, asymmetrical chlorophthalic acid (m. p. 150—150·5°). A. R. L.

Metadiamidotetramethylbenzidine. By C. Lauth (*Compt. rend.*, **114**, 1208—1211).—Metazodimethylaniline, $N_2(C_6H_4{\cdot}NMe_2)_2$, is obtained in long, orange or red needles, which melt at 118°, by the action of zinc and caustic soda on nitrodimethylaniline in presence of alcohol. It is insoluble in water, but dissolves easily in dilute acids and in about 15 parts of boiling alcohol. It is rapidly attacked by reducing agents. When heated at about 100° with aniline hydrochloride, it yields a blue-violet induline, and with paraphenylenediamine and hydrochloric acid it forms a blue-grey induline.

When reduced with zinc and sodium hydroxide, in presence of alcohol, metazodimethylaniline yields a hydrazo-derivative, which very readily oxidises. To convert this into metadiamidotetramethylbenzidine, the solution is filtered, in an atmosphere of coal-

gas, into boiling hydrochloric acid. It is boiled for 15 minutes, and the base is precipitated with sodium carbonate, and crystallised from alcohol. The azo-derivative may also be reduced by stannous chloride in presence of excess of acid, and the base extracted with benzene.

Metadiamidotetramethylbenzidine forms colourless needles and melts at 165°. It is very soluble in warm benzene or warm alcohol, but is practically insoluble in these liquids when cold; its salts are very soluble in water. With ferric chloride or potassium dichromate, its solutions give an orange coloration; with lead peroxide and acetic acid, a yellow-brown coloration, and with nitrous acid, a beautful violet colour, changing rapidly to brown. Metadiamidotetramethylbenzidine forms no diazo-compounds. With nitrosodimethylaniline, in presence of acetic acid, it yields an azine which imparts a red-violet tint to silk and to cotton mordanted with tannin. It yields no colouring matters with phthalic acid in presence of zinc chloride, or with formaldehyde or benzaldehyde. C. H. B.

Polymethylene Bases from Benzidine and Tolidine. By H. Schiff (*Ber.*, **25**, 1936—1940).—When benzidine is dissolved in an excess of hydrochloric acid, and formaldehyde added to the solution at 70—80°, a red, flocculent precipitate forms after a while; this is collected, and dried between filter-paper. It is a hydrochloride, which gradually loses hydrogen chloride on keeping, the largest amount of chlorine found in the freshly-prepared substance being 19·9 per cent. The free base separates when a dilute solution of the hydrochloride is heated for half an hour with sodium carbonate. It is a yellow powder, insoluble in water and cold alcohol, and only sparingly soluble in boiling alcohol; it decomposes at a high temperature without melting, and formaldehyde distils over when it is boiled with water. It may have one of the two formulæ $OH\cdot CH<\begin{matrix}C_6H_3\cdot N:CH_2\\ |\\ C_6H_3\cdot N:CH_2\end{matrix}$ or $O<\begin{matrix}CH_2\cdot C_6H_3\cdot N:CH_2\\ |\\ CH_2\cdot C_6H_3\cdot N:CH_2\end{matrix}$; the analytical values agree best with the second. Tolidine yields a similar base, $C_{17}H_{16}N_2O$ or $C_{18}H_{18}N_2O$.

When sulphanilic acid is dissolved in an excess of aqueous formaldehyde, by the aid of heat, the solution saturated with barium hydroxide, and the excess precipitated by carbonic anhydride, an amorphous and crystalline barium salt may be separated; the latter is derived from an acid of the composition $C_{15}H_{14}N_2O_6S_2$. A. R. L.

Acridone Derivatives. By M. Schöpff (*Ber.*, **25**, 1980—1984; compare Graebe and Lagodzinski, this vol., p. 1086).—*3-Acridonesulphonic acid*, $C_6H_4<\begin{matrix}NH\\ CO\end{matrix}>C_6H_3\cdot SO_3H$, is obtained by the action of concentrated sulphuric acid on anilidosulphobenzoic acid

$$[NHPh : COOH : SO_3H = 1 : 2 : 4];$$

it dissolves in water and concentrated sulphuric acid, forming a yellow solution having an intensely blue fluorescence; the *barium* salt crystallises with $1\frac{1}{2}$ mols. H_2O. Although the author has not

succeeded in converting xanthone into acridone by the action of ammonia, even at as high a temperature as 260°, he thinks it probable that the carboxy-, hydroxy-, and sulphonic derivatives of xanthone will be found capable of undergoing an analogous change. When anilidoisophthalic acid is distilled under diminished pressure, there is obtained, besides diphenylamine, a small quantity of a compound which is perhaps acridone. The author confirms Graebe and Lagodzinski's statement (*loc. cit.*) that phenylanthranilic acid is obtained on oxidising acetylorthotolylaniline, and he has obtained an acid melting at 152° by the oxidation of diacetylmetahydroxyphenylorthotoluidine. β-Naphthylanthranilic acid is produced by heating together acetylanthranilic acid and β-naphthol for several hours at 200—250°, and, after the whole of the acetic acid has passed over, raising the temperature to 290—295°. The investigation is proceeding.

A. R. L.

Isomeric Change in the Stilbene Series. By J. J. Sudborough (*Ber.*, **25**, 2237—2239).—Zinin has shown (*Annalen*, **149**, 375) that deoxybenzoïn is converted into chlorostilbene when it is treated with phosphoric chloride. The author has prepared methyl-, ethyl-, and benzyl-chlorostilbene from the corresponding alkyldeoxybenzoïns; the products are purified by heating them with dilute alcoholic potash on the water-bath.

Methylchlorostilbene, CMePh:CClPh, is a transparent oil boiling at 316° (corr.), which, when distilled, or boiled in a reflux apparatus, is converted into a solid isomeride melting at 117—118° and boiling at 311° (corr.). Zinin's chlorostilbene is converted in an analogous manner into an isomeride melting at 54°. Benzylchlorostilbene melts at 80°. As to the nature of these isomerides, it is shown that the two methyl derivatives have the same vapour density, so that it is improbable that they are polymerides, but they may be stereoisomerides, or the solid compounds may be phenanthrene derivatives containing 2 atoms of hydrogen less than the liquid ones.

Cetyldeoxybenzoïn, $C_{16}H_{33}$·CHPh·COPh, melts at 76° and boils with partial decomposition at 430°.

A. R. L.

Hydroxyketone Dyes. By C. Graebe and A. Eichengrün (*Annalen*, **269**, 295—317; compare Abstr., 1891, 706).—*Sodiotrihydroxybenzophenone*, $C_{13}H_9O_4Na$, prepared by warming trihydroxybenzophenone with sodium carbonate and water, crystallises in yellow needles, and is only sparingly soluble in water. The *potassium* derivative, $C_{13}H_9O_4K$, is a yellow powder. The *lead* derivative, $C_{13}H_8O_4Pb$, is obtained when an ammoniacal solution of trihydroxybenzophenone is treated with lead acetate; it is a yellow powder, insoluble in water. The *triacetyl* derivative, $C_{13}H_7O_4Ac_3$, prepared by boiling the ketone with acetic anhydride, crystallises in colourless plates, melts at 117°, and is soluble in alcohol, glacial acetic acid, and benzene, but insoluble in water, ether, and light petroleum; when heated with phenylhydrazine in alcoholic solution, it is converted into a colourless, crystalline *hydrazone*, $C_{13}H_7O_3Ac_3{:}N_2HPh$, which melts at 130°, and, when treated with hydroxylamine, it yields a yellowish, crystalline *oxime*, $C_{13}H_7O_3Ac_3{:}N{\cdot}OH$, which melts at 135°.

The *methyl* derivative, $C_{13}H_9O_4Me$, is formed as principal product when trihydroxybenzophenone is heated at 100° with potash (3 mols.) and methyl iodide (3 mols.); it separates from alcohol in yellow crystals, melts at 165°, and is readily soluble in chloroform, but more sparingly in alcohol, ether, and glacial acetic acid, and very sparingly in benzene; it is soluble in dilute soda and in alkaline carbonates, yielding yellow solutions. The *dimethyl* derivative, $C_{13}H_8O_4Me_2$, can be obtained by heating sodiotrihydroxybenzophenone with methyl iodide and solid sodium carbonate at 160°; it separates from alcohol in colourless crystals, melts at 131°, and dissolves freely in ether, chloroform, and alkalis, but is only very sparingly soluble in soda, and insoluble in sodium carbonate; when heated with acetic anhydride, it is converted into the *acetyl* derivative, $C_{13}H_7O_4Me_2Ac$, which crystallises from glacial acetic acid in colourless prisms and melts at 98°. The trimethyl derivative could not be obtained.

Nitrotrihydroxybenzophenone, $C_{13}H_9O_4{\cdot}NO_2$, is obtained, together with benzoic acid and a volatile nitro-compound, when trihydroxybenzophenone is carefully warmed with 20 per cent. nitric acid; it separates from hot water in yellowish crystals, melts at 123°, and is soluble in alcohol and ether; it dissolves in alkalis, yielding a yellow solution, and on oxidation with alkaline potassium permanganate it gives benzoic acid. The *dinitro*-compound, $C_{13}H_8O_4(NO_2)_2$, prepared by treating the ketone with nitric acid of sp. gr. 1·4 at the ordinary temperature, is a yellow substance, melts at 133° with decomposition, and dissolves in water, alcohol, and alkalis, yielding yellow solutions. The *trinitro*-compound, $C_{13}H_7O_4(NO_2)_3$, melts at 118°, and is only sparingly soluble in water, but readily in alcohol.

Bromotrihydroxybenzophenone, $C_{13}H_9O_4Br$, is formed when the ketone is treated with bromine in alcoholic glacial acetic acid solution; it crystallises from alcohol in lemon-yellow prisms, melts at 149°, and is moderately easily soluble in alcohol, ether, and glacial acetic acid, but only sparingly in benzene; on oxidation with potassium permanganate, it yields benzoic acid, and, when treated with nitric acid, it is converted into the mononitro-compound described above.

Tetrahydroxybenzophenone, $C_{13}H_{10}O_5 + H_2O$ (*loc. cit.*), crystallises in greenish-yellow plates, sublimes in nearly colourless needles, and is readily soluble in alcohol, ether, and glacial acetic acid, but only sparingly in water, benzene, and light petroleum; it loses its water at 100°, the anhydrous substance melting at 149°. It dissolves in potash, yielding a yellowish-red solution which rapidly turns dark green on exposure to the air, with separation of a dark precipitate; it is also soluble in sodium carbonate and in ammonia, but is reprecipitated by carbonic acid. In solutions of the sodium or ammonium derivative, aluminium salts produce a golden-yellow, lead and magnesium salts a reddish-yellow, calcium chloride a greenish-yellow, and ferric chloride a yellowish-brown, precipitate. The *sodium* derivative, $C_{13}H_9O_5Na + H_2O$, is quickly deposited in yellow crystals when the ketone is suspended in hot water and treated with sodium carbonate; it is rather sparingly soluble in water. The *tetracetyl* derivative, $C_{13}H_6O_5Ac_4$, crystallises from alcohol and acetic acid in colourless scales, melts at 118°, and combines with phenylhydrazine to form a

colourless, crystalline *hydrazone*, which melts at 129°. The *bromo*-derivative, $C_{13}H_9BrO_5$, is formed when tetrahydroxybenzophenone is treated with bromine in cold glacial acetic acid solution; it crystallises from dilute alcohol in yellow prisms, melts at 200°, and dissolves in sodium carbonate and in dilute potash with a yellow coloration.

Bromodihydroxyxanthone, $C_{13}H_7BrO_4$, is obtained when bromine is added to a glacial acetic acid solution of tetrahydroxybenzophenone and the mixture heated to boiling; it crystallises from alcohol in almost colourless needles, and turns brown at 310°, but does not melt at 360°; it dissolves in potash with a blood-red coloration.

Tribromodihydroxyxanthone, $C_{13}H_5Br_3O_4$, can be prepared by boiling tetrahydroxybenzophenone with a large excess of bromine in glacial acetic acid solution; it is an almost colourless compound, does not melt at 360°, and dissolves in potash, yielding a deep-red solution.

Hydroxynaphthyl trihydroxyphenyl ketone, $OH{\cdot}C_{10}H_6{\cdot}CO{\cdot}C_6H_2(OH)_3 + H_2O$, is formed when gallic acid is heated with α-naphthol and zinc chloride; it crystallises from alcohol in greenish-yellow prisms or needles, loses its water at 100°, melts at 246°, and is only moderately easily soluble in alcohol and glacial acetic acid, and insoluble in water, benzene, and light petroleum; it dissolves in concentrated sulphuric acid with a deep-red, and in alkalis with a yellowish-red, coloration. The *potassium* derivative, $C_{17}H_{11}O_5K$, is a brown powder. The *sodium* derivative, $C_{17}H_{11}O_5Na$, crystallises in brown needles, and is only sparingly soluble in water. The *hydrazone*, $C_{17}H_{12}O_4{\cdot}N_2HPh$, crystallises from alcohol in yellowish-brown plates, melts at 210° with decomposition, and is soluble in ether and glacial acetic acid, but insoluble in benzene. The *tetracetyl* derivative, $C_{17}H_8O_5Ac_4$, forms yellow crystals, melts at 129°, and is readily soluble in alcohol, benzene, and glacial acetic acid, but only sparingly in ether. When the ketone is heated with sulphuric acid, it is decomposed into naphthol and gallic acid; it is completely decomposed by warm concentrated nitric acid.

A bromo-derivative of the composition $C_{34}H_{16}O_9Br_6$ is formed when hydroxynaphthyl trihydroxyphenyl ketone is treated with excess of bromine in glacial acetic acid solution at the ordinary temperature; it separates from alcohol in crystals, melts at 293°, and is moderately easily soluble in alcohol, glacial acetic acid, and ether, but almost insoluble in benzene and light petroleum. When bromine is gradually added to an alcoholic solution of the ketone until a permanent coloration is produced, a considerable development of heat occurs, and, on cooling, a yellow, crystalline compound, which melts at 246° and has probably the composition $C_{17}H_7Br_3O_4$, is deposited.

A *dinitro*-compound of the composition $C_{17}H_{10}O_5(NO_2)_2$ is formed when hydroxynaphthyl trihydroxyphenyl ketone is heated at 40—50° with dilute nitric acid; it crystallises from alcohol in yellow needles, melts at 134° with decomposition, and is soluble in potash.

F. S. K.

Behaviour of Aromatic Hydroxyketones with Sulphuric Acid and with Ammonia. By C. Graebe and A. Eichengrün (*Annalen*, **269**, 318—323; compare preceding abstract).—When the hydroxy-derivatives of benzophenone are treated with sulphuric acid

under suitable conditions, they are decomposed, and the more readily the greater the number of hydroxy-groups in the molecule; that part of the molecule which is combined with the smaller number of hydroxyl groups is converted into an acid, whilst the remainder is transformed into a phenol or phenolsulphonic acid. Hydroxybenzophenones, such as orthodihydroxybenzophenone, which are readily converted into xanthone derivatives form exceptions to the above rule.

Hydroxyamidobenzophenone, $OH\cdot C_6H_4\cdot CO\cdot C_6H_4\cdot NH_2$, is formed when orthodihydroxybenzophenone is boiled with dilute ammonia, but the yield is better when the ketone is treated with excess of alcoholic ammonia at the ordinary temperature. It is a yellow, crystalline compound, melts at 222°, and is soluble in hot alcohol, chloroform, and ethyl acetate, but only sparingly in ether and benzene; it dissolves in cold alkalis, and in warm alkaline carbonates with a yellow, and in concentrated sulphuric acid with a red, coloration, but its solutions in dilute acids are colourless. The *hydrochloride* crystallises from dilute alcohol in colourless prisms, and melts at 242°; when this salt, or the base itself, is submitted to dry distillation, it is converted into xanthone with liberation of ammonia.

When tetrahydroxybenzophenone (m. p. 149°) is heated with dilute ammonia at 150°, it is converted into the corresponding dihydroxyxanthone (compare Abstr., 1891, 706); paradihydroxybenzophenone and orthoparadihydroxybenzophenone, on the other hand, are not acted on by ammonia. Salicylresorcinol is readily decomposed by ammonia at the ordinary temperature, yielding salicylamide and resorcinol. F. S. K

Derivatives of Deoxybenzoïn. By P. Petrenko-Kritschenko (*Ber.*, **25**, 2239—2242).—Parachlorodeoxybenzoïn is prepared from paranitrophenylacetic acid (prepared from benzoyl cyanide) by reducing it, and converting the amido-acid thus formed into the chloro-acid by Sandmeyer's method; the latter is then dissolved in chloroform, the solution heated with phosphorus pentachloride, and the non-volatile residue, left on distilling the product under diminished pressure, is dissolved in benzene, and heated on the water-bath with a small quantity of aluminium chloride. The parachlorodeoxybenzoïn, when crystallised from alcohol, melts at 133°. When it is dissolved in sodium ethoxide solution, benzyl chloride (2 mols.) added, and the mixture heated for about 12 hours, the *benzyl* derivative, $C_6H_4Cl\cdot CH(CH_2Ph)\cdot COPh$, melting at 138°, is obtained.

Parachlorodesaurin, $C_6H_4Cl\cdot C(CS)\cdot COPh$, is formed by heating parachlorodeoxybenzoïn with potassium hydroxide in fine powder (2 parts) and carbon bisulphide (20—30 parts) on the water-bath. It separates from xylene as a bright-yellow, microcrystalline mass, and melts at 280°.

Paranitrodeoxybenzoïn, prepared from paranitrophenylacetic chloride by the Friedel-Craft reaction, melts at 145°, and is, perhaps, identical with the compound Golubeff obtained by nitrating deoxybenzoïn (Abstr., 1879, 150 and 790). Experiments are now in progress on the action of benzyl chloride on the nitro-compound. A. R. L.

The Fluoresceïn Group. By R. Meyer and H. Hoffmeyer (*Ber.*, **25**, 2118—2121).—The formula ascribed by the authors in a former paper (this vol., p. 970) to fluoran was not experimentally established.

Hydrofluoranic acid, which has been obtained both by v. Baeyer and by the authors by reducing fluoran, and which may be represented by the formula $COOH{\cdot}C_6H_4{\cdot}CH{<}\begin{smallmatrix}C_6H_4\\C_6H_4\end{smallmatrix}{>}O$, was distilled with lime (3 parts), xanthone being isolated. The latter is also formed, together with benzene, when fluoran is distilled with lime (4 parts); these facts prove, therefore, the accuracy of the formulæ assigned to fluoran and fluoresceïn (*loc. cit.*), as also that given above to hydrofluoranic acid.

When hydrofluoranic acid is distilled with baryta or soda-lime, or when fluoran is distilled with soda-lime and zinc-dust, a compound is obtained crystallising in white needles and melting at 143°. It is being further investigated. A. R. L.

Condensation of Cinnamic Acid with Hydrocarbons. By C. Liebermann and A. Hartmann (*Ber.*, **25**, 2124—2131).—When cinnamic acid (25 grams) is mixed with benzene (50 grams) and concentrated sulphuric acid (125 grams), and the mixture heated on the water-bath for 1—2 hours, then poured into water and extracted with ether, the aqueous acid liquid is found to contain sulphonic acids, which give diphenylpropionic acid on heating them with hydrochloric acid at 220°. The ethereal solution is distilled, and the residue extracted with sodium carbonate solution, when phenylhydrindone (see below) remains, whilst diphenylpropionic acid and a smaller quantity of phenylenediphenyldipropionic acid pass into solution. The two acids are subsequently separated by means of the difference in their solubility in ether, the former being more readily soluble in that solvent than the latter. To obtain the maximum yield of diphenylpropionic acid, the above quantity of sulphuric acid is diluted with 10 per cent. of water.

When the diphenylpropionic acid (*loc. cit.*) is dissolved in alkali carbonate, a 5 per cent. solution of potassium permanganate dropped in, and, simultaneously, a current of steam passed through the mixture, benzophenone is driven over.

Phenylenediphenyldipropionic acid, $C_6H_4(CHPh{\cdot}CH_2{\cdot}COOH)_2$, crystallises from alcohol in small, white needles, and melts at 235°; the *barium* salt crystallises with $7H_2O$. The acid owes its origin to the condensation of diphenylpropionic acid with cinnamic acid.

Phenylhydrindone, $C_6H_4{<}\begin{smallmatrix}CHPh\\CO\end{smallmatrix}{>}CH_2$, forms colourless, lustrous needles, dissolves readily in alcohol, ether, benzene, and glacial acetic acid, and melts at 78°; the *oxime* melts at 141°, and the *hydrazone* melts at 130° (compare v. Miller and Rohde, this vol., p. 1220).

When v. Pechmann's β-phenylumbelliferone (Abstr., 1884, 67) is dissolved in alcohol, and allowed to remain for two days with an excess of sodium amalgam at 50—60°, phenylhydroxyhydrocoumarin (m. p. 137°), identical with that prepared by the condensation of cinnamic acid and resorcinol, is obtained. A. R. L.

Nitro-β-naphthols. By F. Gaess (*J. pr. Chem.* [2], **45**, 614—616).—1′ : 2′-*Nitronaphthol* is prepared by heating 1′ : 2′-nitronaphthol ethyl ether (Abstr., 1891, 459) in 15 parts of a mixture of glacial acetic acid (10 parts) and strong hydrochloric acid (5 parts) for 6—8 hours at 160—170°; the solution is poured into water, the acid nearly neutralised, and the precipitated naphthol filtered off, and purified by solution in ammonia and reprecipitation by hydrochloric acid. It crystallises from hot water in golden needles, melts at 144—145°, and dissolves easily in alcohol, ether, chloroform, acetone, and benzene; it has feebly acid properties, and forms unstable salts. The *acetyl* derivative crystallises from aqueous alcohol in long, pale-yellow needles, melts at 101—102°, and dissolves easily in alcohol and ether, but more sparingly in water.

2 : 2′-Nitronaphthol ethyl ether is not so easily decomposed. By using a mixture of 15 parts of hydrogen chloride and 85 parts of glacial acetic acid, and heating at 200—210°, both 2 : 2′-nitronaphthol and chloro-2 : 2′nitronaphthol are produced; they may be separated by crystallisation from aqueous alcohol or aqueous acetic acid, in both of which the chloro-derivative is less soluble. 2 : 2′-*Nitronaphthol* forms yellow needles, and melts at 156—158°; the *acetyl* derivative crystallises in colourless needles, and melts at 151—152°. *Chloro*-2 : 2′-*nitronaphthol* crystallises in yellow needles, and melts at 192°. A. G. B.

Nitro-β-naphthaquinone. By T. Zincke (*Annalen*, **268**, 257—260).—The author and his pupils have studied the action of chlorine on nitro-β-naphthaquinone; the results of the investigation are given in the following abstracts. F. S. K.

Action of Chlorine on Nitro-β-naphthaquinone in Glacial Acetic Acid Solution. By T. Zincke and M. Latten (*Annalen*, **268**, 260—297).—*Orthodichloronitrethylbenzoylcarboxylic acid*,

$$OH\cdot NO{:}CCl\cdot CHCl\cdot C_6H_4\cdot CO\cdot COOH,$$

is obtained, together with an oily bye-product, when a rapid stream of dry chlorine is passed into glacial acetic acid containing finely-divided nitro-β-naphthaquinone in suspension, the saturated solution kept for 24 hours, then filtered, and evaporated at the ordinary temperature; on keeping, the acid is gradually deposited in crystals and is separated from the yellow mother liquors by filtration. It separates from glacial acetic acid in large, lustrous, seemingly monoclinic crystals, and from hot benzene in colourless needles or prisms, turns yellow at 163—165°, and melts at 174° with effervescence; it dissolves freely in alcohol, ether, and glacial acetic acid, but is only sparingly soluble in benzene, and almost insoluble in light petroleum. It is soluble in cold water, but is reprecipitated from the solution on the addition of hydrochloric acid; it is quickly decomposed by hot water and by carbonates. It dissolves in ammonia and in an alcoholic solution of hydroxylamine yielding beautiful, blue solutions, from which a dark-blue, amorphous substance is precipitated either immediately or on the addition of an acid; when warmed with stannous chloride

and hydrochloric acid, it is decomposed, with liberation of carbonic anhydride and ammonia; it crystallises unchanged from concentrated nitric acid, but on oxidation with chromic acid it yields a lactone of the composition $C_9H_6ClNO_4$ (see later). When the acid is heated at 105—110°, it loses 1 mol. H_2O; the anhydride obtained in this way takes up water very readily, and is reconverted into the acid on recrystallisation even from dry solvents. An *acetyl* derivative, $C_{10}H_8Cl_2NO_5Ac$, is formed when the acid is heated at 100° with acetic chloride; it crystallises from benzene in transparent, quadratic, efflorescent plates, melts at 154°, and is insoluble in alkalis; it is decomposed by warm dilute soda, yielding a dirty, flocculent substance. The *methyl* salt, $C_{11}H_9Cl_2NO_5$, prepared by treating the acid with methyl alcohol and sulphuric acid, crystallises from a mixture of benzene and light petroleum in colourless needles, melts at 139°, and is soluble in ether, benzene, and soda, but insoluble in sodium carbonate; its *acetyl* derivative, $C_{11}H_8Cl_2NO_5Ac$, crystallises from methyl alcohol in transparent plates, and melts at 130—131°.

A *lactone* of the composition $C_{10}H_6ClNO_5$ is formed when the ketonic acid is treated with 10 per cent. sodium carbonate solution; it crystallises from hot benzene in slender, colourless needles, melts at 139°, and is only sparingly soluble in ether, but moderately easily in alcohol and glacial acetic acid; it frequently decomposes on keeping, especially when impure, with evolution of ruddy fumes, and it is readily oxidised to phthalic acid on treatment with nitric acid. Chromic acid converts it into a lactone of the composition $C_9H_6ClNO_4$ (see below) with liberation of carbonic anhydride, but acetic chloride is without action; its behaviour with stannous chloride, ammonia, and hydroxylamine is the same as that of the ketonic acid. It is not acted on by chlorine in glacial acetic acid solution, but on treatment with calcium hypochlorite it is converted into dichloronitromethylphthalide; its constitution is probably represented by the formula

$$CO<\begin{matrix}CO\cdot O\\ C_6H_4\end{matrix}>CH\cdot CCl{:}NO\cdot OH.$$

When the lactone just described is dissolved in water and the acid solution extracted with ether, a syrupy hydroxy-acid is obtained; this is not reconverted into the lactone on warming, and forms no well-characterised salts; its *acetyl* derivative is insoluble in water, but soluble in alkaline carbonates, a fact which indicates the presence of two hydroxyl groups in the molecule of the acid. The *dimethyl* derivative, $C_{12}H_{12}ClNO_6$, prepared by treating the hydroxy-acid with methyl alcohol and sulphuric acid, separates from methyl alcohol in lustrous, well-defined crystals, melts at 125—131°, and is insoluble in sodium carbonate. The constitution of the hydroxy-acid could not be determined, but it is evidently not expresesd by the formula $NO_2\cdot CHCl\cdot CH(OH)\cdot C_6H_4\cdot CO\cdot COOH$.

The *lactone* of orthochloronitrohydroxyethylbenzoic acid,

$$\begin{matrix}CO\cdot O\\ |\\ C_6H_4\end{matrix}>CH\cdot CCl{:}NO\cdot OH,$$

is formed when the ketonic acid described above is dissolved in sodium

carbonate, the solution acidified with glacial acetic acid, and then warmed with excess of chromic acid; it crystallises in colourless needles or plates, melts at 127° with previous softening, and is readily soluble in alcohol, glacial acetic acid, and benzene, but more sparingly in ether and light petroleum; it dissolves in sodium carbonate and in soda, but is reprecipitated on the addition of an acid. It is decomposed by stannous chloride with liberation of ammonia, but it is not acted on by aniline and hydroxylamine.

Orthochloronitromethoxyethylbenzoic acid,

$$OH{\cdot}NO{:}CCl{\cdot}CH(OMe){\cdot}C_6H_4{\cdot}COOH,$$

is formed when the preceding compound is treated with ice-cold methyl alcoholic potash, and the solution then poured into excess of cold hydrochloric acid. It crystallises from benzene in lustrous, quadratic plates, melts at 171° with decomposition, and dissolves freely in alcohol, glacial acetic acid, ether, and sodium carbonate. The *methyl* salt $C_{11}H_{12}ClNO_5$ crystallises from methyl alcohol in lustrous, colourless needles melting at 111°. When the methoxy-acid is treated with chlorine in sodium carbonate solution, it is converted into a compound of the constitution

$$NO_2{\cdot}CCl_2{\cdot}CH(OMe){\cdot}C_6H_4{\cdot}COOH;$$

this substance crystallises from benzene in lustrous prisms, and melts at 189°.

Nitromethylenephthalyl, $\begin{matrix}CO{\cdot}O\\ |\\ C_6H_4-\end{matrix}\!>\!C{:}CH{\cdot}NO_2$, is obtained by oxidising the bye-product formed in the preparation of chloronitrethylbenzoylcarboxylic acid. The mother liquors from the crystalline acid (see above) are diluted with acetic acid, the mixture warmed with sodium acetate, then strongly acidified with hydrochloric acid, and the heating continued until only a slight turbidity is produced on the addition of water; the dilute solution is then filtered from resinous products, boiled with excess of chromic acid, and the precipitate repeatedly treated with hot alcohol, which extracts the lactone of orthochloronitrohydroxyethylbenzoic acid. The nitromethylenephthalyl remains undissolved and is purified by recrystallisation from hot glacial acetic acid, from which it separates in yellowish needles or plates melting at 194°. It is only sparingly soluble in alcohol, ether, and benzene, is decomposed by hot soda, and is not acted on by chlorine in glacial acetic acid solution; on treatment with stannous chloride, it is decomposed with liberation of ammonia.

When nitromethylenephthalyl is dissolved in ice-cold methyl alcoholic potash, and the solution acidified with cold, dilute hydrochloric acid, a compound of the composition $C_{10}H_{10}O_4$ is obtained; this substance crystallises from a mixture of benzene and light petroleum in long, dirty-white needles, melts at 147°, and is probably *methoxyacetophenonecarboxylic acid*, $OMe{\cdot}CH_2{\cdot}CO{\cdot}C_6H_4{\cdot}COOH$.

Dichloronitromethylphthalide, $\begin{matrix}CO{\cdot}O\\ |\\ C_6H_4-\end{matrix}\!>\!CH{\cdot}CCl_2{\cdot}NO_2$, the lactone of orthodichloronitrohydroxyethylbenzoic acid, is formed, with evolution

of carbonic anhydride, when a glacial acetic acid solution of nitro-β-naphthaquinone, which has been saturated with chlorine, is poured into a large volume of cold water; it can also be prepared by treating either the lactone melting at 139°, or the lactone melting at 127°, already described, with a concentrated solution of calcium hypochlorite. It crystallises in colourless, lustrous needles, melts at 94°, and is readily soluble in alcohol, glacial acetic acid, benzene, and chloroform, but more sparingly in light petroleum; it is very stable and is not acted on by aniline, hydroxylamine, acetic chloride, or concentrated nitric acid, but when warmed with stannous chloride it is decomposed with liberation of ammonia; it is quickly decomposed by warm concentrated sulphuric acid, yielding phthalic acid. When heated with potassium acetate in alcoholic solution, it is converted into dichloromethylenephthalyl (m. p. 129°), identical with the compound previously described by Zincke and Cooksey (Abstr., 1890, 786). F. S. K.

Action of Chlorine on Nitro-β-naphthaquinone in Chloroform Solution. By T. Zincke and O. Scharfenberg (*Annalen*, **268**, 297—305).—*Dichloronitro-αβ-diketohydronaphthalene hydrate*,

$$C_6H_4<\begin{matrix}CO\cdot CO\\ CHCl-\end{matrix}>CCl\cdot NO_2 + H_2O,$$

is obtained as sole product when nitro-β-naphthaquinone is treated with chlorine in chloroform solution in absence of water. It crystallises from a mixture of benzene and light petroleum in almost colourless needles, melts at 115—116° with decomposition, and dissolves freely in benzene, chloroform, and ether, but is only sparingly soluble in light petroleum. It does not lose its water over sulphuric acid under reduced pressure, but when heated at 100—105° it is partially converted into dichloronitrethylbenzoylcarboxylic acid (see preceding abstract); this acid is also formed when the hydrate is dissolved in glacial acetic acid, anhydrous ether, or benzene. It dissolves in sodium carbonate, and, on acidifying the solution, the lactone (m. p. 139°) already described is precipitated. When treated with methyl alcohol, it is converted into the methyl salt of dichloronitrethylbenzoylcarboxylic acid, and when heated for a short time with acetic chloride at 100° it is transformed into dichloro-β-naphthaquinone (m. p. 183°); with stannous chloride in glacial acetic acid solution, it yields nitro-β-naphthaquinone.

When finely-divided nitro-β-naphthaquinone is treated with a concentrated solution of calcium hypochlorite, it is quickly converted into dichloronitromethylphthalide. F. S. K.

Nitration of β-Naphthylamine. By P. Friedländer and S. Szymanski (*Ber.*, **25**, 2076—2083).—The authors have obtained the 2 : 4′- and 2 : 1′-nitronaphthylamines by treating β-naphthylamine nitrate with concentrated sulphuric acid.

β-Naphthylamine nitrate, dried at 100° and in a fine state of division, is gradually added to 10 times the quantity of well-cooled, concentrated sulphuric acid. The temperature is kept below 5° by

means of a freezing mixture. When the nitrate is dissolved, the mixture is poured into 6—8 times the quantity of water, and the hot solution separated from the resin which is formed. On cooling, the sulphates of the nitro-compounds separate as a brownish-yellow, crystalline mass. The nitro-bases are obtained from the sulphates by treatment with ammonia, and are fractionally crystallised from benzene or alcohol. The less soluble 2 : 4′-nitro-β-naphthylamine is thus easily obtained pure. The 2 : 1′-compound is obtained by acetylating the mixed bases with acetic anhydride, crystallising the acetyl compound from alcohol, with the addition of animal charcoal, until it melts at 195·5°, hydrolysing with dilute sulphuric acid (1 : 1), and finally treating the sulphate with ammonia.

2 : 4′-*Nitro-β-naphthylamine* crystallises in beautiful, red, lustrous needles, melts at 143·5°, and is easily soluble in hot alcohol, benzene, and acetic acid, more sparingly in hot water, and insoluble in cold water and light petroleum. The *hydrochloride* is easily soluble in hot water, and crystallises in colourless needles. The *sulphate* is sparingly soluble, and crystallises in yellowish-white leaflets. Both salts partially decompose when warmed with a large quantity of water or alcohol. The *acetyl compound* crystallises from alcohol in thick, yellowish-brown rhombs, and from benzene in yellow, radiating needles, melts at 185·5°, and is easily soluble in alcohol and acetic acid, sparingly so in benzene. The *benzoyl compound* crystallises in needles, and melts at 181·5°.

2 : 4′-*Nitro-β-naphthol* is obtained by diazotising the preceding amido-compound and heating the dilute solution of the diazo-compound, acidified with sulphuric acid, with the addition of a small quantity of carbamide as long as nitrogen is evolved. It crystallises from water in bright, yellow needles, melts at 147°, and is sparingly soluble in cold water, easily so in hot water, in the other usual solvents, and in alkalis. The salts are easily soluble in water, with a bright, yellowish-red coloration. The *ethyl salt*, obtained by boiling an alcoholic solution of the potassium salt with ethyl iodide, crystallises from alcohol in yellow needles, and melts at 115°.

2 : 4′-*Amido-β-naphthol* was not obtained pure on account of the ease with which it oxidises on exposure to air. By cautiously reducing the nitronaphthol with excess of stannous chloride, the stannochloride of the amidonaphthol is obtained in white needles which are completely converted into the hydrochloride when crystallised from concentrated hydrochloric acid. The amidonaphthol is obtained by decomposing the hydrochloride with sodium hydrogen carbonate. It forms a white, crystalline mass, and is easily soluble in the ordinary solvents, alkalis, and acids. The aqueous and alcoholic solutions have a beautiful, violet-blue fluorescence.

2 : 4′-*Naphthylenediamine* is obtained by reducing the above nitro-β-naphthylamine with iron filings and acetic acid. The product is boiled out with water, converted into sulphate, and the sulphate purified by crystallisation from water. The free base is obtained by decomposing the sulphate with sodium hydroxide. It crystallises in short, white needles, melts at 77·5°, is easily soluble in hot water, alcohol, benzene, and acetic acid, less so in cold water and ether, and

darkens on exposure to air. The aqueous solution has a strong, blue fluorescence, and gives a violet-brown coloration with ferric chloride or calcium chloride. The *hydrochloride* is easily soluble in water, sparingly so in hydrochloric acid. The *sulphate* forms sparingly soluble, white needles which turn violet on exposure to the air. The *diacetyl compound* crystallises in colourless needles, melts at 257°, and is sparingly soluble in alcohol. When the diamine is treated with the calculated quantity of nitrite in strongly acid solution, it is easily converted into a tetrazo-compound which yields brownish-violet dyes with naphtholsulphonic acids. These dyes, however, have scarcely any affinity for unmordanted cotton.

2 : 4′-Dichloronaphthalene is obtained from the preceding diamine by converting it into the tetrazo-compound and decomposing the latter with copper-dust and hydrochloric acid. It melts at 48°, and has all the properties assigned to it by Erdmann and Kirchhoff.

2 : 1′-*Nitro-β-naphthylamine* crystallises in beautiful, red, lustrous needles, melts at 103·5°, is easily soluble in most solvents, sparingly so in hot water, and insoluble in light petroleum. The *sulphate* and *hydrochloride* are somewhat less soluble than the salts of the 2 : 4′-compound, and are partially decomposed when heated with water or alcohol. The *acetyl compound* crystallises in long, yellow needles, melts at 195·5°, and is sparingly soluble in benzene and alcohol, more easily so in acetic acid. The *benzoyl compound* crystallises from alcohol in greenish-yellow needles, and melts at 162°.

2 : 1′-*Nitro-β-naphthol* crystallises from dilute alcohol in long, deep-yellow needles, melts at 142°, and is easily soluble in most solvents, sparingly so in water. It yields salts with the alkalis and alkaline earths which dissolve with a deep, dark-red coloration.

2 : 1′-*Amido-β-naphthol* crystallises from ether in small, white needles which darken on exposure to air, blackens at 180°, decomposes at 212—218° without melting, and is easily soluble in alkalis, acids, water, alcohol, and ether.

2 : 1′-*Naphthylenediamine* crystallises from benzene in white leaflets, from water in feathery needles, melts at 117·5°, darkens on exposure to air, and is easily soluble in acetic acid, alcohol, and benzene, less so in water, and very sparingly so in ether and light petroleum. With ferric chloride, the aqueous solution gives a beautiful violet coloration. The *sulphate* and *hydrochloride* are easily soluble in water. The *diacetyl derivative* crystallises from alcohol in small rhombohedra, and melts at 213°. The 2 : 1′-diamine yields brownish-violet disazo-dyes similar to those from the 2 : 4′-compound. The 2 : 1′-dichloronaphthalene obtained from it melts at 61°.

E. C. R.

Natural Synthesis of the Vegetable Hydrocarbons. By Maquenne (*Compt. rend.*, **114**, 677—680).—Whilst it is easy to trace the connection between the carbohydrates, the fatty acids, and the paraffins, and to form some idea of the mode in which substances of these groups are formed in nature, there has been hitherto no direct connection established between the carbohydrates and the benzene family, much less with the terpenes and resins which are so abundant

in the vegetable kingdom. Now, however, it is shown that the heptine, C_7H_{12}, obtained by reducing perseïtol with boiling hydriodic acid, and therefore a product of direct synthesis, is not only identical with the heptine extracted by Renard from resin oil, but has the characteristic properties of the terpenes, and may, in fact, be regarded as a lower member of that, or perhaps of the menthene, family.

Heptine is very oxidisable, resinifies in air, forms a crystalline hydrate with water, $C_7H_{14}O_2$, homologous with terpene hydrate, $C_{10}H_{20}O_2$, unites directly with bromine and hydrogen chloride and iodide to form compounds, $C_7H_{12}Br_2$, $C_7H_{13}Cl$, $C_7H_{13}I$, and forms a nitrosochloride, $C_7H_{12}NOCl$. Hence there is little doubt as to its nature. Further confirmation is given by the fact that the differences between the observed and calculated molecular refractions for wave lengths $H\alpha$ and ∞ are 2·15 and 1·97, numbers which agree closely with 1·78 and 1·60, those found by Brühl and Landolt to hold for single ethylene linkings. Hence heptine is built on a cycloïd nucleus, probably intermediate between benzene and hexamethylene. It is especially interesting as the first example of a complete synthesis effected in the terpene group, other than by polymerisation of a simpler hydrocarbon, and seeing that the synthesis has been effected directly from a natural carbohydrate, it opens up a suggestive field of speculation around the processes occurring in nature.

Heptine nitrosochloride, $C_7H_{12}NOCl$, is formed by adding solid sodium nitrite gradually to a cooled mixture of heptine and hydrochloric acid. The supernatant layer turns green, crystallises, is removed, cautiously drained and washed at the pump, and finally dried in a vacuum. The nitrosochloride thus prepared consists of a mass of pale-blue, microscopic needles, and has a strong odour of camphor; it melts about 92° with partial volatilisation and decomposition. It is very unstable, and can be kept only for a few hours; even in a vacuum it soon resinifies. JN. W.

Terpin Hydrate from Eucalyptus Oil. By E. MERCK (*Arch. Pharm.*, **230**, 169—173).—The terpin hydrate, produced by mixing turpentine oil with nitric acid and alcohol and setting it aside for some time (Wallach, Abstr., 1886, 70), is also produced when eucalyptus oil is similarly treated. The author has not yet succeeded in discovering which constituent of the oil yields the terpin hydrate; both *Ol. eucalypt. globuli* and *Ol. eucalypt. Australe* give the reaction, but there is little or no evidence that any sample of eucalyptus oil, as supplied by the trade, is from only one source. A. G. B.

Oil of Lavender and of Bergamot. By J. BERTRAM and H. WALBAUM (*J. pr. Chem.* [2] **45**, 590—603).—French lavender oil consists for the most part of an alcohol, $C_{10}H_{18}O$, and ethereal salts, chiefly the acetate, derived therefrom. In its reactions and physical properties this alcohol is identical with linalol obtained by Semmler from linaloes (Abstr., 1891, 540); it absorbs 4 atoms of bromine, yields the chloride, $C_{10}H_{18}Cl_2$, with hydrogen chloride, and is oxidised to citral (geranaldehyde, *loc. cit.*) by chromic acid mixture. De-

hydrating agents eliminate from the alcohol, hydrocarbons of the formula $C_{10}H_{16}$, among which terpinene and dipentene are to be recognised.

Bergamot oil also contains the acetate derived from linalol, and owes its odour to this. A. G. B.

Essential Oil of Licari Kanali. By P. Barbier (*Compt. rend.*, **114**, 674—675).—The essential oil of *Licari kanali* was found by Morin to contain a substance, $C_{10}H_{18}O$, which the present author terms *licareol*. It is a colourless, somewhat oily liquid, which boils at 199—200°, and has a sp. gr. of 0·8819 at 0°, and 0·8662 at 15·4°. Its rotatory power at 15·4° is $[\alpha]_D = -18° 21'$, and its refractive indices at the same temperature are 1·4635 for the red, and 1·4775 for the blue rays. It reacts with dry hydrogen chloride to form a liquid *dichloro-derivative*, $C_{10}H_{18}Cl_2$, which boils at 155—157° under a pressure of 39 mm., and has a sp. gr. of 1·0447 at 0°, and 1·0246 at 19·5°, and refractive indices 1·4789 for the red, and 1·4926 for the blue rays at 17·2°. When the dichloro-compound is boiled with a solution of potassium acetate in glacial acetic acid, it loses its chlorine, and is converted into an *acetate*, $C_{10}H_{17}OAc$, which is also formed when licareol is heated with acetic anhydride in a sealed tube for eight hours at 140°, and is a colourless liquid of agreeable odour, boiling at 241—242°, and having a density of 0·9298 at 0°. It is not the acetate of licareol, since the difference between its boiling point and that of the parent substance is much greater than the normal, and when, moreover, it is hydrolysed, it yields an isomeric alcohol boiling at 226—227°.

Along with the acetate there are also formed an ether, $(C_{10}H_{17})_2O$, which is a viscous, colourless liquid, boiling with partial decomposition at 320°, and a liquid hydrocarbon, $C_{10}H_{16}$, which boils at 176—178°.

The methyl and ethyl derivatives of licareol, *methyl licaryl ether*, $C_{10}H_{17}\cdot OMe$, and *ethyl licaryl ether*, are liquids boiling at 189—192°, and at about 210°.

Licareol is energetically attacked by chromic acid mixture, and among the products of oxidation a ketone, *licareone*, $C_{10}H_{16}O$, occurs as a liquid of penetrating odour, boiling at 188—190°, and having a density of 0·8913 at 0°. It does not combine with sodium bisulphite, but it reduces alcoholic ammoniacal silver nitrate, and combines with hydroxylamine to form a liquid oxime. It therefore contains two secondary alcohol groups and an ethylene bond. Jn. W.

Studies in the Camphor and Fenchone Series. By O. Wallach (*Annalen*, **269**, 326—347; compare Abstr., 1891, 218 and 1086).—The compound (fenchonitrile) of the composition $C_{10}H_{15}N$, obtained by treating the oxime of fenchone (fenchole) with dilute sulphuric acid, behaves just like an unsaturated compound, and combines directly with the halogen acids to form rather unstable, crystalline, additive products. The *bromo*-compound, $C_9H_{16}Br\cdot CN$, melts at 60°; the *iodo*-compound, $C_9H_{16}I\cdot CN$, at 54—55°; and the *chloro*-compound, $C_9H_{16}Cl\cdot CN$, at 57—58°; the last-named compound is, in the

dry state, the most stable of the three, but is readily decomposed when boiled with alcohol or water.

Camphonitrile, $C_{10}H_{15}N$, boils at 226—227°, and has a sp. gr. of 0·910 at 20°. Its refractive power is $n_{(D)} = 1·46648$ at 20°, from which M = 45·39; this number agrees with the value calculated on the assumption that the nitrile contains a single double-linking. Camphonitrile behaves chemically like an unsaturated compound, and combines directly with halogen acids, but the products do not crystallise.

β-Isofenchonoxime, $C_{10}H_{17}NO$, is obtained when the α-isofenchonoxime (m. p. 113—114°) previously described (*loc. cit.*) is boiled for a few hours with dilute sulphuric acid, and the cold solution then neutralised with an alkali. It crystallises well from alcohol and hot water, melts at 137°, distils unchanged, and is much more readily soluble in hot water than the α-oxime; it has a pronounced basic character, forms with hydrogen chloride in ethereal solution a colourless, unstable hydrochloride, and, like the α-oxime, is only very slowly acted on by boiling alcoholic potash. When warmed with phosphorus pentoxide, it seems to be converted into fenchonitrile, and on oxidation with potassium permanganate, it yields, like fenchone, dimethylmalonic acid.

Fencholenic acid, $C_{10}H_{16}O_2$ (*loc. cit.*), boils at 260—261°, and has a sp. gr. of 1·0045 at 16°; its refractive power is $n_{(D)} = 1·4768$, from which M = 47·24, the calculated value being M = 47·34. The *ammonium* salt, prepared by passing anhydrous ammonia into an ethereal solution of the acid, is a colourless, very hygroscopic powder. The *silver* salt, $C_{10}H_{15}O_2Ag$, is a colourless, comparatively stable powder, sparingly soluble in water and alcohol. The acid is unsaturated, and combines with concentrated hydriodic acid to form a crystalline additive compound. The corresponding *chloro*-compound, $C_{10}H_{17}ClO_2$, prepared by shaking fencholenic acid with concentrated hydrochloric acid, is more stable than the iodo-additive product, and separates from light petroleum in small crystals which melt at 97—98°; it is readily decomposed by alkalis. When fencholenic acid is distilled with soda-lime, it yields an oil, which consists of a mixture of hydrocarbons and compounds containing oxygen.

Campholenic acid boils at 258—261°, and its sp. gr. is 0·9920 at 19°; its refractive power is $n_{(D)} = 1·47125$, from which M = 57·36; its electrical conductivity is K = 0·00170, that of fencholenic acid being K = 0·00100. Campholenic acid is unsaturated, and combines with bromine in alcoholic or glacial acetic acid solution, yielding a crystalline substance, which is insoluble in alkalis.

An *acid* of the composition $C_{10}H_{18}O_4$ is formed when campholenic acid is oxidised with potassium permanganate in alkaline solution; it separates from hot water in transparent crystals, melts at 144—145°, and distils without appreciable decomposition; its electrical conductivity is K = 0·00250. The *silver* salt, $C_{10}H_{17}O_4Ag$, is amorphous, and moderately easily soluble in water.

A saturated *hydrocarbon*, which has probably the molecular formula C_9H_{18}, is produced when fencholenic acid is heated with concentrated hydriodic acid and amorphous phosphorus at 180—200°; it boils at

141—142°; its sp. gr. is 0·7900 at 20°, and its refractive power $n_{(D)} = 1·43146$. The same hydrocarbon appears to be obtained when fenchonitrile is reduced in like manner.

When campholenic acid is heated with concentrated hydriodic acid and amorphous phosphorus, it is converted into a saturated *hydrocarbon*, which boils at 134—136°, and seems to have the molecular formula C_9H_{18}; the sp. gr. of this hydrocarbon is 0·773 at 20°, and its refractive power $n_{(D)} = 1·42491$.

These experiments show that in both campholenic acid and fencholenic acid there is a closed carbon chain, and only one double linking; this is also true as regards camphonitrile and fenchonitrile.

F. S. K.

Comparison of Bornylamine and Fenchylamine. By O. Wallach and J. Griepenkerl (*Annalen*, **269**, 347—369).—*Bornylamine tartrate*, $C_{10}H_{17}·NH_2,C_4H_6O_6 + H_2O$, crystallises from hot alcohol in needles, and is readily soluble in water. The *picrate*, $C_{10}H_{17}·NH_2,C_6H_3N_3O_7$, crystallises in yellow needles, and is readily soluble in alcohol, but almost insoluble in ether. The hydrochloride sublimes at a high temperature without decomposition.

When bornylamine, or its formyl derivative, is heated with acetic anhydride at 200—210°, it is converted into camphene; when formylbornylamine is boiled with an aqueous solution of chromic acid, it yields bornylamine and a very volatile crystalline compound, which melts at 159°, and contains oxygen.

Dibornylthiocarbamide, $CS(NH·C_{10}H_{17})_2$, is formed when bornylamine is boiled with carbon bisulphide and alcohol; it separates from alcohol in transparent crystals, and melts at 223—224°.

Benzylbornylamine, $C_{10}H_{17}·NH·CH_2Ph$, is a thick oil, boiling at 184° under a pressure of 14 mm.; its *hydrochloride*, $C_{17}H_{25}N,HCl$, separates from water and alcohol in colourless crystals; its *platinochloride*, $(C_{17}H_{25}N)_2,H_2PtCl_6$, crystallises in transparent, red prisms, and is almost insoluble in water; its *methiodide*, $C_{17}H_{25}N,MeI$, crystallises from hot alcohol in needles.

Benzylidenebornylamine, $C_{10}H_{17}N{:}CHPh$, is a colourless oil, but its *hydrochloride*, $C_{17}H_{23}N,HCl$, crystallises in small needles.

Dibornylamine, $C_{20}H_{35}N$, a compound which was first isolated by Leuckart (Abstr., 1887, 376), from the product of the action between camphor and ammonium formate, crystallises from alcohol in lustrous plates, melts at 43—44°, and boils at 180—181° under a pressure of 12 mm.; molecular weight determinations by the boiling point method gave results agreeing with those required by a compound of the molecular formula given above. Although dibornylamine has a neutral reaction towards litmus, it combines with hydrogen chloride in ethereal solution to form the *hydrochloride*, $C_{20}H_{35}N,HCl$; this compound crystallises in needles or plates, melts at 260° with partial decomposition, and is readily soluble in hot, but only sparingly in cold, water; the *platinochloride*, $(C_{20}H_{35}N)_2,H_2PtCl_6$, crystallises from alcohol in red needles. The *nitrite*, $C_{20}H_{35}N,HNO_2$, crystallises unchanged from boiling alcohol, and is only moderately easily soluble in water. The *nitrate* is very sparingly soluble in water.

When dibornylamine is treated with bromine in light petroleum solution, a *salt* of the composition $C_{20}H_{35}Br_2N,HBr$ is precipitated; it crystallises from alcohol in golden plates, melts at 184°, and is reconverted into dibornylamine on treatment with sulphurous acid and an alkali. Dibornylamine seems not to give an acetyl or a benzoyl derivative; on prolonged heating with acetic anhydride at 100—130°, it is transformed into a crystalline substance which melts at 59°, and seems to be an isomeride.

Fenchylamine hydriodide, $C_{10}H_{17}\cdot NH_2,HI$, crystallises well, and is moderately easily soluble in water and dilute alcohol; both the hydrochloride (Abstr., 1891, 1086) and the *picrate* are readily soluble in ether. The *tartrate* is very sparingly soluble in alcohol. The *nitrite*, $C_{10}H_{17}\cdot NH_2,HNO_2$, crystallises in lustrous needles, is very readily soluble in water, and decomposes at 100—115°.

Fenchylcarbamide, $NH_2\cdot CO\cdot NH\cdot C_{10}H_{17}$, crystallises from water and dilute alcohol in small needles, and melts at 170—171°.

Fenchylphenylthiocarbamide, $NHPh\cdot CS\cdot NH\cdot C_{10}H_{17}$, is formed when fenchylamine is treated with phenylthiocarbimide in ethereal solution; it separates from alcohol in colourless, well-defined crystals, and melts at 153—154°.

Difenchylthiocarbamide, $CS(NH\cdot C_{10}H_{17})_2$, crystallises in colourless plates, and melts at 210°.

Acetylfenchylamine, $C_{10}H_{17}\cdot NHAc$, melts at 98°, not at 92·5° as previously stated (*loc. cit.*); the benzoyl derivative, $C_{10}H_{17}\cdot NHBz$, melts at 133—135°, not at 89·5°.

Benzylfenchylamine, $C_{10}H_{17}\cdot NH\cdot CH_2Ph$, is a thick oil of sp. gr. 0·9735 at 20°, and boils at 190—191° under a pressure of 16 mm. The *hydrochloride*, $C_{17}H_{25}N,HCl$, separates from water in well-defined crystals. The *platinochloride*, $(C_{17}H_{25}N)_2,H_2PtCl_6$, separates from alcoholic hydrochloric acid in ruby-red crystals. The nitroso-derivative, $C_{10}H_{17}N(NO)\cdot CH_2Ph$, crystallises from alcohol and ether in prisms, and melts at 93°.

Benzylidenefenchylamine, $C_{10}H_{17}N{:}CHPh$, crystallises from methyl alcohol in needles, and melts at 42°. The *hydrochloride*, $C_{17}H_{23}N,HCl$, is very hygroscopic and unstable. The *platinochloride*,

$$(C_{17}H_{23}N)_2,H_2PtCl_6,$$

crystallises in yellowish-red needles, and is very unstable.

Hydroxybenzylidenefenchylamine, $C_{10}H_{17}N{:}CH\cdot C_6H_4\cdot OH$, prepared by heating fenchylamine with salicylaldehyde, crystallises in yellow needles, melts at 95°, and is readily decomposed by acids and alkalis.

When fenchylamine is treated with chloral, it is converted into formylfenchylamine (*loc. cit.*); with ethyl acetoacetate, it gives a condensation product which has the composition $C_{16}H_{27}NO_2$.

Difenchyloxamide, $C_{22}H_{36}N_2O_2$, crystallises from alcohol in long prisms or quadratic plates melting at 188°.

Fenchylamine fenchylcarbamate, $C_{10}H_{17}\cdot NH_2,C_{10}H_{17}\cdot NH\cdot COOH$, is formed when carbonic anhydride is passed into an alcoholic solution of fenchylamine; it separates from alcohol in crystals, and is almost insoluble in water.

Methylfenchylamine, $C_{10}H_{17}\cdot NHMe$, is an oil of sp. gr. 0·8950 at

20·5°; it boils at 201—202°, has a refractive power $n_{(D)} = 1·46988$ at 20·5°, and is only sparingly soluble in water. The *hydriodide*, $C_{11}H_{21}N,HI$, is only very sparingly soluble in water. The *hydrochloride*, $C_{11}H_{21}N,HCl$, forms prismatic crystals, and is insoluble in ether. The *platinochloride*, $(C_{11}H_{21}N)_2,H_2PtCl_6$, is crystalline. The *nitroso*-derivative, $C_{10}H_{17}·NMe·NO$, is a crystalline compound melting at 52—53°. F. S. K.

Fencholenamine. By O. Wallach and L. Jenckel (*Annalen*, **269**, 369—376; compare Abstr., 1891, 1086).—*Fencholenamine*, $C_{10}H_{17}·NH_2$, is obtained, together with compounds of higher boiling point, when fenchonitrile is reduced with sodium and alcohol; it is a mobile oil, and boils at 205°. The *nitrate*, $C_{10}H_{17}·NH_2,HNO_3$, separates from water in crystals. The *sulphate*, $(C_{10}H_{17}·NH_2)_2,H_2SO_4$, crystallises in colourless plates, and is sparingly soluble in water. A compound of the composition $C_{10}H_{21}Cl_2N$ is precipitated in crystals when hydrogen chloride is passed into a methyl-alcoholic solution of fencholenamine; when treated with alkalis, it loses nearly the whole of its chlorine. The *benzoyl* derivative, $C_{10}H_{17}·NHBz$, separates from alcohol in crystals, and melts at 88—89°. The *acetyl* derivative, $C_{10}H_{17}·NHAc$, is an oil, and boils at 180° under a pressure of 21 mm. When fencholenamine is treated with sodium nitrite and dilute sulphuric acid, it yields, as principal product, an oil of the composition $C_{10}H_{18}O$, which is probably fencholen alcohol; this compound boils at 96° under a pressure of 17 mm., has a sp. gr. of 0·8980 at 20°, and a refractive power $n_{(D)} = 1·4739$ at the same temperature; it has a strong odour of terpineol, and seems to be only slowly oxidised by chromic acid. F. S. K.

Camphene and Camphoric Acid. By J. W. Brühl (*Ber.*, **25**, 2087—2095).—This paper is of a purely controversial nature, being an answer to Wallach (this vol., p. 868). The author maintains the accuracy of the value observed by him for the melting point of borneocamphene (this vol., p. 624) against that given by Wallach, and he is of opinion that the difference in the value is due to the greater purity of his own preparation. Wallach (*loc. cit.*) has reassured himself as to the efficiency of his method of preparing the camphene by heating bornyl chloride with aniline; the author complains, however, that information as to the yield obtained is wanting. It is shown by the aid of formulæ that Wallach's objection to the tetramethylene formula for camphoric acid, on the ground that it is difficult to explain the formation of hydrogenised metaxylenes from the latter, is unfounded. A. R. L.

Absinthin from Artemisia absinthum. By O. Senger (*Arch. Pharm.*, **230**, 94—108).—Pure absinthin is best prepared by shaking the ethereal extract of the plant with water, and treating the aqueous solution with freshly-precipitated aluminium hydroxide; the solution may then be directly evaporated in a vacuum or shaken with ether, and the ethereal solution subsequently distilled. Absinthin, $C_{15}H_{20}O_4$, is pale yellow and amorphous; it has an intensely bitter

taste, melts at 65°, and dissolves in water, alcohol, and ether. It is a glucoside, being decomposed by hydrolysis into dextrose, a liquid substance, and a resinous compound, $C_{21}H_{26}O_6$, which belongs to the aromatic series, and behaves like a hydroxy-acid. Phloroglucinol is one of the products of the decomposition of absinthin by alkalis, and formic, acetic, and propionic acids occur among the products of its oxidation by potassium dichromate and sulphuric acid. With concentrated nitric acid, it yields oxalic and picric acids. A. G. B.

Anemonin. By H. Beckurts (*Arch. Pharm.*, **230**, 182—206).—Several species of *Anemone* and *Ranunculus* owe their acrid taste to the presence of anemone-camphor (Abstr., 1886, 365); this readily decomposes, even during the drying of the plant, into anemonin and isoanemonic acid. There are also obtained from the plant anemonic acid and anemoninic acid.

Anemonin, $C_{10}H_8O_4$, melts at 152°; its new formula (compare *loc. cit.*) was determined by the cryoscopic method. It would appear to be the anhydride of anemonic acid, into the lead salt of which it is easily converted by treatment with lead oxide. By dilute acids and by alkalis, it is converted into anemoninic acid and its salts. It would appear to contain both an aldehyde and a ketone group, for it yields the characteristic reactions with phenylhydrazine, hydroxylamine, sodium hydrogen sulphite, and sodium nitroprusside; a hydroxyl or oxalyl group could not be recognised. The *amide*, $C_{10}H_{15}N_3O_3$, a yellow, microcrystalline powder, which melts at 68—69°, and is soluble in alcohol and water, is formed when anemonin is heated with alcoholic ammonia. When anemonin is heated with acetic anhydride, it becomes *isoanemonin*, a yellowish-white powder insoluble in the usual solvents. When acted on by bromine in chloroform, anemonin yields the tetrabromide, $C_{10}H_8Br_4O_4$; this is a white, crystalline powder which begins to melt at 180°, and melts with decomposition at 205°.

Anemonic acid, $C_{10}H_{10}O_5$, crystallises in hard, white needles, and melts at 210°; it has an acid reaction, is bibasic, and forms colourless salts, of which the *lead salt* was prepared. It contains an aldehyde or ketone group. *Isoanemonic acid* is produced during the isolation of anemonic acid; it is tasteless, inodorous, amorphous, and insoluble in water, alcohol, and ether.

Anemoninic acid, $C_{10}H_{12}O_6$, is a brownish-white powder, easily soluble in water, and acid to test paper. It is bibasic, its constitution being probably $C_7H_8(COOH)_2{\cdot}C(OH)_2$; its *sodium*, *potassium*, *barium*, and *lead* salts were prepared, and found to be amorphous. It reduces Fehling's solution and silver solution, and forms an amorphous *phenylhydrazide*. A. G. B.

Digitalonic Acid. By H. Kiliani (*Ber.*, **25**, 2116—2118).—The author has recently shown (*Arch. Pharm.*, **230**, 250) that when the sugars which are obtained from pure digitalin are oxidised by means of bromine, *d*-gluconic acid and digitalonic acid, $C_7H_{14}O_8$, are formed; if, however, the hydrolysis of digitalin be accomplished in two stages, the sugar yielding digitalonic acid is formed in the second stage.

It is more convenient to separate the digitalonic and *d*-gluconic acids by the following method than by that previously given (*loc. cit.*). The solution containing the two acids is evaporated to a thin syrup, mixed with one-third its weight of 93 per cent. alcohol, and shaken four times with ether, when the digitalonic lactone is extracted, and may be purified by recrystallisation from water. It forms short, rhombic crystals, $a : b : c = 0{\cdot}9243 : 1 : 0{\cdot}3662$, does not reduce alkaline copper solution, and has a specific rotatory power $[\alpha]_{D28^\circ} = -79{\cdot}4$. When the lactone is heated with excess of silver oxide at 50° for 14 hours, hydrochloric acid continuously added, and the filtrate distilled, acetic acid passes over; the presence of a methyl group in digitalonic acid is therefore probable. The research is proceeding.

A. R. L.

Origin of the Colouring Matters of the Vine: Ampelochroïc Acids. By A. Gautier (*Compt. rend.*, **114**, 623—629).—The rapidity with which grapes ripen in Mid Europe led the author to suppose that the skin pigment to which the colour is due is formed by the oxidation of aldehydic or catecholic substances, originating in the leaves and travelling thence to the fruit. This view was borne out by the effects following the removal of the leaves from grapes about to ripen, or by the partial or complete stoppage of the circulation between the leaves and stem, the grapes in the first case remaining in a state of arrested development, whilst in the second the leaves changed in colour to red or brown, and not the grapes.

The colouring matter of leaves thus reddened (from plants of the Carignan stock) was extracted with tepid water and purified by fractional precipitation with lead acetate, with which it finally formed an olive-green precipitate; this, on decomposition with hydrogen sulphide and purification, yielded a mixture of two coloured crystalline acids, α- and β-ampelochroïc acids. These were separated by means of cold water, in which the latter alone is soluble.

α-Ampelochroïc acid, $C_{19}H_{16}O_{10}$, is bibasic and forms a cochineal-coloured powder consisting of ruby-red plates or spindles, soluble in boiling water or cold alcohol, but insoluble in ether. Its solutions are feebly acid to litmus. The *zinc* salt is olive-green, and turns indigo-blue on heating; the *acid zinc* salt is rose-coloured and soluble; the *lead* salt is dark green, and blackens at 50°; the *acid lead* salt is wine red. Solutions of α-ampelochroïc acid are turned greenish-brown by alkalis, and oxidise on exposure to the air; they are precipitated by bromine-water; they give a greenish-black precipitate with ferric salts, a dark-brown precipitate with mercuric nitrate, a yellowish-grey precipitate with silver nitrate, especially in presence of ammonia, a rose-coloured precipitate with gelatin solution, and a chestnut-brown precipitate with cinchonine acetate. The acid therefore belongs to the classes of tannins and polyphenolic substances.

β-Ampelochroïc acid, which is stated to have the composition $C_{26}H_{24}O_{15}$, bears a general resemblance to the α-acid. It forms cochineal-coloured crystals, and its aqueous solution is feebly acid to litmus and feebly astringent to the taste. It is precipitated by gelatin and by cinchonine acetate; it gives a violet precipitate with tartar emetic, a dark green precipitate with zinc acetate, a dirty, rose-

coloured precipitate with mercuric nitrate, a yellowish-brown precipitate with copper acetate, and a chestnut-brown precipitate with hot silver nitrate. Potash turns the colour of its solution to yellowish-green, and ferric chloride gives a dark violet coloration, changing to a brown precipitate.

A third acid of the same general character as the others was obtained from the first fraction or blue precipitate formed in their preparation. The precipitate was suspended in water, decomposed with hydrogen sulphide, partially saturated with baryta-water, and the whole evaporated to dryness in a vacuum. The residue was extracted with ether to remove impurities, and the new acid was dissolved out with alcohol.

γ-Ampelochroïc acid, $C_{17}H_{18}O_{10}$, crystallises in reddish-brown octahedra and dissolves readily in water to a red solution, astringent to the taste. With gelatin and tartar emetic, it forms rose-coloured precipitates which dissolve on heating; with mercuric nitrate, it gives a pale, greenish-blue precipitate, a green precipitate with calcium acetate, an olive-green precipitate with basic lead acetate, a dark violet to brown precipitate with ferric salts, and an orange to yellow precipitate with bromine-water. Potash changes the colour of its solutions to olive-green. Jn. W.

Synthesis of Tetrahydropyridine Derivatives and Conversion of the same into Piperidine Derivatives. By A. Lipp (*Ber.*, **25**, 2190—2197).—Δ^2-*Tetrahydropicoline* (Δ^2-*Tetrahydro-2-methylpyridine*), C_6NH_8Me, is obtained by the action of aqueous or alcoholic ammonia on bromobutyl methyl ketone. It is a colourless liquid, boils at 131—132° at 716 mm., has an odour resembling that of piperidine, dissolves easily in water, and turns brown on exposure to the air. The *platinochloride*, $(C_6H_{11}N)_2,H_2PtCl_6$, crystallises in small prisms or rhombic tablets, melts and decomposes at 193—194°, and is somewhat easily soluble in water, very sparingly so in alcohol. The *aurochloride* forms small, fern-like crystals, melts at 144—145°, and is sparingly soluble in water. The *picrate* crystallises in yellow needles or short prisms, and melts at 119—120°. The base also yields a nitroso-compound and a well crystallised thiocarbamate. The base is probably identical with Ladenburg's α-pipecoleïn (*Ber.*, **20**, 1645). When reduced with tin and hydrochloric acid, it yields α-methylpiperidine. The latter agrees in properties with α-methylpiperidine prepared from picoline.

1-*Methyl*-Δ^2-*tetrahydropicoline* or 1 : 2-*dimethyl*-Δ^2-*tetrahydropyridine*, $C_5NH_7Me_2$, is obtained by the action of methylamine on the bromide of acetobutyl alcohol. It is a colourless, strongly refractive liquid, has an odour resembling that of piperidine, boils at 145° under 720 mm. pressure, turns brown when kept, and slowly dissolves in water. The *platinochloride* forms short prismatic crystals, melts at 200—205° with decomposition, and is somewhat easily soluble in water and insoluble in strong alcohol. The *aurochloride* crystallises in aggregates resembling ammonium chloride, melts at 180—182°, and is easily soluble in hot water, sparingly so in cold. The *picrate* crystallises in yellow, lustrous prisms, and is somewhat easily soluble in cold water. The

base combines with methyl iodide to yield the hydriodide of an ammonium base. When reduced with tin and hydrochloric acid, it yields *n*-α-dimethylpiperidine. The latter was also prepared from α-methylpiperidine. Both preparations had the same properties.

1-*Phenyl*-Δ^2-*tetrahydropicoline* or 1-*phenyl*-Δ^2-*tetrahydro*-2-*methylpyridine*, $C_5NH_7MePh + H_2O$, is obtained by the action of aniline on bromobutyl methyl ketone. It crystallises in colourless prisms or tablets, melts at 54—55°, decomposes when heated at its boiling point, and is odourless at the ordinary temperature, but at higher temperatures has a peculiarly characteristic odour. It is insoluble in cold water, sparingly soluble in hot water and cold light petroleum, easily so in alcohol, ether, and hot light petroleum. The *hydrochloride* is hygroscopic. With platinic chloride and picric acid, it yields well crystallised compounds, and combines with methyl iodide with evolution of heat.

Dimethylacetobutylamine, $COMe\cdot[CH_2]_4\cdot NMe_2$, is obtained by the action of dimethylamine on bromobutyl methyl ketone. It is a colourless liquid, having a faint ammoniacal odour, boils at 195° under 720 mm. pressure, and is easily soluble in water, ether, and alcohol. The *hydrochloride* is very hygroscopic. The *aurochloride* and the *platinochloride* were not obtained crystalline. The *picrate* crystallises in yellow leaflets, and is sparingly soluble in cold water. The base combines with hydroxylamine hydrochloride and with phenylhydrazine with development of heat. E. C. R.

1-Methyl-Δ^2-tetrahydro-2-hydroxyethylpyridine. By A. Lipp (*Ber.*, **25**, 2197—2200).—1-*Methyl*-Δ^2-*tetrahydro*-2-*hydroxyethylpyridine*, $CH_2<\begin{matrix}CH_2—CH\\CH_2\cdot NMe\end{matrix}>C\cdot CH_2\cdot CH_2\cdot OH$, is formed on gradually adding formaldehyde to 1-methyltetrahydropicoline dissolved in twice its weight of water and allowing the mixture to remain; it is then distilled in a current of steam, the distillate acidified with hydrochloric acid, evaporated, and the hydrochloride of the base decomposed with potassium hydroxide. It is a colourless, limpid liquid, turns brown on exposure to the air, has a faint ammoniacal odour, boils at 198—199° under 710 mm. pressure, dissolves in water in all proportions, and is not solid at −20°. The *hydrochloride* is very easily soluble in water, and melts at 155—157°. The *aurochloride* crystallises in leaflets, melts at 119—121°, and is easily soluble in hot, sparingly so in cold water. The *platinochloride* crystallises in needles, melts at 200—205° with decomposition, and is sparingly soluble in water, insoluble in alcohol. The *picrate* crystallises from water in small prisms, and from alcohol in long, lustrous needles, and melts at 126—127°. The *mercurochloride*, $C_8H_{15}ON,HCl + 6HgCl_2$, forms small, lustrous crystals, melts at 161—162° with decomposition, and is sparingly soluble in water.

The above methyltetrahydrohydroxyethylpyridine should have similar properties to tropine if the latter has the constitution assigned to it by Ladenburg. This is not the case, however, and the author considers that Merling's formula for tropine is the correct one.

The above base is easily reduced with sodium and alcohol, and the

reduction product should be identical with Ladenburg's 1-methylpipecolylalkine (*Ber.*, **24**, 1622), which, however, is not the case.

1-*Methylpipecolylalkine*, prepared from the above base, is a syrupy liquid having a faint ammoniacal odour, boils at 215—216° under 720 mm., is strongly alkaline, and is very soluble in water and alcohol, more sparingly so in ether. The *hydrochloride* crystallises in colourless needles and prisms, and is very hygroscopic. The *platinochloride* was not obtained crystalline. The *aurochloride*,

$$C_7H_{14}MeON,HAuCl_4,$$

crystallises in small leaflets, begins to coagulate at 120°, melts at 127—128°, and is somewhat easily soluble in warm water. The *double salt* with *mercuric chloride*, $C_8H_{17}NO,HCl,6HgCl_2$, forms small, lustrous crystals, and melts partially at 165—166° with decomposition. E. C. R.

Synthesis of Quinaldine. By W. v. Miller (*Ber.*, **25**, 2072—2074; see also Abstr., 1891, 1101).—Under the conditions of the quinaldine synthesis, it is probable that ethylidene- and propylideneaniline occur as bimolecular secondary bases. When ethylideneaniline and propylideneaniline are heated with hydrochloric acid, they are converted into quinaldine and α-ethyl-β-methylquinoline respectively, the reaction taking place in the four stages—

$$NPh{:}CH{\cdot}CH_2{\cdot}CHMe{\cdot}NHPh, \qquad NHPh{\cdot}CH\begin{matrix}<\\ \\ \end{matrix}\begin{matrix}CH_2\cdot CHMe\\ |\\ C_6H_4\cdot NH\end{matrix},$$

$$NH_2Ph + CH\begin{matrix}<\\ \\ \end{matrix}\begin{matrix}CH-CHMe\\ |\\ C_6H_4\cdot NH\end{matrix}, \text{ and } CH\begin{matrix}<\\ \\ \end{matrix}\begin{matrix}CH-CMe\\ ||\\ C_6H_4\cdot N\end{matrix} + 2H.$$

Only 22 per cent. of the theoretical yield is, however, obtained. E. C. R.

Methylphenylpyrazolone and its Derivatives. By C. Mölleneoff (*Ber.*, **25**, 1941—1951).—Methylphenylpyrazolonesulphonic acid, $SO_3H{\cdot}C_6H_4{\cdot}N\begin{matrix}<\\ \\ \end{matrix}\begin{matrix}N=CMe\\ |\\ CO\cdot CH_2\end{matrix}$, is best prepared by heating methylphenylpyrazolone with 30 per cent. anhydrosulphuric acid (4 parts) on the water-bath; the product is added to water, when the acid separates in the crystalline state. It crystallises from water in small needles, containing 1 mol. H_2O, darkens at 290°, and decomposes at 320°; it is sparingly soluble in alcohol and glacial acetic acid, more readily in water, but is insoluble in ether. It reduces Fehling's solution on warming, does not give pyrazole blue (Knorr, Abstr., 1887, 602) on heating with ferric chloride, but a red coloration, which is destroyed by boiling or on the addition of hydrochloric acid. The *calcium* and *barium* salts were prepared, but on attempting to prepare the silver salt by means of silver carbonate, metallic silver was produced. The same sulphonic acid is obtained when paraphenylhydrazinesulphonic acid is heated with an excess of ethyl

acetoacetate at 150—160°. When a solution of the acid is boiled with bromine (3 mols.), *methylbromophenyldibromopyrazolone*,

$$C_6H_4Br\cdot N<\begin{matrix}N=CMe\\ |\\ CO\cdot CBr_2\end{matrix},$$

melting at 83·5°, is formed; the same compound is furnished when the methylphenylpyrazolone, dissolved in glacial acetic acid, is brominated. The corresponding trichloro-derivative is obtained on passing chlorine through a solution of the sulphonic acid. When the methylphenylpyrazolone is heated at 120° with a large excess of bromine, a tetrabromo-derivative melting at 134—135° is produced.

The *compound* $SO_3H\cdot C_6H_4\cdot N<\begin{matrix}N=CMe\\ |\\ CO\cdot C:N_2HPh\end{matrix}$ separates as an oil, which subsequently solidifies when the calculated quantity of diazobenzene chloride solution is added to a strongly alkaline solution of the above mentioned sulphonic acid, with cooling; it crystallises from acetic acid in small, brownish-yellow crystals, melts at 262° with decomposition, dyes wool yellow, and is readily soluble in water and alcohol.

Dichloromethylphenylpyrazolonesulphonic chloride,

$$SO_2Cl\cdot C_6H_4\cdot N<\begin{matrix}N=CMe\\ |\\ CO\cdot CCl_2\end{matrix},$$

is prepared by heating the sulphonic acid (1 mol.) with phosphorus pentachloride (3 mols.) on the water-bath, distilling off phosphorus compounds under diminished pressure, and crystallising the residue from benzene. The pure compound is sparingly soluble in ether and light petroleum, and melts at 103·5°; when heated at 50° with sodium ethoxide, it yields the compound $SO_2Cl\cdot C_6H_4\cdot N<\begin{matrix}N=CMe\\ |\\ CO\cdot C(OEt)_2\end{matrix}$, which crystallises from alcohol in small, reddish needles, melts at 68°, and gives the corresponding sulphonic acid on boiling with water.

When methylphenylpyrazolonesulphonic acid is fused with potash, phenol is formed. The blue *colouring matter*,

$$SO_3H\cdot C_6H_4\cdot N<\begin{matrix}N=CMe & CMe:N\\ |\\ CO\cdot C & C—CO\end{matrix}>N\cdot C_6H_4\cdot SO_3H,$$

is prepared by passing bromine vapour (avoiding excess) into an aqueous solution of bismethylphenylpyrazolonedisulphonic acid (Knorr, *Annalen*, **238**, 170), and precipitating with a saturated solution of common salt; its aqueous solution is fairly stable in the cold, but decomposes on heating.

Dimethylphenylpyrazolone (antipyrine) and the corresponding bisdimethylphenylpyrazolone give sulphonic acids when heated with 30 per cent. anhydrosulphuric acid. A. R. L.

Azonium Bases. By O. N. Witt and C. Schmidt (*Ber.*, **25**, 2003—2008).—In a former paper (*Ber.*, **25**, 1014), the authors stated that certain observations of Meldola and his pupils were not

quite in agreement with their own; they, however, now acknowledge having erroneously compared their own work on the reduction of anilineazo-α-naphthol derivatives with that of Meldola and his pupils on the corresponding β-naphthol derivatives.

When ethoxyphenylnaphthostilbazonium chloride (this vol., p. 863) is heated with an excess of alcoholic ammonia in a sealed tube at 120°, and the melt dissolved in boiling dilute acetic acid, hydrochloric acid precipitates a substance which is the hydrochloride of a saffranine base, and, after purification, forms small, scarlet needles having a green reflex; it dyes silk, wool, and cotton a rose colour, dissolves in water and alcohol forming a scarlet solution with a greenish-red fluorescence, and in concentrated sulphuric acid forming a reddish-violet solution, which, on the addition of water, changes successively to green, red, and orange, and has the constitution $NH_2\cdot C_{10}H_5<\begin{matrix}NPhCl\cdot CPh\\ |\quad\quad\quad ||\\ N\text{——}CPh\end{matrix}$.

The corresponding *paratoluidine* derivative,

$$C_6H_4Me\cdot NH\cdot C_{10}H_5<\begin{matrix}N\cdot PhCl\cdot CPh\\ |\quad\quad\quad ||\\ N\text{——}CPh\end{matrix},$$

is obtained by heating the ethoxy-compound in a sealed tube at 110—120° for 8—10 hours; it dyes cotton a beautiful reddish-violet, is sparingly soluble in water, and dissolves in concentrated sulphuric acid forming a slate-blue solution, which, on dilution, passes from pure blue to violet.

When ethoxyphenylnaphthostilbazonium chloride is heated to fusion, ethyl chloride distils over, and at a higher temperature *phenylnaphthostilborosindone*, $C_{10}H_5\cdot O<\begin{matrix}N\cdot PhCPh\\ |\quad\quad ||\\ N\text{——}CPh\end{matrix}$, sublimes; the latter is also formed when a solution of the stilbazonium chloride in aniline, paratoluidine, phenol, &c., is heated quickly to boiling. The rosindone is most conveniently prepared by heating the stilbazonium chloride with dimethylaniline (6 parts) when it dissolves with a carmine colour, and the new compound separates from the filtrate on cooling. It is a feeble base, its hydrochloride being decomposed by water and when heated alone at 100°. Silk is dyed red when immersed into an aqueous alcoholic solution of one of its salts. Fuming sulphuric acid converts it into a sulphonic acid which dyes silk a red colour in an acid bath. A. R. L.

Action of Ethylenediamine on Thiamides. By G. Forssel (*Ber.*, **25**, 2132—2142; compare Abstr., 1891, 1003).—The base $\begin{matrix}CH_2\text{—}N\\ |\quad\quad\\ CH_2\cdot NH\end{matrix}>C\cdot C<\begin{matrix}N\text{—}CH_2\\ |\quad\quad\\ NH\cdot CH_2\end{matrix}$ is prepared by heating dithiooxamide with ethylenediamine hydrate (2 parts) on the water-bath until the evolution of gas ceases. It crystallises from alcohol in almost colourless needles which are strongly electrical when rubbed, commence to soften at 240°, and melt between 290° and 300°; it is insoluble in benzene and ether, and sparingly soluble in cold alcohol and water.

The *hydrochloride*, $C_6H_{10}N_4,2HCl$, forms needles, insoluble in alcohol; the *platinochloride* and the *picrate* are also described; the *dinitroso-derivative*, $C_6H_8N_4(NO)_2$, obtained on adding potassium nitrite to a concentrated solution of the base in glacial acetic acid, crystallises from alcohol in greenish-white needles melting at 173° with decomposition; whilst the *diacetyl derivative* melts at 250°, and dissolves in water with decomposition.

Ethylenebenzenyldiamine, described by v. Hofmann (Abstr., 1888, 1050), is obtained by heating thiobenzamide with somewhat more than the calculated quantity of ethylenediamine hydrate. The *platinochloride* melts at 200°, the *mercurochloride* at 192—195°, and the *picrate* at 233°. The *nitroso-derivative*, melting at 66—67°, and the *benzoyl derivative* were also prepared.

β-Naphthoethylenediamine, $C_{10}H_7\cdot C\leqslant \begin{matrix} NH\cdot CH_2 \\ | \\ N-CH_2 \end{matrix}$, is formed when β-naphthothiamide (10 parts) is heated on the water-bath with ethylenediamine hydrate (7 parts); it crystallises in short, white, opaque needles, melts at 116°, and is sparingly soluble in water, ether, and light petroleum, readily so in alcohol and benzene. The *platinochloride*, $(C_{13}H_{12}N_2)_2,H_2PtCl_6$, melts at 219—221°; the *mercurochloride*, $C_{13}H_{12}N_2,HHgCl_3$, melts at 180—186°; whilst an *additive* compound, $C_{13}H_{12}N_2,2HgCl_2$, obtained by mixing alcoholic solutions of the base and mercuric chloride, melts between 230° and 250°. The *picrate* melts at 196°, and the *nitrate* at 166—167°, whilst the *nitroso*-derivative melts at 101°, and the *acetyl* derivative at 160—166°. When the base is treated on the water-bath with acetic anhydride, a *compound*, $C_{17}H_{18}N_2O_3$, is produced, which is, perhaps, an open chain derivative.

A *base*, $C_{13}H_{12}N_2$, isomeric with that just described, is obtained by a similar process from α-naphthothiamide and ethylenediamine; it forms small, yellowish-white needles, and melts at 131°. The *platinochloride* melts at 214°, the *mercurochloride* melts at 185—190°, whilst a mercuric chloride *additive* product, corresponding with that described above, melts between 250° and 260°. The *picrate* melts at 237°, and the nitroso-derivative at 155—156°. When the base is treated with benzoic chloride by the Baumann-Schotten method, it gives a compound melting at 161°, having, probably, the constitution $C_{10}H_7\cdot CO\cdot NBz\cdot C_2H_4\cdot NHBz$ (compare Bamberger and Berlé, this vol., p. 632). A. R. L.

Phthalamidones. By A. Bistrzycki and G. Cybulski (*Ber.*, **25**, 1984—1990).—An extension of the method of preparing phthalamidones (Abstr., 1891, 746). The phthalamidones to be described crystallise from alcohol in yellow needles, and are all more or less soluble in hot alcohol, glacial acetic acid, and benzene, but insoluble, or only very slightly soluble, in water, ether, and light petroleum. They dissolve, moreover, in concentrated sulphuric acid with a yellowish-red colour, which disappears on the addition of water.

Toluylenephthalamidone, $\begin{matrix} C_6H_3Me\cdot N\cdot CO \\ | \quad\quad | \\ N=\!=\!=C\cdot C_6H_4 \end{matrix}$, is prepared from toluyl-

eneamidinebenzenylorthocarboxylic acid, and melts at 188°; *bromotoluylenephthalamidone*, $\begin{matrix} C_6H_2MeBr\cdot N\cdot CO \\ | \quad\quad\quad | \quad | \\ N\!=\!\!=\!\!=\!C\cdot C_6H_4 \end{matrix}$, formed from the bromo-acid, melts at 212—213°.

αβ-Naphthylenedimethoxyphthalamidone, $\begin{matrix} C\ H_6\cdot N\cdot CO \\ | \quad\quad | \quad | \\ N\!=\!\!=\!C\cdot C_6H_2(OMe)_2 \end{matrix}$, is prepared from *αβ-naphthylenamidinedimethoxybenzenylorthocarboxylic acid* [m. p. 242°; from orthonaphthylenediamine (1 mol.) and opianic acid (2 mols.)], and melts at 191—192°.

When nitropianic acid is heated with 1 : 3 : 4-toluylenediamine (2 mols.; opianic acid reacts with 1 mol.), *toluylenaldehydenitrodimethoxybenzenylorthocarboxylic acid*,

$$\begin{matrix} C_6H_3Me\cdot N\cdot CH_2\cdot C_6H(OMe)_2(NO_2)\cdot COOH \\ | \quad\quad\quad\quad | \\ N\!=\!\!=\!C\cdot C_6H(OMe)_2(NO_2)\cdot COOH \end{matrix},$$

is formed. Bromopianic acid reacts in like manner with 1 : 3 : 4-toluylenediamine, forming the *acid*

$$\begin{matrix} C_6H_3Me\cdot N\cdot CH_2\cdot C_6HBr(OMe)_2\cdot COOH \\ | \quad\quad\quad\quad | \\ N\!=\!\!=\!C\cdot C_6HBr(OMe)_2\cdot COOH \end{matrix},$$

of melting point 213°.

The formation of phthalamidones from the amidinecarboxylic acids is a reversible action, the latter being obtained from the former by the assimilation of a molecule of water. The phthalamidones, moreover, unite with 1 mol. of alcohol; a *compound*, for example, is formed when bromotoluylenephthalamidone is crystallised from alcohol; it melts at 255—256°, and an *isomeride*, melting at 137—138°, is produced by boiling bromotoluylenephthalamidone with alcohol containing a trace of potash; by the latter method also, a *compound* which melts at 163—164° can be obtained from toluylenephthalamidone; and one melting at 173° from toluylenedimethoxyphthalamidone. When zinc-dust is added to hot solutions of phthalamidones, they are decolorised, and ammonia precipitates tetrahydro-derivatives, which are basic substances. Tetrahydrotoluylenephthalamidone melts at 186—187°; whilst tetrahydrotoluylenedimethoxyphthalamidone melts at 248°. A. R. L.

Cinchona Alkaloïds. By A. Claus (*Annalen*, **269**, 232—294). —In this paper, the author gives an account of experiments some of which he and his pupils carried out some years ago, but which have not yet been published in any chemical journal.

Quinidine methiodide, $C_{20}H_{24}N_2O_2,MeI + H_2O$, is formed when quinidine is treated with methyl iodide; it crystallises in lustrous, colourless needles, loses its water at 110°, melts at 248° with decomposition, and is only sparingly soluble in cold water, but readily in alcohol and boiling water. The *ethiodide*, $C_{20}H_{24}N_2O_2,EtI$, crystallises in colourless needles, melts at 248° with decomposition, and is only very sparingly soluble in cold water, but more readily in hot water and alcohol. The *ethobromide*, $C_{20}H_{24}N_2O_2,EtBr + H_2O$, crystallises in long, colourless needles, loses its water at 120°, and melts at about 238° with decomposition.
